This handbook is dedicated to those who have lent a hand and lit the way.

And I said to the man who stood at the gate of the year:

"Give me a light, that I may tread safely into the unknown!"

And he replied:

"Go out into the darkness and put your hand into the Hand of God.

That shall be to you better than light and safer than a known way."

King George VI in his New Year's message to his embattled people
at the beginning of the Second World War

Contents

PART I Humans in HCI

PART II Computers in HCI

PART III Designing Human–Computer Interactions

PART IV Application-/Domain-Specific Design

PART V Designing for Diversity

PART VI The Development Process
SECTION A Requirements Specification

SECTION B Design and Development

SECTION C Testing, Evaluation, and Technology Transfer

PART VII Emerging Phenomena in HCI

Series Foreword

The third edition of this classic handbook is published at an opportune time when interactive technologies are a dominating presence in work, leisure, and social settings and when ambient intelligence is gaining accelerated momentum. The field of human–computer interaction (HCI) has matured to such an extent that even the words comprising the term have taken on new, expanded, and reinterpreted meanings. That is, the field has advanced significantly from its origins. Researchers in HCI are called upon now more than ever to develop new knowledge, which often resides at the intersection of multiple disciplines and spans various and innovative platforms of applications. Information technology is more ubiquitous today than ever, successfully interacting with the technologies that ensure it is more enjoyable and more productively accessible and usable by all segments of society across all five continents.

This handbook is the premier resource for the theoretical and operational foundations of HCI, providing readers access to the latest scientific breakthroughs coupled with the state of the art in the field. The book provides detailed descriptions of approaches and methodologies that are frequently illustrated with case studies and examples on how to conceptualize, design, and evaluate interactive systems with human beings at the center of the endeavor. As such, this handbook will be invaluable to researchers, practitioners, educators, and students working in, or at the intersection of, computer science, information technology, information science, informatics, engineering, psychology, design, and human factors and ergonomics.

This book is part of the Human Factors and Ergonomics series, published by the Taylor & Francis Group. The 145 authors of this handbook include 92 from academia, 49 from industry, and 4 from government agencies. These individuals are among the very best and most respected in their fields across the globe. The more than 80 tables, 400 figures, and nearly 7000 references in this book provide the single most comprehensive depiction of this field that exists in a single volume.

The handbook authors come from 14 countries: Australia, Canada, Cyprus, Denmark, Finland, France, Germany, Greece, Ireland, Japan, South Africa, the Netherlands, United Kingdom, and the United States.

Gavriel Salvendy, Series Editor
Purdue University/Tsinghua University, China

Foreword

The Expanding Impact of Human–Computer Interaction

The remarkable growth of human–computer interaction (HCI) over the past 30 years has transformed this nascent interdisciplinary field into an intellectually rich and high impact worldwide phenomenon. We have grown from a small rebellious group of researchers who struggled to gain recognition as we broke disciplinary boundaries to a broad influential community with potent impact on the daily lives of every human. There are dozens of relevant journals, plus conferences and workshops worldwide.

The aspirations of early HCI researchers and practitioners were to make better menus, design graphical user interfaces based on direct manipulation, improve input devices, design effective control panels, and present information in comprehensible formats. HCI software developers contributed innovative tools that enabled programmers and nonprogrammers to create interfaces for widely varying applications and diverse users. HCI professionals developed design principles, guidelines, and sometimes standards dealing with consistency, informative feedback, error prevention, shortcuts for experts, and user control. Success was measured by individual performance metrics such as learning time, speed, error rates, and retention for specific tasks, whereas user satisfaction was assessed by detailed questionnaires filled with numbered scales.

In the early days, HCI researchers and professionals fought to gain recognition and often still have to justify HCI's value with academic colleagues or corporate managers. However, the larger world embraced our contributions and now has high expectations of what we can deliver. Few fields can claim such rapid expansion and broad impact as those who design the desktop, web, mobile, and cellphone interfaces that have spread around the world into the hands of at least 5 billion users. HCI designs now influence commercial success, reform education, change family life, affect the political stability of nations, are embedded in military systems and play a significant role in shaping a peaceful or conflict-ridden world.

The Handbook of Human–Computer Interaction: Third Edition details the progress of this extraordinary discipline, inviting newcomers to learn about it and helping experienced professionals to understand the rapid and continuing changes. The carefully written chapters and extensive references will be useful to readers who want to scan the territory or dig deep into specific topics. This handbook's prominent authors thoughtfully survey the key topics, enabling students, researchers, and professionals to appreciate HCI's impact.

As HCI progresses, there is a greater acceptance in the academic environment, where HCI is now part of most computer science, iSchool, business, engineering, and other departments and has advocates in medicine, social sciences, journalism, humanities, etc. Although the term *human–computer interaction* has achieved widespread recognition, many insiders feel that it is no longer an accurate description. They complain that it suggests one human interacting with one computer to complete narrow tasks. Instead, these critics believe that the discipline should reflect user-oriented technologies that are ubiquitous, pervasive, social, embedded, tangible, invisible, multimodal, immersive, augmented, or ambient. Some want to break free from the focus on computer use and emphasize user experiences, interaction design, emotional impact, aesthetics, social engagement, empathic interactions, trust building, and human responsibility.

New terms have been proposed such as *human-centered computing, social computing, human–information interaction, human–social interaction, human-centered informatics,* or just *human interaction*. Novel, but already thriving applications areas include computational biology, computational social science, e-commerce (and m-commerce), digital humanities, information visualization, open government, sustainability, biodiversity, and citizen science. Although these broader visions are important, many researchers are still working on innovative display designs, input devices, multimedia output, programming toolkits, and predictive models of user performance.

New names and applications are a good sign of success, but finding the balance between sticking with an established term and welcoming innovative directions is difficult. Maybe an old aphorism helps: "make new friends and keep the old, one is silver and the other gold." Can we retain the brand name recognition of HCI but embrace new directions by discussing *micro-HCI* and *macro-HCI*?

Micro-HCI researchers and developers would design and build innovative interfaces and deliver validated guidelines for use across the range of desktop, web, mobile, and ubiquitous devices. The challenges for micro-HCI are to deal with rapidly changing technologies, while accommodating the wide range of users: novice/expert, young/old, literate/illiterate, abled/disabled, and their cultural plus linguistic diversity. These distinctions are tied to skills, but there are further diversities in gender, personality, ethnicity, skills, and motivation that are now necessary to address in interface designs. Micro-HCI researchers can take comfort in dealing with well-stated requirements, clear benchmark tasks, and effective predictive models.

Macro-HCI researchers and developers would explore new design territories such as affective experience, aesthetics, motivation, social participation, trust, empathy, responsibility, and privacy. The challenges for macro-HCI are to deal with new opportunities across the range of human experience: commerce, law, health/wellness, education, creative arts, community relationships, politics, policy negotiation, conflict resolution, international development, and peace studies. Macro-HCI researchers have to face the challenge of more open tasks, unanticipated user goals, and even conflicts among users in large communities.

Although micro-HCI and macro-HCI have healthy overlaps, as do micro-economics and macro-economics, they attract different types of researchers, practitioners, and activists, thereby further broadening the scope and impact. As commercial, social, legal, and ethical considerations play an increasing role, educational curricula and professional practices need to be updated regularly and midcareer continuing education for HCI professionals will keep them current.

An important goal will be to develop new metrics and evaluation methods for micro-HCI and macro-HCI. Moore's Law has been useful in charting the growth of computing, enabling everyone to admire and benefit from the increase in gigahertz, terabytes, and petaflops. These are still useful, but we need newer metrics to understand the impact of HCI designs that have enabled the spread of billions of mobile devices and the emergence of YouTube, Facebook, twitter, Wikipedia, and so on. Understanding this transformation would be facilitated by measures of giga-hellos, teracontribs, and peta-thankyous and by newer metrics of trust, empathy, responsibility, privacy, and so on.

Traditional evaluation approaches of controlled experiments and usability testing are being continuously refined to fit the needs of micro-HCI, whereas the newer methods of qualitative, ethnographic, and case study methods are being explored to match the needs of macro-HCI. Both groups will benefit from the remarkable increased opportunities to log usage on a massive scale through the increasingly connected communications, data, and sensor networks. Traditional surveys of a small sample of users who offer biased perceptions or reports of attitudes are giving way to actual measurement of usage that reveals the learnability, efficacy, utility, and satisfaction of users. Even more exciting is the potential to capture the manifestations of trust, empathy, responsibility, privacy, security, and motivation. Researchers are also beginning to measure brand loyalty, parental engagement, political leaning, potential for violence, community commitment, and much more. The dangers of inappropriate intrusion, misguided applications, scamming/spamming, deception, and bullying are now part of macro-HCI. Even greater concerns come from criminals, terrorists, and oppressive governments who can use these technologies in ways that threaten individuals, intimidate communities, or destroy the environment.

The power of widely used social technologies that stem from HCI's success means that we will face ethical challenges similar to what the nuclear physicists dealt with during the 1940s and beyond. We cannot and should not avoid these responsibilities. Rather, we should embrace them and show leadership in shaping technology to produce positive outcomes. This is never easy, but every worthy project that improves the health, environment, or education of children or builds capacity for constructive communities should be recognized, disseminated, scaled up, and continuously improved. Even more ambitious should be our efforts to promote open government, independent oversight, deliberative systems, and citizen participation. The research agenda for HCI should include the UN Millennium Development Goals such as eradicating extreme hunger and poverty, ensuring universal childhood education, promoting maternal health, and ensuring environmental sustainability. If HCI professionals also courageously address conflict resolution, international development, and peace studies, we can inspire others and help build a better world.

We should be proud of what HCI has accomplished, but there is much work to be done. Let's get on with it!

ACKNOWLEDGMENTS

Ben Shneiderman
University of Maryland

Preface

This third edition of the HCI handbook represents the single largest, most complete compilation of HCI theories, principles, advances, case studies, and more that exist within a single volume. The construction of the handbook has been a massive community effort of which it was a tremendous privilege for this author and editor to be a part. The 145 authors of the 62 chapters within this book are people who have not only dedicated themselves to laying the foundation for this field but also dared to address the grand challenges that have been posed along the way, thus advancing the field of HCI by leaps and bounds. The HCI community from which these authors hail is remarkably diverse and collaborative. You will see the artifacts of this ethos throughout the book.

The handbook opens with an insightful and thought-provoking introduction written by Jonathan Grudin, which sets the tone for the entire book. Within the introduction you will find a unique and compelling depiction of the evolution of HCI. The handbook closes with a look at the evolving nature of HCI to change the world. The closing chapter is written by the largest collection of authors in the book, led by Susan Dray. The global focus of this chapter is personified by the authors' origins, which literally span the globe. The chapters in between are organized very much like those in the second edition; however, the content of the chapters has been dramatically updated to reflect the state of the art and current state of the science in HCI. There have been numerous notable additions to the third edition, which reflect the ever-growing nature of this field, including, for example, chapters on social networks and social media, grounded theory, choices and decisions of users, and the naturalistic approach to evaluation.

I offer my heartfelt thanks to Ben Shneiderman, who kindly agreed to contribute his revolutionary perspective in the Foreword to the third edition. He not only chronicles the impact of HCI but also presents a challenge to each and every one of us to embrace the responsibility of shaping technology to produce positive outcomes. With this challenge he is asking us to be the best citizen scholars we can be. This is classic Ben Shneiderman and just one of the many reasons why I respect and admire him. This handbook would simply not have been possible without the guiding influence of my longtime mentor and good friend, Gavriel Salvendy. Gavriel sets the standard for successfully coalescing people and communities around shared goals and mutual aspirations. He has been an unwavering source of inspiration, support, advice, opportunity, and kindness for me. This book is part of a larger book series of which Gavriel is the series editor. His Series Foreword to the third edition enables us to see this book in the context of the larger whole. Both these luminaries, Ben and Gavriel, have transformed the field of HCI in their own signature ways, and I salute both of them.

A very special individual worked hand in hand with me in constructing the third edition. Molly McClellan, PhD, is a research associate with SimPORTAL at the University of Minnesota, performing postdoctoral research in the area of perioperative simulation. Completing a book of this scale and scope requires incredible persistence and perseverance. Molly demonstrates both these attributes and so much more. She is a creative problem solver with an uncanny ability to organize vast quantities of information from disparate and geographically distributed sources. She is smart, generous, and exceedingly committed to excellence. I have admired her as a scholar and as a human being. It is a privilege to serve as her major professor and mentor.

Last but not the least, I wish to recognize the support offered me by my husband François and our son Nico. They are both, quite simply, my *raison de vivre*.

Julie A. Jacko
University of Minnesota

Editor

Julie A. Jacko, PhD, is a professor of Public Health at the University of Minnesota and a faculty fellow in the Academic Health Center's Institute for Health Informatics. She is the principal investigator and director of the University Partnership for Health Informatics (UP-HI). This $5.1-million grant from the Office of the National Coordinator for Health Information Technology is one of the nine awarded nationally and represents the first public–private partnership funded in the upper Midwest United States to infuse our nation's workforce with individuals who have been trained to perform one of six mission-critical health information technology roles.

Dr. Jacko has expertise in the design, implementation, and evaluation of interactive computing systems in complex domains such as population health and health care delivery, with the purpose of enhancing human performance and satisfaction. This is accomplished through research that is focused on the cognitive processes underlying the interaction of people with complex systems with the ultimate goal of combining robust empirical results with the development of engineering models of human performance that can aid in the design of real-world systems. Dr. Jacko has an exemplary research track record spanning nearly 20 years during which over 160 scientific publications have been generated in these research areas. She has generated nearly $25 million by way of research funding in the last 10 years and is one of the only 20 recipients of a National Science Foundation Presidential Early Career Award for Scientists and Engineers, the highest honor awarded to young investigators by the U.S. government. Dr. Jacko served as co-author on the #1-rated published article for 2005 in the *International Journal of Medical Informatics*. She has an extensive track record of professional leadership excellence, including the following awards and honorable positions.

- Received commendation from the Office of the National Coordinator for Health Information Technology (ONC) for her innovation and leadership in the University Partnership for Health Informatics (2011).
- Ranked one of the Top Ten Influential Informatics Professors by HealthTechTopia on September 14, 2010. (http://mastersinhealthinformatics.com/2010/top-10-most-influential-informatics-professors/).
- Published an invited comment paper in 2011, Issue 470, in *Nature* titled, "Narrow the Gap in Health Literacy."
- Appointed by the State of Minnesota Commissioner of Health to serve on the Minnesota e-health Advisory Committee, representing academics and clinical research for the State of Minnesota.
- Elected to the Office of the President, the Association for Computing Machinery's Special Interest Group on Computer–Human Interaction (ACM SIGCHI) (2006–09).
- Elected to the Association for Computing Machinery Special Interest Group Governing Board Executive Committee, elected Member at Large (2007–2009).
- Elected to the Office of the Vice President for Membership and Communications—the Association for Computing Machinery's Special Interest Group on Computer–Human Interaction (ACM SIGCHI) (2003–06).
- Editor-in-chief of the *International Journal of Human–Computer Interaction*, published by Taylor & Francis.
- Co-editor of the 1st and 2nd Editions of the *Human–Computer Interaction Handbook*, the premier compendium of research and practice in the field of human–computer interaction.

In addition, during the last 15 years, Dr. Jacko has chaired or co-chaired numerous technical conferences and technical conference programs in the fields of human factors and human–computer interaction. She received her BS, MS, and PhD in industrial and systems engineering from Purdue University in West Lafayette, Indiana, where she held the NEC Graduate Fellowship.

Introduction

A Moving Target: The Evolution of Human–Computer Interaction

Jonathan Grudin

PREAMBLE: HISTORY IN A TIME OF RAPID OBSOLESCENCE

> "What is a typewriter?" my six-year-old daughter asked.
> I hesitated. "Well, it's like a computer," I began.

Why Study the History of Human–Computer Interaction?

A paper widely read 20 years ago concluded with the advice to design a word processor by analogy to something familiar to everyone: a typewriter. Even then, one of my Danish students questioned this reading assignment noting that "the typewriter is a species on its last legs." For most of the computing era, interaction involved 80-column punch cards, paper tape, line editors, 1920-character displays, 1-megabyte diskettes, and other extinct species. Are the interaction issues of those times relevant today? No.

Of course, aspects of the human side of human–computer interaction (HCI) change very slowly if at all. Much of what was learned about our perceptual, cognitive, social, and emotional processes when we interacted with older technologies applies to our interaction with emerging technologies as well. Aspects of how we organize and retrieve information persist, even as the specific technologies that we use change. The handbook chapters lay out relevant knowledge of human psychology; how and when that was acquired may not be critical and is not the focus here.

Nevertheless, there is a case for understanding the field's history, and the rapid pace of change may strengthen it:

- Several disciplines are engaged in HCI research and application, but few people are exposed to more than one. By seeing how each has evolved, we can identify possible benefits of expanding our focus and obstacles to doing so.
- Celebrating the accomplishments of past visionaries and innovators is part of building a community and inspiring future contributors, even when some past achievements are difficult to appreciate today.
- Some visions and prototypes were quickly converted to widespread application, whereas others took decades and some remain unrealized to this day. By understanding the reasons for different outcomes, we can assess today's visions more realistically.
- Crystal balls are notoriously unreliable, but anyone planning or managing a career in a rapidly changing field must consider the future. Our best chance to anticipate change is to find trajectories that extend from the past to the present. One thing is certain: The future will not resemble the present.

This account does not emphasize engineering "firsts." It focuses on technologies and practices as they became widely used, reflected in the spread of systems and applications. This was often paralleled by the formation of new research fields and changes in existing disciplines, which were marked by the creation and evolution of professional associations and publications. More a social history than a conceptual history, this survey points to trends and trajectories you might download into your crystal balls.

A historical account is a perspective. It emphasizes some things while de-emphasizing or omitting others. A history can be wrong in details, but is never right in any final sense. Your questions and your interests will determine how useful a perspective is to you. This introduction covers several disciplines, but the disciplines of Communication, Design, and Marketing receive less attention than another account might provide.

A blueprint for intellectual histories of HCI was established by Ron Baecker in the opening chapters of the 1987 and 1995 editions of *Readings in Human–Computer Interaction*. It was followed in Richard Pew's chapter in the 2003 version of this handbook. Brian Shackel's (1997) account of European contributions and specialized essays by Brad Myers (1998) on HCI engineering history and Alan Blackwell (2006) on the history of metaphor in design provide further insights and references. Perlman, Green, and Wogalter (1995) is a compendium of early HCI papers that appeared in the Human Factors literature. Research on HCI within Information Systems is covered by Banker and Kaufmann (2004) and Zhang et al. (2009). Rayward (1983, 1998) and Burke (1994, 2007) review the predigital history of information science; Burke (1998) provides a focused study of an early digital effort in this field.

In recent years many popular books covering the history of personal computing have been published (e.g., Hiltzik 1999;

Bardini 2000; Hertzfeld 2005; Markoff 2005; Moggridge 2007). This introduction extends my contribution to the previous handbook. It includes new research and draws on *Timelines* columns that have appeared in *ACM Interactions* since March 2006.

Few of the aforementioned writers are trained historians. Many lived through much of the computing era as participants and witnesses, yielding rich insights and questionable objectivity. This account draws on extensive literature and hundreds of formal interviews and discussions, but everyone has biases. Personal experiences that illustrate points can enliven an account by conveying human consequences of changes that otherwise appear abstract or distant. Some readers enjoy anecdotes, whereas others find them irritating. I try to satisfy both groups by including personal examples in a short Appendix, akin to "deleted scenes" on a DVD.

Recent years have also seen the appearance of high-quality, freely accessed digital reproductions of some early works. My references include links to several such works. The reproductions do not always preserve the original pagination, but quoted passages can be found with a search tool. Finally, all prices and costs have been converted to U.S. dollars as of 2010.

Definitions: HCI, CHI, HF&E, IT, IS, LIS

The most significant term, HCI (human–computer interaction), is defined very broadly to cover major threads of research in four disciplines: (1) Human Factors/Ergonomics (HF or HF&E), (2) Information Systems (IS), (3) Computer Science (CS), and (4) Library and Information Science (LIS). The relevant literatures are difficult to explore because they differ in the use of simple terms. This is discussed later. Here I explain how several key disciplinary labels are used. CHI (Computer-Human Interaction) has a narrower focus, associated mainly with Computer Science, the Association for Computing Machinery Special Interest Group (ACM SIGCHI), and the latter's annual CHI conference. I use human factors and ergonomics interchangeably and refer to the discipline as HF&E—the Human Factors Society (HFS) became the Human Factors and Ergonomics Society (HFES) in 1992. (Some writers define ergonomics more narrowly around hardware.) Information Systems (IS) refers to the management discipline that has also been labeled Data Processing (DP) and Management Information Systems (MIS). I follow common parlance in referring to organizational information systems specialists as IT professionals or IT pros. With IS taken, I do not abbreviate Information Science. LIS (Library and Information Science) represents an old field with a new digital incarnation that includes important HCI research. Increasingly this discipline goes by simply "Information," as in newly christened Schools of Information.

HUMAN–TOOL INTERACTION AND INFORMATION PROCESSING AT THE DAWN OF THE COMPUTING ERA

In the century prior to the advent of the first digital computers, advances in technology gave rise to two fields of research that later contributed to HCI: One focused on making the human use of tools more efficient, whereas the other focused on ways to represent and distribute information more effectively.

Origin of Human Factors

Frederick Taylor (1911) employed technologies and methods developed in the late nineteenth century—photography, moving pictures, and statistical analysis—to improve work practices by reducing performance time. Time and motion studies were applied to assembly-line manufacturing and other manual tasks. Despite the uneasiness with "Taylorism" reflected in Charlie Chaplin's popular satire *Modern Times*, scientists and engineers strove to boost efficiency and productivity using this approach.

Lillian Gilbreth (1914) and her husband Frank were the first engineers to combine psychology and scientific management. Lillian Gilbreth focused more holistically than Taylor on efficiency and worker experience; she is regarded by some as the founder of modern Human Factors. Her PhD was the first awarded in industrial psychology. She went on to advise five U.S. presidents and became the first woman inducted into the National Academy of Engineering.

World War I and World War II accelerated efforts to match people to jobs, train them, and design equipment that could be more easily mastered. Engineering psychology was born during World War II after simple flaws in the design of aircraft controls (Roscoe 1997) and escape hatches (Dyson 1979) led to aircraft losses and thousands of casualties. Two legacies of World War II were respect for the potential of computing, based on its use in code breaking, and an enduring interest in behavioral requirements for design.

During the war, aviation engineers, psychologists, and physicians formed the Aeromedical Engineering Association. After the war, the terms "human engineering," "human factors," and "ergonomics" came into use, the latter primarily in Europe. For more on this history, see Roscoe (1997), Meister (1999), and HFES (2010).

Early tool use, whether by assembly-line workers or pilots, was not discretionary. If training was necessary, people were trained. One research goal was to reduce training time, but a more important goal was to increase the speed and reliability of skilled performance.

Origin of the Focus on Information

H. G. Wells, known for writing science fiction, campaigned for decades to improve society through information dissemination. In 1905, he outlined a system that might be built using another new technology of the era: index cards!

> These index cards might conceivably be transparent and so contrived as to give a photographic copy promptly whenever it was needed, and they could have an attachment into which would slip a ticket bearing the name of the locality in which the individual was last reported. A little army of attendants would be at work on this index day and night.… An incessant stream of information would come of births, of deaths, of arrivals at inns, of applications to post offices for letters,

> of tickets taken for long journeys, of criminal convictions, marriages, applications for public doles, and the like. A filter of offices would sort the stream, and all day and all night forever a swarm of clerks would go to and fro correcting this central register and photographing copies of its entries for transmission to the subordinate local stations in response to their inquiries. . . .

Would such a human-powered "Web 2.0" be a tool for social control or public information access? The image evokes the potential, and also the challenges, of the information era that is taking shape around us now, a century later.

In the late nineteenth century, technologies and practices for compressing, distributing, and organizing information bloomed. Index cards, folders, and filing cabinets—models for icons on computer displays much later—were important inventions that influenced the management of information and organizations in the early twentieth century (Yates 1989). Typewriters and carbon paper facilitated information dissemination, as did the mimeograph machine, patented by Thomas Edison. Hollerith cards and electromechanical tabulation, celebrated steps toward computing, were heavily used to process information in industry.

Photography was used to record information as well as behavior. For almost a century, microfilm was the most efficient way to compress, duplicate, and disseminate large amounts of information. Paul Otlet, Vannevar Bush, and other microfilm advocates played a major role in shaping the future of information technology.

As the cost of paper, printing, and transportation dropped in the late nineteenth and early twentieth centuries, information dissemination and the profession of librarianship grew explosively. Library associations were formed. The Dewey Decimal and Library of Congress classification systems were developed. Thousands of relatively poorly-funded public libraries sprang up to serve local demand in the United States. In Europe, government-funded libraries were established to serve scientists and other specialists in medicine and the humanities. This difference led to different approaches to technology development on either side of the Atlantic.

In the United States, library management and the training of thousands of librarians took precedence over technology development and the needs of specialists. Public libraries adopted the simple but inflexible Dewey Decimal Classification System. The pragmatic focus of libraries and emerging library schools meant that research into technology was in the province of industry. Research into indexing, cataloging, and information retrieval was variously referred to as bibliography, documentation, and documentalism.

In contrast, the well-funded European special libraries elicited sophisticated reader demands and pressure for libraries to share resources, which promoted interest in technology and information management. The Belgian Paul Otlet obtained Melvyn Dewey's permission to create an extended version of the Dewey Decimal System that supported what we would today call hypertext links. Otlet had to agree not to implement his "universal decimal classification" (UDC) in English for a time, an early example of a legal constraint on technology development. UDC is still in use in some places.

In 1926, the Carnegie Foundation dropped a bombshell: It endowed the Graduate Library School (GLS) at the University of Chicago to focus solely on research. For two decades, University of Chicago was the only university granting PhDs in library studies. GLS positioned itself in the humanities and social sciences, with research into the history of publishing, typography, and other topics (Buckland 1998). *An Introduction to Library Science*, the dominant library research textbook for 40 years, was written at Chicago (Butler 1933). *It did not mention information technology at all*. Library science was shaped by the prestigious GLS program until well into the computer era, and human–tool interaction was not among its major concerns. Documentalists, researchers who focused on technology, were concentrated in industry and government agencies.

Burke (2007, p. 15) summarized the early history with its emphasis on training librarians and other specialists: "Most information professionals … were focusing on providing information to specialists as quickly as possible. The terms used by contemporary specialists appeared to be satisfactory for many indexing tasks and there seemed no need for systems based on comprehensive and intellectually pleasing classification schemes. The goal of creating tools useful to nonspecialists was, at best, of secondary importance."

My account emphasizes when computer technologies came into what might be called "nonspecialist use." The early history of information management is significant, however, because the Web and declining digital storage costs have made it evident that everyone will soon become their own information managers, just as we are all now telephone operators. But I am getting ahead of our story. This section concludes with accounts of two individuals who, in different ways, shaped the history of information research and development.

Paul Otlet and the Mundaneum

Like his contemporary H.G. Wells, Otlet envisioned a vast network of information. But unlike Wells, Otlet and his collaborators built one. Otlet established a commercial research service around facts that he had been cataloging on index cards since the late nineteenth century. In 1919, the Belgian government financed the effort, which moved to a record center called the Mundaneum. By 1934, 15 million index cards and millions of images were organized using UDC, whose formula enabled the linking of items. Curtailed by the Depression and damaged during World War II, the work was largely forgotten. It was not cited by developers of the metaphorically identical Xerox NoteCards, an influential hypertext system of the 1980s.

Technological innovation continued in Europe with the development of mechanical systems of remarkable ingenuity (Buckland 2009). Features included the use of photoreceptors to detect light passing through holes in index cards positioned to represent different terms, enabling rapid retrieval of items on specific topics. These innovations inspired a well-known American scientist and research manager to go ahead with his endeavors.

Vannevar Bush and Microfilm Machines

Massachusetts Institute of Technology (MIT) professor Vannevar Bush was one of the most influential scientists in American history. He advised Presidents Franklin Roosevelt and Harry Truman, served as director of the Office of Scientific Research and Development, and was president of the Carnegie Institute.

Bush is remembered today for "As We May Think," his 1945 *Atlantic Monthly* essay. It described the MEMEX, a hypothetical microfilm-based electromechanical information-processing machine. The MEMEX was to be a personal workstation that enabled a professional to quickly index and retrieve documents or pictures and create hypertext-like associations among them. The essay, excerpted later in this section, inspired computer engineers and computer scientists who made major contributions to HCI in the 1960s and beyond.

Not so well known is that Bush wrote the core of his essay in the early 1930s. Then, shrouded in secrecy he spent two decades and unprecedented resources on the design and construction of several machines that comprised a subset of MEMEX features. None were successful. The details are recounted in Colin Burke's (1994) comprehensive book *Information and Secrecy: Vannevar Bush, Ultra, and the Other Memex*.

Microfilm—photographic miniaturization—had qualities that attracted Bush, as they had Otlet. Microfilm was light, could be easily transported, and was as easy to duplicate as paper records (Xerox photocopiers did not appear until 1959). The cost of handling film was brought down by technology created for the moving picture industry. Barcodelike patterns of small holes could be punched on a film and read very quickly by passing the film between light beams and photoreceptors. Microfilm was tremendously efficient as a storage medium. Memory based on relays or vacuum tubes would never be competitive, and magnetic memory, when it eventually arrived, was less versatile and far more expensive. It is easy today to overlook the compelling case that existed for basing information systems on microfilm.

Bush's machines failed because he set overly ambitious compression and speed goals, ignored patent ownership issues, and most relevant to our account, was unaware of what librarians and documentalists had learned through decades of work on classification systems. American documentalists were active, although not well funded in their work. In 1937, the American Documentation Institute (ADI) was formed, predecessor of present-day American Society for Information Science and Technology (ASIST). Had he worked with them, Bush, an electrical engineer by training, might have avoided the fatal assumption that small sets of useful indexing terms could easily be defined and agreed upon. Metadata design is still a research challenge.

At times Bush considered libraries and the public as potential users, but his machines cost far too much for library patrons to be plausible users. He began with the Federal Bureau of Investigation (FBI) in mind and focused on military uses of cryptography and information retrieval, and a major project was for the Central Intelligence Agency (CIA). Despite the classified nature of this work, through his academic and government positions, his writings, the vast resources he commandeered, and the scores of brilliant engineers he enlisted to work on microfilm projects, Bush promoted his vision and exerted influence for two decades, well into the computer era.

> Bush's vision emphasized both associative linking of information sources and discretionary use: Associative indexing, the basic idea of which is a provision whereby any item may be caused at will to select immediately and automatically another. This is the essential feature of the MEMEX.… Any item can be joined into numerous trails.… New forms of encyclopedias will appear, ready-made with a mesh of associative trails [which a user could extend].…
>
> The lawyer has at his touch the associated opinions and decisions of his whole experience and of the experience of friends and authorities. The patent attorney has on call the millions of issued patents, with familiar trails to every point of his client's interest. The physician, puzzled by a patient's reactions, strikes the trail established in studying an earlier similar case and runs rapidly through analogous case histories, with side references to the classics for the pertinent anatomy and histology. The chemist, struggling with the synthesis of an organic compound, has all the chemical literature before him in his laboratory, with trails following the analogies of compounds and side trails to their physical and chemical behavior.
>
> The historian, with a vast chronological account of a people, parallels it with a skip trail which stops only on the salient items, and can follow at any time contemporary trails which lead him all over civilization at a particular epoch. There is a new profession of trail blazers, those who find delight in the task of establishing useful trails through the enormous mass of the common record. (Bush 1945).

Bush knew that the MEMEX was not realistic. None of his many projects included designs for the "essential" associative linking. His inspirational account nicely describes present-day hands-on discretionary use of computers by professionals. But that would arrive 50 years later, built on technologies then undreamt of. Bush did not support the early use of computers, which were slow, bulky, and expensive. Computers were clearly inferior to microfilm.

1945–1955: MANAGING VACUUM TUBES

World War II changed everything. Prior to the war, government funding of research was minimal and primarily managed by the Department of Agriculture. The unprecedented investment in science and technology during the war years revealed that huge sums could be found—*for academic or industrial research that addressed national goals.* Research expectations and strategies would never again be the same.

Sophisticated electronic computation machines built before and during World War II were designed for specific purposes, such as solving equations or breaking codes. Each of the extremely expensive cryptographic machines that helped win the war was designed to attack a specific encryption device. A new one was needed whenever the enemy changed machines. These limitations spurred interest in general-purpose computational devices. Wartime improvements in technologies such as vacuum tubes made them more feasible, and their deployment brought HCI into the foreground.

When engineers and mathematicians emerged from military and government laboratories (and secret project rooms on university campuses), the public became aware of some of the breakthroughs. Development of ENIAC, arguably the first general-purpose computer, was begun in secret during the war but announced publicly as a "giant brain" only when it was completed in 1946. (Its first use, for calculations supporting hydrogen bomb development, was not publicized.) Accounts of the dimensions of ENIAC vary, but it stood 8–10-feet high, occupied about 1800 square feet, and consumed as much energy as a small town. It provided far less computation and memory than what can be acquired today for a few dollars, slipped into a pocket, and powered with a small battery.

Memory was inordinately expensive. Even the largest computers of the time had little memory, so they were used for computation and not for symbolic representation or information processing. Reducing operator burden was a key HCI focus, including replacing or resetting vacuum tubes more quickly, loading stored-program computers from tape rather than by manually attaching cables, and setting switches. Following "knobs and dials" human factors improvements, one computer operator could accomplish work that had previously required a team.

Libraries installed simple microfilm readers to assist the retrieval of information as publication of scholarly and popular material soared. Beyond that, library and library school involvement with technology was limited, even as the foundation for information science came into place. The war had forged alliances among the documentalists, electrical engineers, and mathematicians interested in communication and information management. Vannevar Bush's collaborators who were involved in this effort included Claude Shannon and Warren Weaver, coauthors in 1949 of the seminal work on information theory (called communication theory at that time). Prominent American documentalist Ralph Shaw joined Bush's efforts. Library schools continued to focus on librarianship, social science, and historical research. The GLS orientation still dominated the field. If anything the split was greater: In the 1930s, the technology-oriented ADI had included librarians and support for systems that spanned the humanities and sciences; with the coming of the war and continuing after it, ADI's concerns became those of government and Big Science.

Three Roles in Early Computing

Early computer projects employed people in the following roles: managers, programmers, and operators. Managers oversaw the design, development, and operation of projects. They specified the programs to be written and distributed the output. Scientists and engineers wrote the programs, working with mathematically adept programmers who decomposed a task into components that the computer could manage (for ENIAC, this was a team of six women). A small army of operators was needed. Once written, a program could take days to load by setting switches, dials, and cable connections. Despite innovations that boosted reliability, including operating vacuum tubes at lower power than normal and providing visible indicators of their failure, ENIAC was often stopped to locate and replace failed tubes. Vacuum tubes were reportedly wheeled around in shopping carts.

Eventually, each occupation—computer operation, management and systems analysis, and programming—became a major focus of HCI research, centered respectively in human factors, information systems, and computer science. Computers and our interaction with them evolved, but our research spectrum still reflects aspects of this early division of labor.

Grace Hopper: Liberating Computer Users

As computers became more reliable and capable, programming became a central activity. Computer languages, compilers, and constructs such as subroutines facilitated "programmer–computer interaction." Grace Hopper was a pioneer in these areas. She described her goal as freeing mathematicians to do mathematics (Hopper 1952; see also Sammet 1992). This is echoed in today's usability goal of freeing users to do their work. HCI professionals often argue that they are marginalized by software developers; in much the same way, Hopper's accomplishments have arguably been undervalued by theoretical computer scientists.

1955–1965: TRANSISTORS, NEW VISTAS

Early forecasts that the world would need few computers reflected the limitations of vacuum tubes. Solid-state computers, which first became available commercially in 1958, changed this. Computers were still used primarily for scientific and engineering tasks, but they were reliable enough not to require a staff of computer engineers. The less computer-savvy operators who oversaw them needed better interfaces. And although computers were too expensive and limited to be widely used, the potential of transistor-based computing was evident. Some researchers envisioned possibilities that were previously unimaginable.

Another major force was reaction to the then Soviet Union's launch of the Sputnik satellite in October 1957. This was a challenge to the West to invest in science and technology; becoming part of the response was a way to tie a research program to the national interest, which World War II had revealed to be so effective.

Supporting Operators: The First Systematic Human–Computer Interaction Research

> In the beginning, the computer was so costly that it had to be kept gainfully occupied for every second; people were almost slaves to feed it.
>
> **Brian Shackel (1997, p. 97)**

Almost all computer use of this period involved programs and data that were read in from cards or tape. Programs then ran without interruption until they terminated, producing printed, punched, or tape output along the way. This "batch processing" restricted human interaction to basic operation, programming, and use of the output. Of these, only computer operation, the least intellectually challenging and lowest-paying job, involved hands-on computer use.

Computer operators loaded and unloaded cards and magnetic or paper tapes, set switches, pushed buttons, read lights, loaded and burst printer paper, and put printouts into distribution bins. Operators interacted directly with the system via a teletype: Typed commands interleaved with computer responses and status messages were printed on paper that scrolled up one line at a time. Eventually, they yielded to "glass tty's" (glass teletypes), also called cathode-ray tubes (CRTs) and visual display units/terminals (VDUs/VDTs). For many years, these displays also scrolled commands and computer responses one line at a time. The price of a monochrome terminal that could display alphanumeric characters was equivalent to US$50,000 today—expensive, but only a small fraction of the cost of the computer. A large computer might have one or more consoles. Programmers did not use the interactive consoles. Programs were typically written on paper and keypunched onto cards or tape.

Improving the design of buttons, switches, and displays was a natural extension of human factors. Experts in HF&E authored the first HCI papers. In 1959 British researcher Brian Shackel published "Ergonomics for a Computer," followed in 1962 by "Ergonomics in the Design of a Large Digital Computer Console." These described console redesign for analog and digital computers called the EMIac and EMIdec 2400. Shackel (1997) described the latter as the largest computer of the time.

In the United States, American aviation psychologists created the Human Engineering Society in 1956, which was focused on skilled performance including improving efficiency, reducing errors, and training. The next year it adopted the more elegant title Human Factors Society and in 1958 it initiated the journal *Human Factors*. Sid Smith's (1963) "Man–Computer Information Transfer" marked the start of his long career with the human factors of computing.

Visions and Demonstrations

As transistors replaced vacuum tubes, a wave of imaginative writing, conceptual innovation, and prototype building swept through the research community. Some of the language is dated, notably the use of male generics, but many of the key concepts resonate even today.

J.C.R. Licklider at Bolt Beranek and Newman and Advanced Research Projects Agency

Licklider, a psychologist, played a dual role in the development of this field. He wrote influential essays and backed important research projects as a manager at Bolt Beranek and Newman (BBN) from 1957 to 1962 and as director of the Information-Processing Techniques Office (IPTO) of the Department of Defense Advanced Research Projects Agency (called ARPA and DARPA at different times) from 1962 to 1964.

BBN employed dozens of influential researchers on computer-related projects funded by the government, including John Seely Brown, Richard Pew, and many MIT faculty members such as John McCarthy, Marvin Minsky, and Licklider himself. Funding by IPTO was crucial in creating computer science departments and establishing artificial intelligence (AI) as a discipline in the 1960s. It is best known for a Licklider project that created the forerunner of the Internet called the ARPANET.

In 1960, Licklider outlined a vision he called *man–machine symbiosis*: "There are many man–machine systems. At present, however, there are no man–computer symbioses—answers are needed." The computer was "a fast information-retrieval and data-processing machine" destined to play a larger role: "One of the main aims of man–computer symbiosis is to bring the computing machine effectively into the formulative parts of technical problems" (pp. 4–5).

This required rapid, real-time interaction, which batch systems did not support. In 1962, Licklider and Wes Clark outlined the requirements of a system for "online man–computer communication." They identified capabilities that they felt were ripe for development: time-sharing of a computer among many users; electronic input–output surfaces to display and communicate symbolic and pictorial information; interactive, real-time support for programming and information processing; large-scale information storage and retrieval systems; and facilitation of human cooperation. They foresaw that other desirable technologies, such as speech recognition and natural language understanding, would be very difficult to achieve.

In a 1963 memorandum that cleverly tied computing to the emerging post-Sputnik space program, Licklider addressed his colleagues as "the members and affiliates of the Intergalactic Computer Network" and identified many features of a future Internet (Licklider 1963). His 1965 book *Libraries of the Future* expanded this vision. Licklider's role in advancing computer science and HCI is detailed by Waldrop (2001).

John McCarthy, Christopher Strachey, and Wesley Clark

McCarthy and Strachey worked out details of time-sharing, which made interactive computing possible (Fano and Corbato 1966). Apart from a few researchers who had access to computers built with no-expenses-spared military funding, computer use was too expensive to support exclusive individual access. Time-sharing allowed several (and later dozens) simultaneous users to work at terminals. Languages were developed to facilitate the control and programming of time-sharing systems (e.g., JOSS in 1964).

Clark was instrumental in building the TX-0 and TX-2 at MIT's Lincoln Laboratory to demonstrate time-sharing and other innovative concepts. These machines, which cost on the order of US$10 million, helped establish the Boston area as a center for computer research. The TX-2 was the most powerful and capable computer in the world at the time. It was much less powerful and capable than a present-day smartphone. Clark and Ivan Sutherland discussed this era in a CHI'05 panel, which is accessible online (Buxton 2006).

Ivan Sutherland and Computer Graphics

Sutherland's 1963 PhD thesis may be the most influential document in the history of HCI. His Sketchpad system, built on TX-2 to make computers "more approachable," launched computer graphics, which would have a decisive impact on HCI 20 years later. A nice version restored by Alan Blackwell and Kerry Rodden is available (http://www.cl.cam.ac.uk/TechReports/UCAM-CL-TR-574.pdf).

Sutherland demonstrated iconic representations of software constraints, object-oriented programming concepts, and the copying, moving, and deleting of hierarchically organized objects. He explored novel interaction techniques, such as picture construction using a light pen. He facilitated visualization by separating the coordinate system used to define a picture from the one used to display it, and demonstrated animated graphics, noting the potential for digitally rendered cartoons 20 years before *Toy Story*. His frank descriptions enabled others to make rapid progress in the field—when engineers found Sketchpad too limited for computer-assisted design (CAD), he called the trial a "big flop" and indicated why.

In 1964, with his PhD behind him, Sutherland succeeded Licklider as the director of IPTO. Among those he funded was Douglas Engelbart at the Stanford Research Institute (SRI).

Douglas Engelbart: Augmenting Human Intellect

In 1962, Engelbart published "Augmenting Human Intellect: A Conceptual Framework." Over the next several years he built systems that made astonishing strides toward realizing this vision. He also supported and inspired engineers and programmers who went on to make major independent contributions.

Echoing Bush and Licklider, Engelbart saw the potential for computers to become congenial tools that people would choose to use interactively:

> By 'augmenting human intellect' we mean increasing the capability of a man to approach a complex problem situation, to gain comprehension to suit his particular needs, and to derive solutions to problems.... By 'complex situations' we include the professional problems of diplomats, executives, social scientists, life scientists, physical scientists, attorneys, designers.... We refer to a way of life in an integrated domain where hunches, cut-and-try, intangibles, and the human 'feel for a situation' usefully coexist with powerful concepts, streamlined terminology and notation, sophisticated methods, and high-powered electronic aids.
>
> **(Engelbart 1962, p. 1)**

Engelbart used ARPA funding to rapidly develop and integrate an extraordinary set of prototype applications into his NLS system. In doing so, he conceptualized and implemented the foundations of word processing, invented or refined input devices including the mouse and the multikey control box, and made use of multidisplay environments that integrated text, graphics, and video in windows. These unparalleled advances were demonstrated in a sensational 90-minute live event at the 1968 Fall Joint Computer Conference in San Francisco, California (http://sloan.stanford.edu/MouseSite/1968Demo.html). The focal point for interactive systems research in the United States was moving from the East Coast to the West Coast.

Engelbart, an engineer, supported human factors testing to improve efficiency and reduce errors in skilled use, focusing on effects of fatigue and stress. Engelbart's systems required training. He felt that people should be willing to tackle a difficult interface if it delivered great power once mastered. Unfortunately, the lack of concern for initial usability was a factor in Engelbart's loss of funding. His demonstration became something of a success disaster: DARPA was impressed and installed NLS, but found it too difficult to use (Bardini 2000). Years later, the question "Is it more important to optimize for skilled use or initial use?" was widely debated, and still occasionally surfaces in HCI discussions.

Ted Nelson's Vision of Interconnectedness

In 1960, Ted Nelson, a graduate student in sociology who coined the term hypertext, founded Project Xanadu. The goal was an easily used computer network. In 1965, he published a paper titled "A File Structure for the Complex, the Changing and the Indeterminate." Nelson continued to write stirring calls for systems to democratize computing through a highly interconnected, extensible network of digital objects (e.g., Nelson 1973). Xanadu was never fully realized. Nelson did not consider the early World Wide Web to be an adequate realization of his vision, but lightweight technologies such as weblogs, wikis, collaborative tagging, and search enable many of the activities he envisioned.

Later, Nelson (1996) foresaw intellectual property issues arising in digital domains and coined the term "micropayment." Although his solutions were again not fully implemented, they drew attention to important issues.

From Documentation to Information Science

The late 1950s saw the last major investments in microfilm and other predigital systems. The most ambitious were military and intelligence systems, including Vannevar Bush's final efforts (Burke 1994). Documentalists began to see that declining memory costs would enable computation engines to become information-processing machines. The conceptual evolution was relatively continuous, but at the institutional level change could come swiftly. New professions—mathematicians and engineers—were engaged in technology development, new initiatives were launched that still bore few ties to contemporary librarianship or the humanities orientation of library schools. A new banner was needed.

Merriam Webster dates the term information science to 1960. Conferences held at Georgia Institute of Technology in 1961 are credited with shifting the focus from information as a technology to information as an incipient science. In 1963, chemist-turned-documentalist Jason Farradane taught the first information science courses at City University, London, United Kingdom. The profession of chemistry had long invested in organizing its literature systematically, and another chemist-turned-documentalist Allen Kent was at the center of a major information science initiative at the University of Pittsburgh (Aspray 1999). In the early 1960s, Anthony Debons, a psychologist and friend of Licklider, organized a series of NATO-sponsored congresses at Pittsburgh. Guided by Douglas Engelbart, these meetings centered on people and on how technology could augment their activities. In 1964 the Graduate Library School at the University of Pittsburgh became the Graduate School of Library and Information Sciences, and Georgia Tech formed a School of Information Science initially with one full-time faculty member.

Conclusion: Visions, Demos, and Widespread Use

Progress in HCI can be understood in terms of inspiring visions, conceptual advances that enable aspects of the visions to be demonstrated in working prototypes, and the evolution of design and application. The engine, enabling visions to be realized and soon thereafter to be widely deployed, was the relentless hardware advance that produced devices that were millions of times more powerful than the much more expensive systems designed and used by the pioneers.

At the conceptual level, much of the basic foundation for today's graphical user interfaces (GUIs) was in place by 1965. However, at that time it required individual use of a US$10-million custom-built machine. Pew (2003, p. 3) describes the 1960 Digital Equipment Corporation (DEC) PDP-1 as a breakthrough, "truly a computer with which an individual could interact." The PDP-1 came with a CRT display, keyboard, light pen, and paper tape reader. It cost about US$1 million and had the capacity that a Radio Shack TRS 80 had 20 years later. It required considerable technical and programming support. Even the PDP-1 could only be used by a few fortunate researchers.

Licklider's man–computer symbiosis, Engelbart's augmenting human intellect, and Nelson's "conceptual framework for man–machine everything" described a world that did not exist. It was a world in which attorneys, doctors, chemists, and designers chose to become hands-on users of computers. For some time to come, the reality would be that most hands-on users were computer operators engaged in routine, nondiscretionary tasks. As for the visions, 40 years later some of the capabilities are taken for granted, some are just being realized, and others remain elusive.

1965–1980: HUMAN–COMPUTER INTERACTION PRIOR TO PERSONAL COMPUTING

Control Data Corporation launched the transistor-based 6000 series computer in 1964. In 1965, commercial computers based on integrated circuits arrived with the IBM System/360. These powerful systems, later called mainframes to distinguish them from minicomputers, firmly established computing in the business realm. Each of the three computing roles—operation, management, and programming—became a significant profession.

Operators still interacted directly with computers for routine maintenance and operation, and as time-sharing developed, hands-on use expanded to include data entry and other repetitive tasks. Managers and systems analysts oversaw hardware acquisition, software development, operation, and the use of output. They were usually not hands-on users, although people who relied on printed output and reports did call themselves "computer users."

Apart from those working in research settings, few programmers were direct users until late in this period. Many prepared flowcharts and wrote programs on paper forms. Keypunch operators then punched the program instructions onto cards, which were sent to computer centers for computer operators to load into the computer and run. Printouts and other output were picked up later. Many programmers used computers directly when they could, but the cost generally dictated more efficient division of labor.

We are focusing on broad trends. Business computing took off in the mid-1960s, although the 1951 LEO I was probably the first commercial business computer. This interesting venture, which ended with the arrival of the mainframe era, is detailed in Wikipedia (under 'LEO computer') and the books and articles referenced there.

Human Factors and Ergonomics Embrace Computer Operation

In 1970, Brian Shackel founded the Human Sciences and Advanced Technology (HUSAT) center at Loughborough University in Leicestershire, the United Kingdom, which is devoted to ergonomics research that emphasizes HCI. Sid Smith and other human factors engineers worked on input and output issues, such as the representation of information on displays (e.g., Smith, Farquhar, and Thomas 1965) and computer-generated speech (Smith and Goodwin 1970). The Computer Systems Technical Group (CSTG) of the HFS was formed in 1972, and soon it was the largest technical group in the society.

The general *Human Factors* journal was joined in 1969 by the computer-focused *International Journal of Man–Machine Studies (IJMMS)*. The first widely read HCI book was James Martin's (1973) *Design of Man–Computer Dialogues*. Martin's comprehensive survey of interfaces for operation and data entry began with an arresting opening chapter that described a world in transition. Extrapolating from declining hardware prices, he wrote, "The terminal or console operator, instead of being a peripheral consideration, will become the tail that wags the whole dog.… The computer industry will be forced to become increasingly concerned with the usage of people, rather than with the computer's intestines" (pp. 3–4).

In the mid-1970s, U.S. government agencies responsible for agriculture and social security initiated large-scale data-processing system projects, described by Pew (2003). Although not successful, these efforts led to methodological innovations in the use of style guides, usability laboratories, prototyping, and task analysis.

In 1980, three significant HF&E books were published: two on VDT design (Cakir, Hart, and Stewart 1980; Grandjean and Vigliani 1980) and one general guideline (Damodaran, Simpson, and Wilson 1980). Drafts of a German work on VDT standards, made public in 1981, provided an economic incentive to design for human capabilities by threatening to ban noncompliant products. Later in the same year, a corresponding American National Standards Institute standards group for "office and text systems" was formed.

Information Systems (IS) Addresses the Management of Computing

Companies acquired expensive business computers to address major organizational concerns. Even when the principal concern was simply to appear modern (Greenbaum 1979), the desire to show benefits from a multimillion dollar investment could chain managers to a computer almost as tightly as were the operator and data entry "slaves." In addition to being expected to make use of output, they might encounter resistance to system acceptance.

Beginning in 1967, the journal *Management Science* published a column titled "Information Systems in Management Science." Early definitions of IS included "an integrated man–machine system for providing information to support the operation, management, and decision-making functions in an organization" (Davis 1974) and "the effective design, delivery, and use of information systems in organizations" (Keen 1980 quoted in Zhang, Nah, and Preece 2004). In 1968, an MIS center and degree program was established at Minnesota. It initiated several influential research streams and in 1977 launched *MIS Quarterly*, the leading journal in the field. The MIS field juxtaposed a focus on specific tasks in organizational settings with demands for general theory and precise measurement, a challenging combination.

A historical survey (Banker and Kaufmann 2004) identifies HCI as one of five major IS research streams and dates it back to Ackoff's (1967) paper describing challenges in handling computer-generated information. There was some research into hands-on operator issues such as data entry and error messages, but for a decade most HCI work in IS dealt with the users of information, typically managers. Research included the design of printed reports, but the drive for theory led to a strong focus on cognitive styles: individual differences in how people (notably managers) perceive and process information. Articles on HCI were published in the human factors-oriented *IJMMS* as well as management journals.

Sociotechnical approaches to system design (Mumford 1971, 1976; Bjørn-Andersen and Hedberg 1977) were developed in response to user difficulties and resistance. These involved educating representative workers about technological possibilities and involving them in design, in part to increase their acceptance of the resulting system. Late in this period, sophisticated views of the complex social and organizational dynamics around system adoption and use emerged (e.g., Kling 1980; Markus 1983).

Programming: Subject of Study, Source of Change

Even programmers who were not hands-on users were interacting with computers, and more than 1000 research papers on variables affecting programming performance were published in the 1960s and 1970s (Baecker and Buxton 1987). Most were studies of the behavior of programmers in isolation, independent of organizational context. Influential reviews of this work included Gerald Weinberg's landmark *The Psychology of Computer Programming* in 1971; Ben Shneiderman's *Software Psychology: Human Factors in Computer and Information Systems* in 1980; and Beau Sheil's 1981 review of studies of programming notation (conditionals, control flow, data types), practices (flowcharting, indenting, variable naming, commenting), and tasks (learning, coding, debugging).

Software developers changed the field through invention. In 1970, Xerox Palo Alto Research Center (PARC) was founded to advance computer technology by developing new hardware, programming languages, and programming environments. It attracted researchers and system builders from the laboratories of Engelbart and Sutherland. In 1971, Allen Newell of Carnegie Mellon University (CMU), Pennsylvania, proposed a project to PARC, which was launched 3 years later: "Central to the activities of computing—programming, debugging, etc.—are tasks that appear to be within the scope of this emerging theory [a psychology of cognitive behavior]" (Card and Moran 1986, p. 183).

Like HUSAT, which was also launched in 1970, PARC had a broad charter. HUSAT focused on ergonomics, anchored in the tradition of nondiscretionary use, one component of which was the human factors of computing. PARC focused on computing, anchored in visions of discretionary use, one component of which was also the human factors of computing. Researchers at PARC, influenced by cognitive psychology, extended the primarily perceptual motor focus of human factors to higher-level cognition, whereas HUSAT, influenced by sociotechnical design, extended human factors by considering organizational factors.

Computer Science: A New Discipline

Computer science departments in educational institutions emerged in the mid-1960s. ome originated in engineering, others in applied mathematics. From engineering, computer graphics was a specialization of particular relevance to HCI. Applied mathematics was the background of many early AI researchers, which has interacted with HCI in complex ways in subsequent years.

The expensive early machines capable of interesting work were funded without consideration to cost by branches of the military. Technical success was the sole evaluation criterion (Norberg and O'Neill 1996). Directed by Licklider, Sutherland, and their successors, ARPA played a major role. The need for heavy funding concentrated researchers in a few centers, which bore little resemblance to the batch and time-shared business computing environments of that era.

User needs differed: The technically savvy hands-on users in research settings did not press for low-level interface enhancements.

The computer graphics and AI perspectives that arose in these centers differed from the perspectives of HCI researchers who focused on less expensive, more widely deployed systems. Computer graphics and AI required processing power; hardware advances meant declining cost for the same high level of computation. For HCI researchers, hardware advances meant greater computing capability at the same low price. Only later would this difference diminish, when widely available machines could support graphical interfaces and some AI programs. Despite this gap, between 1965 and 1980 some computer science researchers focused on interaction, which is not surprising given that interaction was an element of the visions formulated in the previous decade.

Computer Graphics: Realism and Interaction

In 1968, Sutherland joined David Evans to establish an influential computer graphics laboratory at the University of Utah. The Utah Computer Science Department was founded in 1965, as part of computer science's first move into academic prominence. Utah contributed to the western migration as graduates of the laboratory, including Alan Kay and William Newman (and later Jim Blinn and Jim Clark), went to California. Most graphics systems at the time were built on the DEC PDP-1 and PDP-7. These expensive machines—the list price of a high-resolution display alone was equivalent to more than US$100,000 in today's dollars—were in principle capable of multitasking, but in practice most graphics programs required all of a processor's cycles.

In 1973 the Xerox Alto arrived, a powerful step toward realizing Alan Kay's vision of computation as a medium for personal computing (Kay and Goldberg 1977). The Alto was too expensive to be widely used—it was never widely marketed—and not powerful enough to support high-end graphics research, but it did support graphical interfaces of the kind Engelbart had prototyped. In doing so, the Alto signaled the approach of inexpensive, interactive, personal machines capable of supporting graphics. Computer graphics researchers had to decide whether to focus on high-end graphics or on more primitive features that would soon run on widely affordable machines.

William Newman, coauthor in 1973 of the influential *Principles of Interactive Computer Graphics*, described the shift in a personal communication: "Everything changed—the computer graphics community got interested in realism; I remained interested in interaction, and I eventually found myself doing HCI." He was not alone. Other graphics researchers whose focus shifted to broader interaction issues included Ron Baecker and Jim Foley. Foley and Wallace (1974, p. 462) identified requirements for designing "interactive graphics systems whose aim is good symbiosis between man and machine." The shift was gradual: A total of 18 papers in the first SIGGRAPH conference, in 1974, had the words "interactive" or "interaction" in their titles. A decade later, there would be none.

At Xerox, Larry Tesler and Tim Mott recognized that Alto could support a graphical interface accessible to untrained people. The latter point had not been important given the prior focus on trained, expert performance. By early 1974, Tesler and Mott had developed the Gypsy text editor. Gypsy and Xerox's Bravo editor developed by Charles Simonyi preceded and influenced Microsoft Word (Hiltzik 1999).

The focus on interaction was highlighted in 1976 when SIGGRAPH sponsored a 2-day workshop in Pittsburgh, User-Oriented Design of Interactive Graphics Systems (UODIGS). Participants who were later active in CHI included Jim Foley, William Newman, Ron Baecker, John Bennett, Phyllis Reisner, and Tom Moran. Licklider and Nicholas Negroponte presented vision papers. The conference was managed by the chair of Pittsburgh's computer science department. One participant was Anthony Debons, Licklider's friend who had helped build Pittsburgh's world-renowned information science program. The UODIGS'76 workshop arguably marked the end of a visionary period, embodying an idea whose time had not quite yet come. Licklider saw it clearly:

> Interactive computer graphics appears likely to be one of the main forces that will bring computers directly into the lives of very large numbers of people during the next two or three decades. Truly user-oriented graphics of sufficient power to be useful to large numbers of people has not been widely affordable, but it will soon become so and, when it does, the appropriateness and quality of the products offered will to a large extent determine the future of computers as intellectual aids and partners of people.
>
> **(Licklider 1976, p. 89)**

UODIGS was not repeated. Despite the stature of its participants, the 150-page proceedings were not cited. Not until 1981 was another user-oriented design conference held, after which such conferences were held every year. Application of graphics was not quite at hand; most HCI research remained focused on interaction driven by commands, forms, and full-page menus.

Artificial Intelligence: Winter Follows Summer

In the late 1960s and early 1970s AI burst onto the scene, promising to transform HCI. It did not go as planned. Logically, AI and HCI are closely related. What are intelligent machines for if not to interact with people? Research on AI has influenced HCI: Speech recognition and natural language are perennial HCI topics; expert, knowledge-based, adaptive, and mixed-initiative systems have been tried, as have applications of production systems, neural networks, and fuzzy logic. Today, human–robot interaction and machine learning are attracting much attention.

Although some AI features make it into systems and applications, frequent predictions that powerful machines would soon bring major AI technologies into wide use and thus become a focus of HCI research were not borne out. AI did not come into focus in HCI, and AI researchers showed limited interest in HCI.

To piece this together one requires a brief review of early AI history. The term "artificial intelligence" first appeared in a 1955 call by John McCarthy for a meeting on machine intelligence that was held in Dartmouth. In 1956, Alan Turing's prescient essay "Computing Machinery and Intelligence" attracted attention when it was reprinted in *The World of Mathematics*. (It was first published in 1950, as were Claude Shannon's "Programming a Computer for Playing Chess" and Isaac Asimov's *I, Robot*, which explored his three laws of robotics.) Newell and Simon presented their logic theory machine in 1956 and then focused on developing a general problem solver. McCarthy invented the LISP programming language in 1958 (McCarthy 1960).

Many AI pioneers were trained in mathematics and logic, where almost everything can be derived from a few axioms and a small set of rules. Mathematical ability is considered a high form of intelligence, even by non-mathematicians. AI researchers anticipated that machines that operate logically and tirelessly would achieve high levels of intelligence—applying a small set of rules to a limited number of objects. Early AI focused on theorem-proving and games and problems that had a strong logical focus, such as chess and go. McCarthy (1988), who espoused predicate calculus as a foundation for AI, summed it up as follows:

> As suggested by the term 'artificial intelligence', we were not considering human behavior except as a clue to possible effective ways of doing tasks. The only participants who studied human behavior were Newell and Simon. (The goal) was to get away from studying human behavior and consider the computer as a tool for solving certain classes of problems. Thus, AI was created as a branch of computer science and not as a branch of psychology.

Unfortunately, by ignoring psychology, mathematicians overlooked the complexity and inconsistency that mark human beings and our social constructs. Underestimating the complexity of intelligence, they overestimated the prospects for creating it artificially. Hyperbolic predictions and AI have been close companions. In the summer of 1949 the British logician and code breaker Alan Turing wrote in the *London Times*:

> I do not see why [the computer] should not enter any one of the fields normally covered by the human intellect, and eventually compete on equal terms. I do not think you can even draw the line about sonnets, though the comparison is perhaps a little bit unfair because a sonnet written by a machine will be better appreciated by another machine.

Optimistic forecasts by the 1956 Dartmouth workshop participants attracted considerable attention. When they collided with reality, a pattern was established that was to play out repeatedly. Hans Moravec (1998) wrote:

> In the 1950s, the pioneers of AI viewed computers as locomotives of thought, which might outperform humans in higher mental work as prodigiously as they outperformed them in arithmetic, if they were harnessed to the right programs.… By 1960 the unspectacular performance of the first reasoning and translation programs had taken the bloom off the rose.

A significant part of the pattern is that HCI thrives on resources that are freed when interest in AI declines. In 1960, with the bloom wearing off the AI rose, the managers of MIT's Lincoln Laboratory looked for new uses for the massive government-funded TX-0 and TX-2 computers. Ivan Sutherland's Sketchpad and early computer graphics were a result.

The response to Sputnik reversed the downturn in AI prospects. Licklider, as director of ARPA's IPTO (1962–1964), provided extensive support for computer science in general and AI in particular. MIT's Project Mac, founded in 1963 by Marvin Minsky and others, initially received US$13 million per year, rising to US$24 million in 1969. ARPA sponsored the AI Laboratory at SRI, AI research at CMU, and Nicholas Negroponte's Machine Architecture Group at MIT. A dramatic early achievement, SRI's Shakey the Robot, was featured in articles in *Life* (Darrach 1970) and *National Geographic* (White 1970). Given a simple but nontrivial task, Shakey could apparently go to the desired location, scan and reason about the surroundings, and move objects as needed to accomplish the goal (for Shakey at work, see http://www.ai.sri.com/shakey/).

In 1970, Negroponte outlined a case for machine intelligence: "Why ask a machine to learn, to understand, to associate courses with goals, to be self-improving, to be ethical—in short, to be intelligent?" He noted common reservations, "People generally distrust the concept of machines that approach (and thus why not pass?) our own human intelligence," and identified a key problem: "Any design procedure, set of rules, or truism is tenuous, if not subversive, when used out of context or regardless of context." This insight, that it is risky to apply algorithms without understanding the situation at hand, led Negroponte to a false inference: "*It follows that a mechanism must recognize and understand the context before carrying out an operation*." (Negroponte 1970, p. 1; my italics).

A perfectly reasonable alternative is that the mechanism is guided by humans who understand the context: Licklider's human–machine symbiosis. Overlooking this, Negroponte built a case for an ambitious research program:

> Therefore, a machine must be able to discern changes in meaning brought about by changes in context, hence, be intelligent. And to do this, it must have a sophisticated set of sensors, effectors, and processors to view the real world directly and indirectly.… A paradigm for fruitful conversations must be machines that can speak and respond to a natural language.… But, the tete-à-tete [*sic*] must be even more direct and fluid; it is gestures, smiles, and frowns that turn a conversation into a dialogue.… Hand waving often carries as much meaning as text. Manner carries cultural information: The Arabs use their noses, the Japanese nod their heads.… Imagine a machine that can follow your design methodology and at the same time discern and assimilate your conversational idiosyncrasies. This same machine after observing

> your behavior could build a predictive model of your conversational performance. Such a machine could then reinforce the dialogue by using the predictive model to respond to you in a manner that is in rhythm with your personal behavior and conversational idiosyncrasies.… The dialogue would be so intimate—even exclusive—that only mutual persuasion and compromise would bring about ideas, ideas unrealizable by either conversant alone. No doubt in such a symbiosis it would not be solely the human designer who would decide when the machine is relevant (pp. 1–13).

The same year, Negroponte's MIT colleague Minsky went further, as reported in *Life*:

> In from three to eight years we will have a machine with the general intelligence of an average human being. I mean a machine that will be able to read Shakespeare, grease a car, play office politics, tell a joke, and have a fight. At that point, the machine will begin to educate itself with fantastic speed. In a few months, it will be at genius level and a few months after that its powers will be incalculable.
>
> **(Darrach 1970, p. 60)**

Other AI researchers told Darrach that Minsky's timetable was ambitious: "Give us 15 years was a common remark—but all agreed that there would be such a machine and that it would precipitate the third Industrial Revolution; wipe out war and poverty; and roll up centuries of growth in science, education, and the arts" (Darrach 1970, p. 60).

Such predictions were common. In 1960, Nobel laureate and AI pioneer Herb Simon wrote: "Machines will be capable, within 20 years, of doing any work that a man can do." (Simon 1960, p. 38). Five years later, I. J. Good, an Oxford mathematician, wrote, "The survival of man depends on the early construction of an ultraintelligent machine" that "could design even better machines; there would then unquestionably be an 'intelligence explosion', and the intelligence of man would be left far behind" (Good 1965, pp. 31–33).

The Darrach article ended by quoting Ross Quillian:

> I hope that man and these ultimate machines will be able to collaborate without conflict. But if they can't, we may be forced to choose sides. And if it comes to choice, I know what mine will be. My loyalties go to intelligent life, no matter in what medium it may arise".
>
> **(Darrach 1970, p. 68)**

It is important to understand the anxieties of the time and the consequences of such claims. The world had barely avoided a devastating thermonuclear war during the Cuban missile crisis of 1962. Leaders seemed powerless to defuse the Cold War. Responding to a sense of urgency, ARPA initiated major programs in speech recognition and natural language understanding in 1971.

Ironically, central to funding this research was a psychologist not wholly convinced by the vision. Citing an Air Force study that predicted that intelligent machines might take 20 years to arrive, Licklider (1960) noted that in this interval HCI would be useful: "That would leave, say, 5 years to develop man–computer symbiosis and 15 years to use it. The 15 may be 10 or 500, but those years should be intellectually the most creative and exciting in the history of mankind." Ten to five hundred years represent breathtaking uncertainty. Recipients of Licklider's funding were on the optimistic end of this spectrum.

Five years later, disappointed with the progress, ARPA discontinued speech and language support—for a while. In Europe, a similar story unfolded. Through the 1960s, AI research expanded in Great Britain. A principal proponent was Turing's former colleague Donald Michie. Then in 1973 the Lighthill report, commissioned by the Science and Engineering Research Council, reached generally negative conclusions about AI's prospects for scaling up to address real-world problems. Almost all government funding was cut off.

The next decade was an AI winter, a recurring season in which research funding is withheld due to disillusionment over unfulfilled promises. The bloom was again off the rose, but it would prove to be a hardy perennial (Grudin 2009).

Library Schools Embrace Information Science

Early information science research and studies of "human information behavior" were initiated in the 1960s and 1970s, which focused on scholarship and application in science and engineering (Fidel 2011). The response to Sputnik proved that Big Science research did not end when the war ended. Aligning their work with national priorities became a priority for many researchers.

The terms "information science,""information technology," and "information explosion" swept into use. The Pittsburgh and Georgia Tech programs flourished. Pittsburgh created the first information science PhD program in the United States in 1970, identifying humans "as the central factor in the development of an understanding of information phenomena" (Aspray 1999, p. 12). The program balanced behavioral sciences (psychology, linguistics, communication) and technical grounding (automata theory, computer science). In 1973, Pittsburgh established the first information science department. Its program developed a strong international reputation. Slowly, the emphasis shifted from behavior to technology. On being awarded a major National Science Foundation (NSF) center grant in 1966, the Georgia Tech school expanded. In 1970 it became a PhD-granting school, rechristened as Information and Computer Science.

In 1968, the American Documentation Institute became the American Society for Information Science, and 2 years later the journal *American Documentation* became *Journal of the American Society for Information Science*. In 1978, the ACM Special Interest Group on Information Retrieval (SIGIR) was formed. It launched an annual conference for "Information Storage and Retrieval" (since 1982, "Information Retrieval"), modeled on a 1971 conference. In 1984, the American Library Association belatedly embraced the i-word by creating the Association for Library and Information Science Education (ALISE), which convened an annual research conference.

By 1980, schools at over a dozen universities had added the word information to their titles. Many were library school transitions. Delivery on the promise of transformative technology lagged, however. For example, from 1965 to 1972 the Ford and Carnegie Foundations, NSF, DARPA, and the American Newspaper Publishers Association invested over US$30 million in MIT's Project Intrex (Burke 1998). The largest nonmilitary information research project of its time, Intrex was to be the library of the future. Online catalogs were to include up to 50 index fields per item, accessible on CRT displays, with full text of books and articles converted to microfilm and read via television displays. None of this proved feasible.

Terminal-based computing costs declined. The ARPANET debuted in 1969, and supported e-mail in 1971 and file sharing in 1973. This spurred visions of a "network society" of the future (Hiltz and Turoff 1978).

As an aside, the technological optimism that marked this era lacked the nuanced psychological insight of E. M. Forster who in 1909 anticipated AI and networking developments in his remarkable story *The Machine Stops*.

1980–1985: DISCRETIONARY USE COMES INTO FOCUS

In 1980, most HF&E and IS research focused on the down-to-earth business of making efficient use of expensive mainframes. The beginning of a major shift went almost unnoticed. Less expensive but highly capable minicomputers based on LSI technology enabled DEC, Wang Laboratories, and Data General to make inroads into the mainframe market. At the low end, home computers gained traction. Students and hobbyists were drawn to these minis and micros, creating a population of hands-on discretionary users. There were experimental trials of online library catalogs and electronic journals.

Then, between 1981 and 1984 a flood of innovative and powerful computers were released: Xerox Star; IBM PC; Apple Lisa; LISP machines from Symbolics and Lisp Machines, Inc. (LMI); workstations from Sun Microsystems and Silicon Graphics; and the Apple Macintosh. On January 1, 1984, AT&T's breakup into competing companies took effect. AT&T had more employees and more customers than any other U.S. company. It was a monopoly: Neither its customers nor its employees had discretion in technology use. Both AT&T and its Bell Laboratories research division had employed human factors research to improve training and increase efficiency. Suddenly freed from a ban on entering the computer business, AT&T launched the ill-fated Unix PC in 1985. AT&T and the new regional operating companies now faced customers who had choices, and their HCI focus broadened accordingly (Israelski and Lund 2003).

In general, lower-priced computers created markets for shrink-wrap software. For the first time, computer and software companies targeted significant numbers of nontechnical hands-on users who received little or no formal training. It had taken 20 years, but early visions were being realized. Nonprogrammers were choosing to use computers to do their work. The psychology of discretionary users intrigued two groups: (1) psychologists who liked to use computers and (2) technology companies who wanted to sell to discretionary users. Not surprisingly, computer and telecommunication companies started hiring a lot of experimental psychologists.

Discretion in Computer Use

Technology use lies on a continuum bracketed by the assembly-line nightmare of *Modern Times* and the utopian vision of completely empowered individuals. To use a technology or not to use it—sometimes we have a choice, other times we do not. On the phone, we may have to wrestle with speech recognition and routing systems. At home, computer use may be largely discretionary. The workplace often lies in between: Technologies are prescribed or proscribed, but we ignore some injunctions or obtain exceptions, we use some features but not others, and we join with colleagues to press for changes.

For early computer builders, work was more a calling than a job, but operation required a staff to carry out essential if less interesting tasks. For the first half of the computing era, most hands-on use was by people with a mandate. Hardware innovation, more versatile software, and steady progress in understanding the psychology of users and tasks—and transferring that understanding to software developers—led to hands-on users who had more choice regarding how they worked. Rising expectations played a role; people learned that software is flexible and expected it to be more congenial. Competition among vendors produced alternatives. With more emphasis on marketing to consumers came more emphasis on user-friendliness.

Discretion is not all-or-none. No one must use a computer, but many jobs and pastimes require it. People can resist, sabotage, or quit their jobs. However, a clerk or a systems administrator has less discretion than someone using technology for a leisure activity. For an airline reservation clerk, computer use is mandatory. For a traveler booking a flight, computer use is discretionary. This distinction, and the shift toward greater discretion, is at the heart of the history of HCI.

The shift was gradual. About 30 years ago, John Bennett (1979) predicted that discretionary use would lead to more emphasis on usability. The 1980 book *Human Interaction with Computers*, edited by Harold Smith and Thomas Green, perched on the cusp. It included an article by Jens Rasmussen, "The Human As a Systems Component," that covered the nondiscretionary perspective. One-third of the book covered research on programming. The remainder addressed "nonspecialist people," discretionary users who are not computer savvy. Smith and Green wrote, "It is not enough just to establish what computer systems can and cannot do; we need to spend just as much effort establishing what people can *and want to do*" (p. viii, italics in original).

A decade later, Liam Bannon (1991) noted broader implications of a shift "from human factors to human actors." The trajectory is not always toward choice. Discretion can be curtailed—for example, word processor use is now often a job requirement and not an alternative to using a typewriter. Even in an era of specialization, customization, and competition, the exercise of choice varies over time and across contexts. Discretion is only one factor, but an analysis of its role casts light on how HCI efforts differ and why they have remained distinct through the years.

Minicomputers and Office Automation

Cabinet-sized minicomputers that could support several people were available from the mid-1960s. By late 1970s, superminis such as the VAX 11/780 supported integrated suites of productivity tools. In 1980, DEC, Data General, and Wang Laboratories were growth companies near Boston.

A minicomputer could handle personal productivity tools or a database of moderate size. Users sat at terminals. With "dumb terminals," the central processor handled each keystroke. Other terminals had a processor that supported a user who entered a screenful of data, which was then on command sent as a batch to the central processor. These minis could provide a small group (or office) with file-sharing, word-processing, spreadsheet, and e-mail, and manage output devices. They were marketed as "office systems," "office automation (OA) systems," or "office information systems" (OIS).

The 1980 Stanford International Symposium on Office Automation marked the emergence of a research field that remained influential for a decade and then faded away. Douglas Engelbart contributed two papers to the proceedings of this symposium (Landau, Bair, and Siegman 1982). In the same year, the American Federation of Information-Processing Societies (AFIPS, the parent organization of ACM and Institute of Electrical and Electronics Engineers [IEEE] at the time) held the first of seven annual OA conferences and product exhibitions. Also in 1980, ACM formed the Special Interest Group on Office Automation (SIGOA), which launched the biennial Conference on Office Information Systems (COIS) 2 years later. In 1983, the journal *ACM Transactions on Office Information Systems (TOOIS)* emerged, which was 1 year after the emergence of the independent journal *Office: Technology and People*.

You might ask "what is all this with offices?" Minicomputers brought down the price of computers to fit into the budget of a small workgroup or an office. (The attentive reader will anticipate: The personal computer era is approaching.) Office Information Systems, which focused on the use of minicomputers, was positioned alongside MIS, which focused on mainframes. Its scope was reflected in the charter of *TOOIS*: database theory, AI, behavioral studies, organizational theory, and communications. Minis were accessible to database researchers. Digital's PDP series was a favorite with AI researchers until LISP machines flourished. Minis were familiar to behavioral researchers who used them to run and analyze psychology experiments. Computer-mediated communication (CMC) was an intriguing new capability: Networking was still rare, but people at different terminals of a minicomputer could exchange e-mail or chat in real time. Minis became interactive computers of choice for many organizations. As a consequence, Digital became the second largest computer company in the world and Dr. Wang the fourth wealthiest American.

Researchers were discretionary users, but few office workers chose their tools. The term "automation" was challenging and exciting to researchers, but it conjured up less pleasant images for office workers. Some researchers, too, preferred Engelbart's focus on augmentation rather than automation.

Papers in the SIGOA newsletter, COIS, and *TOOIS* included technical work on database theory, a modest number of AI papers (the AI winter had not yet ended), decision support and CMC papers from the IS community, and behavioral studies by researchers who later joined CHI. Papers on information systems were prevalent in the newsletter and technical papers in *TOOIS,* which also published numerous behavioral studies until the journal *Human–Computer Interaction* started in 1985.

Although OA/OIS research was eventually absorbed by other fields, it identified and called attention to important emerging topics, including hypertext, CMC, and collaboration support. OIS research was also allied with the technical side of information science, notably information retrieval and language processing.

The Formation of Association for Computing Machinery Special Interest Group on Computer–Human Interaction

Figure 1 identifies research fields that directly bear on HCI. Both HF and IS have distinct subgroups that focus on broad use of digital technologies. Relevant computer science research is concentrated in CHI, the subgroup primarily concerned with discretionary hands-on computer use. Other computer science influences—computer graphics, AI, office systems—have been described but are not included in Figure 1. The fourth field, information, began as support for specialists. It may come to exert the broadest influence of all.

Decreasing microcomputer prices encouraged discretionary hobbyists to use them. In 1980, as IBM prepared to launch the PC, a groundswell of attention on computer user behavior was building up. IBM, which like many hardware companies had not sold software separately, had decided to make software a product focus. Several cognitive psychologists joined an IBM group that included John Gould, who had been publishing human factors research since the late 1960s. They initiated empirical studies of programming and studies of software design and use. Other psychologists who in 1980 led recently formed HCI groups were Phil Barnard at the Medical Research Council Applied Psychology Unit in Cambridge, England; Tom Landauer at Bell Laboratories; Donald Norman at the University of California, San Diego; and John Whiteside at Digital Equipment Corp.

Xerox PARC and CMU collaborators continued research that led to an exceptionally influential project. The 1981 Star, with a carefully designed GUI, was not a commercial success

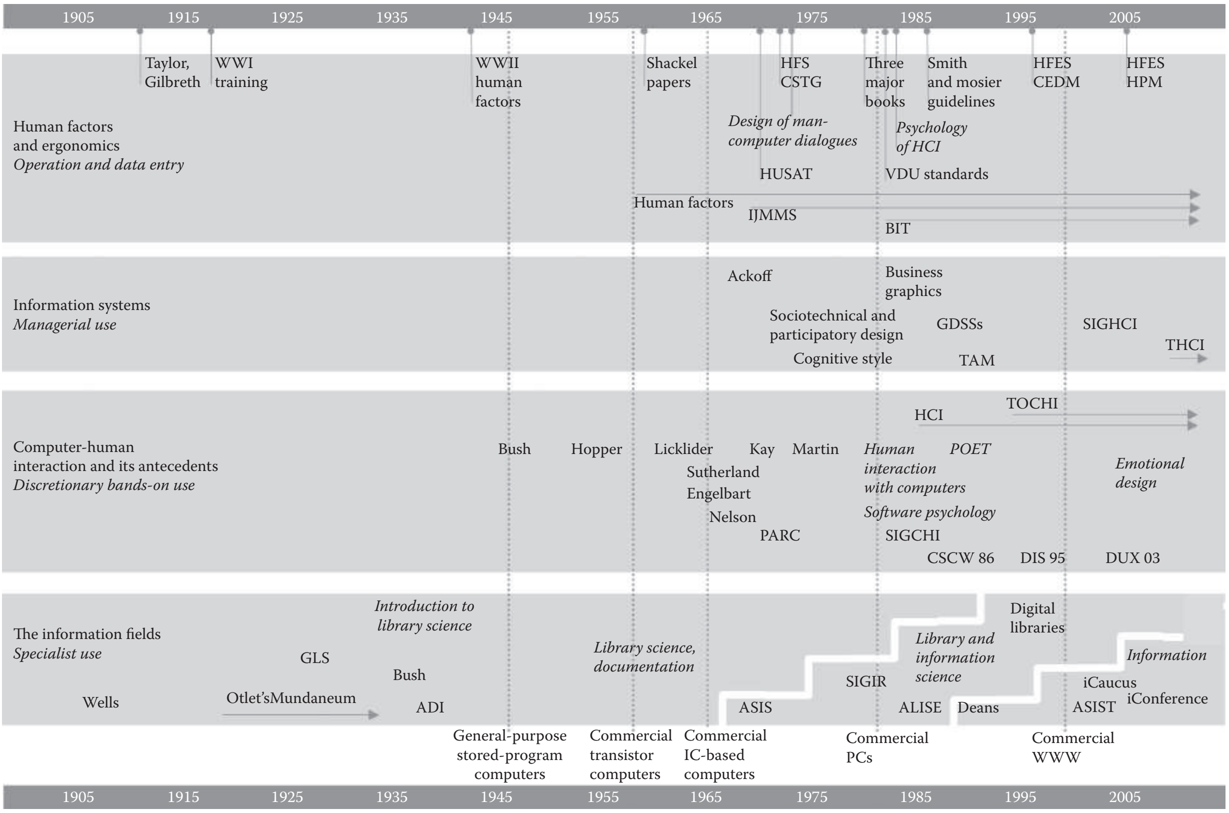

FIGURE 1 Four fields with major human–computer interaction research threads: Acronym expansions are provided in the text.

(nor were a flurry of GUIs that followed, including the Apple Lisa), but it influenced researchers and developers—and the design of the Macintosh.

Communications of the ACM created a "Human Aspects of Computing" department in 1980. The next year, Tom Moran edited a special issue of *Computing Surveys* on "The Psychology of the Computer User." Also in 1981, the ACM Special Interest Group on Social and Behavioral Science Computing (SIGSOC) extended its workshop to cover interactive software design and use. In 1982, a conference in Gaithersburg, Maryland, on "Human Factors in Computing Systems" was unexpectedly well attended. Shortly afterward, SIGSOC shifted its focus to Computer-Human Interaction and changed its name to SIGCHI (Borman 1996).

In 1983, the first CHI conference attracted more than 1000 people. Half of the 58 papers were from the aforementioned seven research laboratories. Cognitive psychologists in industry dominated the program, although the Human Factors Society cosponsored the conference and contributed the program chair Richard Pew; committee members Sid Smith, H. Rudy Ramsay, and Paul Green; and several presenters. Brian Shackel and HFS president Robert Williges gave tutorials on the first day. The International Conference on Human–Computer Interaction (INTERACT), first held in London in 1984 and chaired by Shackel, drew HF&E and CHI researchers.

The first profession to become discretionary hands-on users was computer programming, as paper coding sheets were discarded in favor of text editing at interactive terminals, PCs, and small minicomputers. Therefore, many early CHI papers, by Ruven Brooks, Bill Curtis, Thomas Green, Ben Shneiderman, and others, continued the psychology-of-programming research thread. Shneiderman formed the influential HCI Laboratory (HCIL) at Maryland in 1983. IBM researchers also contributed, as noted by John Thomas in a personal communication (October 2003): "One of the main themes of the early work was basically that we in IBM were afraid that the market for computing would be limited by the number of people who could program complex systems, so we wanted to find ways for 'nonprogrammers' to be able, essentially, to program."

Many experimental psychologists undertook studies of text editing, a tool initially used primarily by programmers. Thomas Green remarked at INTERACT'84 that "text editors are the white rats of HCI." As personal computing spread, studies of other discretionary use contexts were conducted. Studies of programming gradually disappeared from HCI conferences.

CHI focused on novice use. Initial experience is particularly important for discretionary users and for vendors developing software for them. Novice users are also a natural focus when studying new technologies and a critical focus when more people take up computing each year compared with the year before.

Routinized heavy use was still widespread. Databases were used by airlines, banks, government agencies, and other organizations. This hands-on activity was rarely discretionary. Managers oversaw development and analyzed data, leaving data entry and information retrieval to people hired for those jobs. To improve data management tasks was a human factors undertaking. CHI studies of database use were few—I count three over a decade, all focused on novice or casual use.

Fewer European companies produced mass-market software. European HCI research focused on in-house development and use, as reflected in the journal *Behaviour & Information Technology*, which was launched in 1982 by Tom Stewart and published by Taylor & Francis in London. In his perceptive essay cited in the section "Discretion in Computer Use," Bannon urged that more attention be paid to discretionary use, yet criticized CHI's heavy emphasis on initial experience, reflecting the European perspective. At Loughborough University, HUSAT focused on job design (the division of labor between people and systems) and collaborated with the Institute for Consumer Ergonomics, particularly on product safety. In 1984, Loughborough initiated an HCI graduate program drawing on human factors, industrial engineering, and computer science.

The work of the early visionaries was unfamiliar to many CHI researchers who were helping realize some of the early visions. The 633 references in the 58 papers presented at CHI'83 included many authored by cognitive scientists, but Bush, Sutherland, and Engelbart were not cited. A few years later, more computer scientists familiar with the early work joined CHI, notably those working on interactive computer graphics. The psychologists eventually discovered and identified with the pioneers, who shared their concern for discretionary use. This conceptual continuity bestowed legitimacy on a young enterprise that sought to establish itself academically and professionally.

Divergence of Computer–Human Interaction and Human Factors

> Hard science, in the form of engineering, drives out soft science, in the form of human factors.
>
> **Newell and Card (1985, p. 212)**

Between 1980 and 1985, Card, Moran, and Newell (1980a,b) introduced a "keystroke-level model for user performance time with interactive systems," followed by the cognitive model goals, operators, methods, and selection rules (GOMS) in their landmark 1983 book *The Psychology of Human–Computer Interaction*. This work was highly respected by the cognitive psychologists prevalent in CHI at the time. However, these models did not address discretionary, novice use. They focused on the repetitive expert use studied in human factors. In fact, GOMS was explicitly positioned to counter the latter field's stimulus–response bias: "Human-factors specialists, ergonomists, and human engineers will find that we have synthesized ideas from modern cognitive psychology and AI with the old methods of task analysis.… The user is not an operator. He does not operate the computer, he communicates with it" (Newell and Card 1985, p. viii.).

Newell and Card noted that HFs had a role in design, but continued: "Classical human factors … has all the earmarks of second-class status. (Our approach) avoids continuation of the classical human-factors role (by transforming) the psychology of the interface into a hard science" (p. 221).

In 2004, Card noted in an e-mail discussion: "Human Factors was the discipline we were trying to improve.… I personally changed the (CHI conference) call in 1986, so as to emphasize computer science and reduce the emphasis on cognitive science, because I was afraid that it would just become human factors again."

Ultimately, human performance modeling drew a modest but fervent CHI following. Key goals differed from those of other researchers and many practitioners. "The central idea behind the model is that the time for an expert to do a task on an interactive system is determined by the time it takes to do the keystrokes," wrote Card, Moran, and Newell (1980b, p. 397). Modeling was extended to a range of cognitive processes, but it was most useful in helping to design for nondiscretionary users such as telephone operators engaged in repetitive tasks (e.g., Gray et al. 1990). Its role in augmenting human intellect was unclear.

CHI and HFS moved apart, although "Human Factors in Computing Systems" remains the CHI conference subtitle. They were never highly integrated. Most of the cognitive psychologists had turned to HCI after earning their degrees and were unfamiliar with the human factors literature. The Human Factors Society did not again cosponsor CHI. Its researchers disappeared from the CHI program committee. Most CHI researchers who previously published in the human factors literature shifted to CHI, *Communications of the ACM*, and the journal *Human–Computer Interaction* launched in 1985 by Thomas Moran and published by Erlbaum, a publisher of psychology books and journals.

The shift was reflected at IBM T.J. Watson Research Center. John Gould and Clayton Lewis authored a CHI'83 paper that nicely framed the CHI focus on user-centered, iterative design based on prototyping. Cognitive scientists at Watson helped shape CHI, but Gould's principal focus remained human factors; he served as HFS president 4 years later. Reflecting the broader change, in 1984 the Human Factors Group at Watson began to dissolve and a User Interface Institute emerged.

CHI researchers, identifying with "hard" science or engineering, adopted the terms "cognitive engineering" and "usability engineering." In the first paper presented at CHI'83, "Design Principles for Human–Computer Interfaces," Donald Norman (1983) applied engineering techniques to discretionary use, creating "user satisfaction functions" based on technical parameters. These functions would not hold up long—people are fickle, yesterday's satisfying technology is not as gratifying today—but for years CHI emulated engineering, downplaying design, marketing, and other aspects of how humans interact with technology.

Workstations and Another Artificial Intelligence Summer

High-end workstations from Apollo, Sun, and Silicon Graphics appeared between 1981 and 1984. Graphics researchers no longer had to flock to heavily financed laboratories (notably MIT and Utah in the 1960s; MIT, New

York Institute of Technology, and PARC in the 1970s). Workstations were too expensive to reach a mass market, so graphics research that focused on photorealism and animation, which required the processing power of workstations, did not directly exert a broad influence on HCI.

The Xerox Star (formally named Office Workstation), Apple Lisa, and other commercial GUIs appeared, but when the first CHI conference was held in December 1983 none were commercial successes. They cost too much or ran on processors that were too weak to exploit graphics effectively.

In 1981, Symbolics and LMI introduced workstations optimized for the LISP programming language favored by most AI researchers. The timing was fortuitous. In October of that year, a conference on next-generation technology was held in the National Chamber of Commerce auditorium in Tokyo, Japan, and in 1982 the Japanese government established the Institute for New Generation Computer Technology (ICOT) and a 10-year fifth generation project focused on AI. AI researchers in Europe and the United States sounded the alarm. Donald Michie of Edinburgh saw a threat to Western computer technology, and in 1983 Ed Feigenbaum of Stanford and Pamela McCorduck wrote: "The Japanese are planning the miracle product.… They're going to give the world the next generation—the Fifth Generation—of computers, and those machines are going to be intelligent.… We stand, however, before a singularity, an event so unprecedented that predictions are almost silly.… Who can say how universal access to machine-intelligence—faster, deeper, better than human intelligence—will change science, economics, and warfare, and the whole intellectual and sociological development of mankind?" (pp. 8–9, 287).

Parallel distributed processing (often called neural networks) models also seized the attention of researchers and the media. Used for modeling phenomena including signal detection, motor control, and semantic processing, neural networks represented conceptual and technical advances over earlier AI work on perceptrons. Their rise was tied to the new generation of minicomputers and workstations, which had the power to support simulation experiments. Production systems, a computer-intensive AI modeling approach with a psychological foundation, developed at CMU, also gained the attention of researchers.

These developments triggered an AI gold rush. As with actual gold rushes, most of the money was made by those who outfitted and provisioned the prospectors, although generous government funding again flowed to the actual researchers. The European ESPRIT and UK Alvey programs invested over US$200 million per year starting in 1984 (Oakley 1990). In the United States, funding for the DARPA Strategic Computing AI program, begun in 1983, rose to almost US$400 million in 1988 (Norberg and O'Neill 1996). Investment in AI by 150 U.S. companies was estimated at about US$2 billion in 1985 (Kao 1998).

The unfulfilled promises of the past led to changes this time around. General problem solving was emphasized less, whereas domain-specific problem solving was emphasized more. Terms such as intelligent knowledge-based systems, knowledge engineering, expert systems, machine learning, language understanding, image understanding, neural networks, and robotics were often favored over AI.

In 1983, Raj Reddy of CMU and Victor Zue of MIT criticized the mid-1970s abandonment of speech-processing research, and soon funds again became plentiful for these research topics (Norberg and O'Neill 1996, p. 238). Johnson (1985) estimated that 800 corporate employees and 400 academics were working on natural language–processing research. Commercial natural language–understanding (NLU) interfaces to databases such as AI Corporation's Intellect and Microrim Clout appeared.

The optimism is illustrated by two meticulously researched Ovum reports on speech and language processing (Johnson 1985; Engelien and McBride 1991). In 1985, speech and language product "revenue" was US$75 million, comprising mostly income from grants and investor capital. That year, Ovum projected that sales would reach US$750 million by 1990 and US$2.75 billion by 1995. In 1991 sales were under US$90 million, but hope springs eternal and Ovum forecasts US$490 million for 1995 and US$3.6 billion for 2000.

About 20 U.S. corporations banded together, jointly funding the Microelectronics and Computer Technology Corporation (MCC). U.S. antitrust laws were relaxed to facilitate this cooperation. MCC embraced AI, reportedly becoming the leading customer for both Symbolics and LMI. MCC projects included two parallel NLU efforts; work on intelligent advising; and CYC (as in encyclopedic, and later spelled Cyc), Douglas Lenat's ambitious project to build a commonsense knowledge base that other programs could exploit. In 1984, Lenat predicted that by 1994 CYC would be intelligent enough to educate itself. Five years later, CYC was reported to be on schedule and about to "spark a vastly greater renaissance in [machine learning]" (Lenat 1989, p. 257).

Knowledge engineering involved human interaction. This could have brought AI closer to HCI, but AI researchers who were interested in representation and reasoning were frustrated by the difficulty of eliciting knowledge from experts. As many AI systems were aimed at nondiscretionary use, this created opportunities for HF&E, especially in Europe where funding directives dictated work that spanned technical and behavioral concerns. The journal *IJMMS* became a major outlet for both HF&E and AI researchers in the 1980s.

Interaction of AI and CHI was limited. CHI'83 and CHI'85 had a few sessions on speech and language, cognitive modeling, knowledge-based help, and knowledge elicitation. Not many AI researchers and developers worried about usability. They loved powerful tools such as EMACS and UNIX, forgetting the painful weeks required to learn the badly designed command languages. In general, AI technologies did not succeed in the marketplace. Before it disappeared, AI Corporation's primary customer for the database interface Intellect was the government, where discretionary use was not the norm.

1985–1995: GRAPHICAL USER INTERFACES SUCCEED

> "There will never be a mouse at the Ford Motor Company."
> **A high-level acquisition manager, 1985 (personal communication)**

When graphical user interfaces finally succeeded commercially, human–computer interaction was transformed. As with previous disruptive shifts—to stored programs and to interaction based on commands, full-screen forms, and full-screen menus—some people were affected before others. GUIs were particularly attractive to consumers, to new or casual users. Their success immediately transformed CHI, but only after Windows 3.0 succeeded in 1990 did GUIs influence the government agencies and business organizations that are the focus of HF&E and IS researchers. By 1990, the technology was better understood and thus less disruptive. The early 1990s also saw the maturation of local area networking and the Internet, producing a second transformation: computer-mediated communication and information sharing.

Computer–Human Interface Embraces Computer Science

Apple launched the Macintosh with a 1984 Super Bowl ad describing office work, but sales did not follow and by mid-1985 Apple was in trouble. Then Macs appeared with four times as much random access memory (RAM), which was sufficient to manage Aldus PageMaker, Adobe Postscript, the Apple LaserWriter, and Microsoft's Excel and Word for Macintosh as they were released. The more powerful Mac Plus arrived in January 1986. Rescued by hardware and software advances, the Mac succeeded where many commercial GUIs before it could not. It was popular with consumers and became the platform for desktop publishing.

Within CHI, GUIs were initially controversial. They had disadvantages: An extra level of interface code increased development complexity and created reliability challenges. They consumed processor cycles and distanced users from the underlying system that, many believed, experienced users must eventually master. Carroll and Mazur (1986) showed that GUIs confused and created problems for people familiar with existing interfaces. An influential 1986 essay on direct manipulation interfaces by Hutchins, Hollan, and Norman concluded that "it is too early to tell" how GUIs would fare. The GUIs could well prove useful for novices, they wrote, but "we would not be surprised if experts are *slower* with Direct Manipulation systems than with command language systems" (pp. 119-121, italics in the original). Given that most prior HCI research had focused on expert use, this insight seemed significant. However, first-time use proved critical in the rapidly expanding consumer market, and hardware and software improvements overcame some early limitations. GUIs were here to stay. CHI was soon transformed. Previously active research topics, including command naming, text editing, and the psychology of programming, were abandoned. More technical topics such as "user interface management systems" became significant.

Viewed from a higher plane, psychology gave way to computer science as the driving force in interaction design. Researchers had strived for a comprehensive, theoretical, psychological framework based on formal experiments (Newell and Card 1985; Carroll and Campbell 1986; Long 1989; Barnard 1991). Such a framework was conceivable for constrained command- and form-based interaction but could not be scaled to design spaces that included color; sound; animation; and an endless variety of icons, menu designs, and window arrangements. The new mission was to identify the most pressing problems and find satisfactory rather than optimal solutions. Rigorous experimentation, a skill of cognitive psychologists, gave way to quicker, less precise assessment methods championed by Jakob Nielsen (1989; Nielsen and Molich 1990).

Exploration of the dynamically evolving, relatively unconstrained design space required software engineering expertise. The late 1980s saw an influx of computer scientists to the CHI community. HCI entered the curricula of many computer science programs. CHI became a natural home to some computer scientists working on interactive graphics, software engineers interested in interaction, and AI researchers working on speech recognition, language understanding, and expert systems. In 1994, ACM launched the journal *Transactions on Computer–Human Interaction (TOCHI).* Early PCs and Macs were not easily networked, but as the use of local area networks spread, CHI's focus expanded to include collaboration support. This brought it into contact with efforts in MIS and OA research, discussed in the section on Collaboration Support below.

Human Factors and Ergonomics Maintains a Nondiscretionary Use Focus

Human factors and ergonomics research continued to respond to the needs of government agencies, the military, aviation industry, and telecommunications. Governments are the largest consumers of computing, for census, tax, social security, health and welfare, power plant operation, air traffic control, ground control for space missions, military logistics, text and voice processing for intelligence, and so on. The focus is on skilled use—users are assigned technology and trained if necessary. For routine data entry and other tasks, small efficiency gains in individual transactions can yield large benefits over time, justifying the effort to make improvements that might not be noticed by discretionary users. After SIGCHI formed, HFS undertook a study to see how CHI would affect membership in its Computer Systems Technical Group. An unexpectedly small effect was found (Richard Pew, personal communication; September 15, 2004). They had different goals.

Government agencies promoted the development of ergonomic standards to help in defining system requirements for competitive bidding while remaining at arms' length from potential developers, who of course better understood technical possibilities and helped with standards development.

Compliance with standards could then be specified in a contract. In 1986, Sid Smith and Jane Mosier published the last of a series of government-sponsored interface guidelines, with 944 design guidelines organized into sections titled Data Entry, Data Display, Data Transmission, Data Protection, Sequence Control, and User Guidance. The authors recognized that GUIs would expand the design space beyond the reach of this already cumbersome document that omitted icons, pull-down and pop-up menus, mice button assignments, sound, animation, and so on. Smith and Mosier foresaw that requirements definition must shift to specify predefined interface styles and design processes rather than features that would be built from scratch.

DARPA's heavily funded strategic computing AI program set out to develop an autonomous land vehicle, a pilot's associate, and a battle management system. All raised human factors research issues. These systems were to include interactive technologies such as speech recognition, language understanding, and heads-up displays. People might avoid these technologies when given a choice, but pilots guiding autonomous vehicles and officers under stressful conditions might have no better alternative. Speech and language technologies have other nondiscretionary potential, some of it civilian: for translators and intelligence analysts, when a phone system provides no alternative, when a disability limits keyboard use, or when hands are otherwise occupied.

Information Systems Extends Its Range

Although GUIs were not quickly adopted by organizations, spreadsheets and business graphics (charts and tables) were important to managers and thus the foci of IS research. Remus (1984) contrasted tabular and graphic presentations and Benbasat and Dexter (1985) added color as a factor, although color displays were rare in the 1980s. Many studies contrasted online and paper presentations, because most managers worked with printed reports. Although research into individual cognitive styles was abandoned in the early 1980s following a devastating critique on the topic (Huber 1983), the concept of cognitive fit between task and tool was introduced to explain apparently contradictory results in the adoption literature (Vessey and Galletta 1991).

A series of symposia on human factors in IS was initiated in 1986 by Jane Carey, leading to several books on the subject (e.g., Carey 1988). Topics included user interaction with information, design and development and, as corporate adoption of minicomputers and intranets matured, communication and collaboration, including studies of e-mail use.

The involvement of end users in the development process was actively discussed in IS, but rarely practiced outside of the sociotechnical design and the participatory design movements discussed below in the section "Participatory Design and Ethnography" (Friedman 1989). Hands-on managerial use was atypical in this period, but it was central to group decision support systems (GDSS) research. Central to GDSS was support for meetings, including brainstorming, idea organization, and online voting features. GDSS emerged from decision support systems, aimed at supporting individual executives or managers, and later evolved into group support systems. Computer-supported meeting facility research was conducted in the mid-1980s in several laboratories (e.g., Begeman et al. 1986; DeSanctis and Gallupe 1987; Dennis et al. 1988). Extensive research at the University of Arizona is summarized by Nunamaker et al. (1997). These systems were initially too expensive to be mass-market products; hence, the focus was on "decision makers," and research was conducted primarily in schools of management, not computer science departments or software companies. GDSS was a major IS contribution to computer-supported cooperative work (CSCW), discussed in the next section. In 1990, three companies began marketing GDSSs, including IBM and a University of Arizona spin-off, although without much success.

The Technology Acceptance Model (TAM) introduced by Davis (1989) led to considerable IS research. TAM and its offspring focus on perceived usefulness and perceived usability to improve "white-collar performance" that is "often obstructed by users' unwillingness to accept and use available systems" (p. 319). "An element of uncertainty exists in the minds of decision makers with respect to the successful adoption," wrote Bagozzi, Davis, and Warshaw (1992, p. 664). Although TAM is a managerial view of individual behavior, it was influenced by Davis's exposure to early CHI usability research.

TAM is probably the most cited HCI work in IS. The management view of hands-on computer use as nondiscretionary was giving way as use spread to white-collar workers who could refuse to play. TAM's emphasis on *perceived* utility and usability is a key distinction: Consumers choose technologies that they are convinced will be useful; CHI researchers assume utility and focuses on the *experience* of usability. TAM researchers focus on utility and note that perceptions of usability can influence acceptance. CHI addressed usability a decade before TAM, albeit actual usability rather than perceived usability. Perception was a secondary 'user satisfaction' measure to CHI researchers, who believed (not entirely correctly) that measurable reduction in time, errors, questions, and training would eventually translate into positive perceptions. The word "acceptance," that is, the "A" in TAM, is not in the CHI vocabulary. Discretionary users adopt, they do not accept.

The IS and CHI communities rarely mixed. When CHI was over a decade old, *Harvard Business Review*, a touchstone for IS researchers, published "Usability: The New Dimension of Product Design" (March 1994). The article did not mention CHI at all. It concluded that "user-centered design is still in its infancy" (p. 149).

Collaboration Support: Office Information Systems Gives Way to Computer-Supported Cooperative Work

In the late 1980s, three research communities addressed small-group communication and information sharing: (1) OA/OIS, described above in the section "Minicomputers and Office Automation." (2) IS researchers building systems to support organizational decision making could, as computing costs declined, address group decision making more generally. (3) The proliferation of local area networks enabled some CHI researchers to move from individual productivity software to the quest for "killer apps" that would support teams.

OA/OIS led the way, but it declined and was fast disappearing by 1995. The Minicomputers, the platform for most OIS research, did not survive competition from PCs and workstations. The concept of office or group proved to be problematic: Organizations and individuals are persistent entities with goals and needs, but small groups often have ambiguous membership and undergo shifts in character as members join or depart. People in an organization who need to communicate often fall under different budgets, complicating acquisition decisions unless a technology is made available organization-wide.

The rapid shift was reflected in terminology use. First, "automation" fell out of favor. In 1986, ACM SIGOA shifted to SIGOIS and the annual AFIPS OA conferences were discontinued. By 1991, the term "office" followed: *Transactions on Office Information Systems* became *Transactions on Information Systems; Office: Information and People* became *Information Technology and People*; and "Conference on Office Information Systems" became "Conference on Organizational Communication Systems" (COOCS, in 1997 becoming the GROUP Conference).

The AI summer, which contributed to the OA/OIS effort, ended when AI failed to meet expectations: Massive funding did not deliver a pilot's associate, an autonomous land vehicle, or a battle management system for the military. Nor were offices automated. CHI conference sessions on language processing had diminished prior to this AI winter, but sessions on modeling, adaptive interfaces, advising systems, and other uses of intelligence in interfaces increased through the 1980s before declining in the 1990s. Funding for AI became scarce, employment opportunities dried up, and conference participation dropped off.

A 1986 conference, building on a successful private 1984 workshop (Greif 1985), brought together researchers from diverse disciplines interested in issues of communication, information sharing, and coordination under the banner "Computer Supported Cooperative Work." Participants came primarily from IS, OIS, CHI, distributed AI, and anthropology. Four of 13 CSCW program committee members and many papers were from schools of management, with similar participation by the OIS community.

The field coalesced in 1988. The book *Computer-Supported Cooperative Work*, edited by Irene Greif, was published, and SIGCHI sponsored a biennial North American CSCW conference. A European series (ECSCW) was initiated in 1989. With heavy participation from technology companies, North American CSCW had a small-group focus on networked individuals working on PCs, workstations, or minicomputers. Groups were either within an organization or linked by ARPANET, BITNET, or other networks. European participation, primarily from academia and government agencies, focused on organizational use of technologies. It differed methodologically from most IS research in North America. Scandinavian influences, described in the next section, were felt in both CSCW and ECSCW.

Just as human factors researchers left CHI after a few years, most IS researchers who were involved with CSCW left in the early 1990s. One factor was a shift within IS from social psychology to organizational behavior in studying team behavior. The Hawaii International Conference on System Sciences (HICSS) was becoming a major IS prejournal publication venue for work with an organizational orientation. In contrast, the organizational focus conflicted with the CSCW interest in context-independent small-group support, which was the realm of social psychology and the goal of many technology companies. Some IS researchers participated in COOCS and GROUP. The split was not entirely amicable; the IS newsletter *Groupware Report* did not include CSCW on its list of relevant conferences.

The pace of technology change created challenges for CSCW. In 1985, supporting a small team was a technical challenge; 10 years later, the Web had arrived. Applications that provided awareness of the activity of distant collaborators was a celebrated achievement in the early 1990s; several years later, dark linings to the silver cloud arose in the form of privacy concerns and information overload. Phenomena, such as a "productivity paradox" in which IT investments were not returning benefits and health effects of Internet use by young people, were carefully identified only to vanish a few years later. Other changes brought European and North American CSCW into greater alignment. European organizations were starting to acquire commercial software products, a CSCW focus in North America, and North Americans were discovering that organizational context, an ECSCW focus, was often crucial in the design and deployment of products intending to support group activity. Organizational behaviorists and theorists were thriving in their home disciplines, but ethnographers studying technology use, marginalized in traditional anthropology departments, were welcomed into CSCW.

Despite the challenges of building on sands swept by successive waves of technology innovation, CSCW remains a strong research area that attracts a broad swath of HCI researchers. Content ranges from the highly technical to thick ethnographies of workplace activity, from studies of instant messaging dyads to scientific collaboratories involving hundreds of people dispersed in space and time. Chapter 24 by Gary and Judy Olson in this handbook covers the technical side of this topic in depth, with references to other CSCW resources.

Participatory Design and Ethnography

Prior to 1985-1995 some system developers explored methods to involve some of the future users in designing a system. Typically the users were nondiscretionary users of a system being developed by a large enterprise for its own use.

Sociotechnical design took a managerial perspective. Participatory or cooperative design, rooted in the Danish trade union movement, focused on empowering eventual users (Nygaard 1977).

Scandinavian approaches influenced human factors (e.g., Rasmussen 1986) and attracted wide notice with the publication of the proceedings of a conference held in Aarhus, Denmark, in 1985 (Bjerknes et al. 1987). Participatory design was a critique of IS approaches, yet the Scandinavians resonated with CHI researchers. Despite differences in culture, contexts of development (in-house system vs. commercial product), and contexts of use (nondiscretionary vs. discretionary), they shared the goal of empowering hands-on users. Most were also of the generation that grew up in the1960s, unlike the World War II generation that dominated HF&E and IS.

Ethnography was a different approach to obtaining deep insights into potential users. Lucy Suchman managed a Xerox PARC group that presented studies of workplace activity at CSCW. Suchman published an influential critique of artificial intelligence in 1987 and a widely read review of the Aarhus proceedings in 1988, and as program chair she brought many Scandinavians to the CSCW 1988 conference.

Library and Information Science: An Incomplete Transformation

Research universities have always supported prestigious professional schools, but the prestige of library schools declined with the rise of higher-paid IT and software engineering professions. Between 1978 and 1995, 15 American library schools were shut down (Cronin 1995, p. 45). Most of the survivors were rechristened Library and Information Science. The humanities orientation had given way, and librarianship was being changed by technology. New curricula and faculty with different skills were needed.

The changes did not go smoothly or as anticipated. Forced multidisciplinarity is never easy. Exclusion of technology studies may have been a reasonable reaction to the expense and limitations of new technologies. However, Moore's law lowered costs and removed many limitations with such speed that people and organizations had little time to prepare. Young information scientists were not interested in absorbing a century of work on indexing, classifying, and providing access to complex information repositories; their eyes were fixed on a future in which many past lessons would not apply. Those that still applied would likely have to be relearned. The conflicts are exposed in a landmark 1983 collection, *The Study of Information: Interdisciplinary Messages* (Machlup and Mansfield 1983). In the book, W. Boyd Rayward outlines the humanities-oriented perspective and the technological perspective and argues that there was convergence. His essay is followed by commentaries attacking him from both sides.

In a series of meetings beginning in 1988, new library and information school deans at the universities Pittsburgh, Syracuse, Drexel, and subsequently Rutgers discussed approaches to explaining and managing multidisciplinary schools. Despite this progressive effort, Cronin (1995) depicted LIS at loggerheads and in a "deep professional malaise." He suggested that librarianship be cut loose in favor of stronger ties to cognitive and computer sciences. Through the 1990s, schools at several universities dropped the word "library" and became schools of information (see Figure 2). More would follow.

1995–2010: THE INTERNET ERA ARRIVES

How did the spread of the Internet and the emergence of the Web affect HCI research threads? CHI researchers were Internet savvy. Although excited by the prospects, they took these changes in stride. Over time, CHI-related research, development, and use evolved. The Internet and the Web were not disruptive to HF&E either. The Web was initially a return to a form-driven interface style, and it was rarely a locus of routine work. However, the Web had a seismic impact on IS and on information science, so this section begins with these disciplines.

The Formation of Association for Information Systems Special Interest Group in Human–Computer Interaction

The use of computers in organizations has changed. Organizations are no longer focused on maximizing computer use—almost everywhere, screen savers have become the main consumer of processor cycles. Advent of the Internet created more porous organizational boundaries. Employees in many organizations could download software such as instant-messaging clients, music players, and weblog tools inside organizational firewalls despite IT concerns about productivity and security. These are not the high-overhead applications of the past. Increasingly, software can be used from a web browser without requiring a download. Experience with all of this at home leaves employees impatient with poor software at work. In addition, many managers who had been hands-off users became late adopters in late 1990s or were replaced by younger managers. Today, managers and executives are hands-on early adopters of many technologies.

Significant as these changes are, the Web had a more dramatic effect on organizational information systems. Corporate IT groups had been focused solely on internal operations. They lived inside firewalls. Their customers were other employees. Suddenly, organizations were scrambling to create Web interfaces to external vendors and customers. Discretionary users! The Internet bubble burst, revealing that IT professionals, IS experts, and everyone else had limited understanding of Web phenomena. Nevertheless, online marketing, services, and business-to-business systems continued to grow. For many, the Web had become an essential business tool. In handling external customers, IT professionals and IS researchers were in much the same place that CHI was 20 years earlier, whether they realized it or (most often) not.

In 2001, the Association for Information Systems (AIS) established a Special Interest Group in Human–Computer

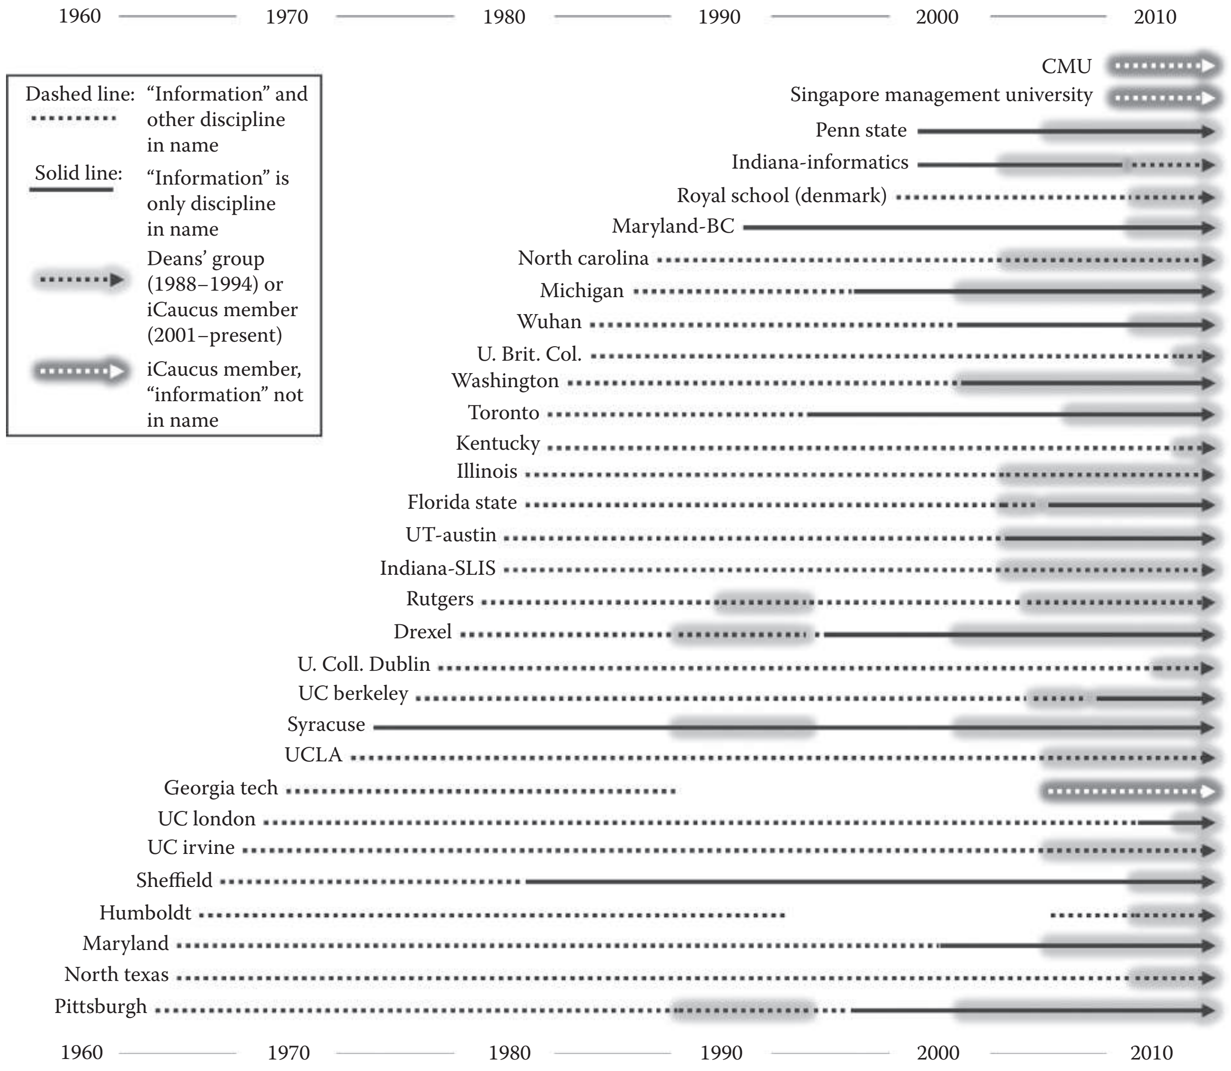

FIGURE 2 The iSchools and when "information" came into the names of the member Schools (Faculties, Colleges, etc.).

Interaction (SIGHCI). The founders defined HCI by citing 12 CHI research papers (Zhang, Nah, and Preece 2004, p. 148). Bridging the CHI and the information science communities was declared a priority. The charter of SIGHCI includes a broad range of organizational issues, but the publications emphasize interface design for e-commerce, online shopping, online behavior "especially in the Internet era" (Zhang 2004, p. 1), and effects of Web-based interfaces on attitudes and perceptions. Eight of the first 10 papers in SIGHCI-sponsored journal issues covered Internet and Web behavior.

In 2009, the journal *AIS Transactions on Human–Computer Interaction* was launched. The shift from an organizational focus to the Web and broader end-user computing is documented in Zhang et al.'s analysis (2009) of the IS literature from 1990 to 2008. This survey omits CHI from a list of the fields related to AIS SIGHCI. The bridging effort had foundered, as had three previous efforts to bridge to CHI: from Human Factors, Office Information Systems, and the Information Systems presence within CSCW.

Digital Libraries and the Evolution of Library Information Science

By 1995, an information wave had swept through universities (Figure 2). Digital technology was in the LIS curriculum. Familiarity with technology use was a prerequisite for librarianship. However, innovative research had not kept pace with professional training (Cronin 1995).

The Internet grew exponentially, but in 1995 it was still a niche activity found mainly on campuses. In the mid-1990s, Gopher, a convenient system for downloading files over the Internet, attracted attention as a possible springboard for indexing distributed materials. Wells's (1938) concept of "world brain" seemed to be within reach. Then the Web hit, transforming information acquisition, management, and access at an ever-increasing pace. Between 1994 and 1999, two NSF/DARPA/NASA/National Library of Medicine/Library of Congress/National Endowment for the Humanities/FBI initiatives awarded close to US$200 million for digital libraries research and development. This and other investments galvanized the research community. In 2000, the American Society for Information Science appended "and Technology" to its name to become ASIST.

By 2000, 10 schools (or equivalent units) had information as the sole discipline in their name. In 2001 a series of deans meetings began, which were modeled on those of the late 1980s. The original members, Syracuse, Pittsburgh, and Drexel, were joined by Michigan; Berkeley, California; and the University of Washington. All are now information schools. In 2005, the first annual "iConference" drew participants from 19 universities with information programs. As of 2011, the "iCaucus" had 27 dues-paying members. Some are transformed library schools, some have closer ties with other disciplines, and some have formed recently as schools of information. Collectively, their faculty includes HCI researchers trained in each of the four disciplines highlighted in this introduction.

Expansion is not without growing pains. Conflicts arise among academic subcultures. The iConference competes with more established conferences in each field. Figure 2 suggests that a shift to a field called information is well underway, but many faculty still consider themselves "a researcher in {X} who is located in an information school," where X could be library science, HCI, CSCW, IS, communication, education, computer science, or another discipline. We do not know how it will evolve, but we can say with confidence that information has become, and will remain, a significant player in HCI.

Human Factors and Ergonomics Embraces Cognitive Approaches

In 1996, the HFES formed a new technical group, Cognitive Engineering and Decision Making. It quickly became the largest technical group. A decade earlier this would have been unthinkable: Some leading human factors researchers disliked cognitive approaches. The CHI community first used the term cognitive engineering in this sense (Norman 1982, 1986). As this development suggests, CSTG declined in size and prominence as the HCI community dispersed. Most HF&E technical groups, from groups on telecommunications to those on medical systems, address digital technology and thereby HCI-related research.

Equally astonishing, in 2005 Human Performance Modeling was a new and thriving HFES technical group, initiated by Wayne Gray and Dick Pew, who had been active in CHI in the 1980s. Card, Moran, and Newell (1983) had introduced human performance modeling to reform the discipline of Human Factors from without. Some work continued within CHI that was focused on expert performance (e.g., a special issue of *Human–Computer Interaction*, vol. 12, number 4, 1997), but today the reform effort has moved within HF&E and remains focused largely on nondiscretionary use.

Government funding of HCI was largely shaped by the focus of HF&E. The Interactive Systems Program of the U.S. NSF—subsequently renamed HCI—was described thus: "The Interactive Systems Program considers scientific and engineering research oriented toward the enhancement of human–computer communications and interactions in all modalities. These modalities include speech/language, sound, images and, in general, any single or multiple, sequential, or concurrent, human–computer input, output, or action" (National Science Foundation 1993).

One NSF program manager identified his proudest accomplishment to be doubling the already ample funding for natural language understanding research. Even after NSF established a separate Human Language and Communication Program in 2003, speech and language research was heavily supported by both the HCI and accessibility programs, with lighter support from AI and other programs. Subsequent NSF HCI program managers emphasized "direct brain interfaces" or "brain–computer interaction" based on brain waves and implants. A review committee noted that a random sample of NSF HCI grants included none by prominent CHI researchers (National Science Foundation 2003). NSF program managers rarely attended CHI conferences, which have little coverage of speech, language, or direct brain interaction. These technologies may prove useful, but they have so far made few inroads into discretionary use situations in homes and offices.

Computer–Human Interaction Evolves, and Embraces Design

The steady flow of new hardware, software features, applications, and systems ensures that people are always encountering and adopting digital technologies for the first time. This is important for technology producers and it generates new research issues. CHI has tracked this, generally focusing on an innovation when it first starts to attract a wide audience.

As an application matures, its use often becomes routine. Technologies such as e-mail and word processing, no longer discretionary for most of us, get less attention from CHI researchers whose gaze is directed toward the discretionary use of the moment, including Web design, ubiquitous and mobile computing, social computing, and use of Wikipedia. New issues include information overload, privacy, and effects of multitasking, and encourage the emergence of new methods, such as ethnography and data mining. At a higher level, continuity is found in CHI: exploration of input devices, communication channels, information visualization techniques, and design methods. Proposals to build HCI theory on these shifting sands (Barnard et al. 2000; Carroll 2003) remain largely aspirational.

Expanding participation in the Internet as its reliability and bandwidth increased steadily through the mid-1990s brought real-time and quasi-real-time communication technologies such as e-mail into greater focus. The Web temporarily slowed this by shifting attention to indirect interaction with static sites, but with the advent of Web 2.0 and greater support for animation and video the pace quickened. The Web was like a new continent. Explorers posted flags here and there. Then came attempts at settlement, with the virtual worlds research and development that blossomed in the late

1990s. Few of the early pioneers survived; there was little to do in virtual worlds other than chat and play games. But slowly some people shifted major portions of their work and play online, relying on online information sources, digital photo management, social software, digital documents, online shopping, multiplayer games, and so on. This evolution is reflected in CHI research.

The content of CSCW in North America has shifted in response to the extraordinary growth of social networking sites, Wikipedia, and other Web phenomena, which are of intense interest to students and academic researchers and the software companies who hire or consult with many of them. These technologies are not yet of great interest to the organizations and government agencies that are the customer for European CSCW research, and the move toward shared interests has been reversed. Europeans have moved more rapidly into basic research in vertical domains. The division resembles that of 20 years ago, based on a new generation of technology. In several years the two research threads may again converge, perhaps under different names: "computer supported cooperative work" is outdated. Many digital devices are not considered computers, they play central rather than support roles, activities around them can be competitive or conflictual, and they may be used more for recreation than work.

The Web curtailed research into one thread of AI research: powerful, self-contained personal productivity tools. Considerable effort is required to embed knowledge in application software, but when access to external information sources was limited, it was worth trying. With today's easy access to information and knowledgeable people online, static, self-contained knowledge representation is less useful. In contrast, adaptive systems that merge and filter local and Internet-based information have a role to play. Steady progress in machine learning is enhancing productivity tools, although implausible AI forecasts have not disappeared.

To the psychologists and computer scientists who formed the CHI community, interface design was a matter of science and engineering. They focused on performance and assumed that people eventually choose efficient alternatives. Because human discretion involves aesthetic preferences and invites marketing and nonrational persuasion, this view was not sustained when computing costs came down. This engineering orientation gripped CHI longer than SIGGRAPH, where aesthetic appeal was a major driver. CHI researchers eventually came around, labeling the study of enjoyment "funology" (Blythe et al. 2003) lest someone think that they were having too good a time.

Some visual designers participated in graphical interface research early on. Aaron Marcus began working full time on computer graphics in the late 1960s. William Bowman's book *Graphic Communication* (1968) was a strong influence on the development of Xerox Star, for which the designer Norm Cox's icons were chosen (Bewley et al. 1983). However, graphic design was considered a secondary activity (Evenson 2005). In 1995, building on workshops at previous conferences, SIGCHI initiated "Designing Interactive Systems" (DIS), a biennial conference that draws more systems designers than visual designers. In 2003, SIGCHI, SIGGRAPH, and the American Institute of Graphic Arts (AIGA) initiated the "Designing for User Experience" (DUX) conference series that fully embraced visual and commercial design. This effort lasted only through 2007, but the significance of design was established. Design is not typically assessed in research papers. The changing sensibility is reflected in *ACM Interactions*, a magazine launched by CHI in 1994, which has steadily increased the focus on design in both its content and its appearance.

Design's first cousin, marketing, has been poorly regarded by the CHI community (Marcus 2004). Website design forced the issue. Site owners wish to keep users interested in a site, whereas users may prefer to escape quickly. Consider supermarkets, which position items that most shoppers want far apart, forcing people to traverse aisles where other products beckon. CHI professionals who align themselves with end users face a stakeholder conflict when designing for a site owner. This was not true in the past: Designers of individual productivity tools had little conflict of interest with prospective customers. Marketing is concerned with identifying and satisfying user needs, as well as shaping them. It will likely find a place in CHI, perhaps labeled "brandology."

Finally, CHI has gradually become more open to work that takes a social or political stance. Accessibility was first addressed in the context of physical constraints. Socioeconomic factors were included in Universal Usability conferences in 2000 and 2003. Sustainability and fitness emerged as topics. This may reflect a distancing from a sense that engineering should strive for value neutrality, a bid for relevance by an increasingly academic group or aging CHI baby boomers who are considering their legacies.

The evolution of CHI is reflected in the influential contributions of Donald Norman. A cognitive scientist who introduced the term cognitive engineering, he presented the first CHI'83 paper. It defined "user satisfaction functions" based on speed of use, ease of learning, required knowledge, and errors. His influential book *Psychology of Everyday Things* (1988) focused on pragmatic usability. Its 1990 reissue as *Design of Everyday Things* reflected a field refocusing on invention. Fourteen years later he published *Emotional Design: Why We Love (or Hate) Everyday Things*, stressing the role of aesthetics in our response to objects.

LOOKING BACK: CULTURES AND BRIDGES

Despite overlapping interests, in a dynamic environment with shifting alliances, the major threads of HCI research—HF&E, IS, LIS, and CHI—have not merged. They have interacted with each other only sporadically, although not for a lack of bridge-building efforts. The Human Factors Society co-organized the first CHI conference. CSCW sought to link CHI and IS. Mergers of OIS with CHI and later CSCW were considered. AIS SIGHCI tried to engage with CHI. Researchers recently hired into Information Schools remain active in the other fields.

Even within computer science, bridging is difficult. Researchers interested in interaction left SIGGRAPH to join the CHI community rather than form a bridge. A second opportunity arose 20 years later, when standard platforms powerful enough to support photorealism loomed, but the DUX conference series managed only three meetings. For AI, SIGART and SIGCHI cosponsor the Intelligent User Interface series, but participation has remained outside mainstream HCI. What are the obstacles to more extensive interaction across fields?

Discretion as a Major Differentiator

HF&E and IS arose before discretionary hands-on use was common. The information field only slowly distanced itself from supporting specialists. CHI occupied a new niche: discretionary use by nonexperts. HF&E and especially IS researchers considered organizational factors; CHI with few exceptions avoided domain-dependent work. As a consequence, HF&E and IS researchers shared journals. For example, Benbasat and Dexter (1985) published their work in *Management Science* and cited five *Human Factors* articles. Apart from LIS, they quickly focused on broad populations. IS countered its organizational focus by insisting that work be framed by theory, which set it apart from CHI in particular.

The appropriateness of a research method is tied to the motivation of the researchers. HF&E and CHI were shaped by psychologists trained in experimental testing of hypotheses about behavior, and hypothesis-driven experimentation was also embraced by IS. Experimental subjects agree to follow instructions for an extrinsic reward. This is a reasonable model for nondiscretionary use, but not for discretionary use. CHI researchers relabeled subjects as "participants," which sounds volitional, and found that formal experimental studies were usually inappropriate: There were too many variables to test formally and feedback from a few participants was often enough. Laboratory studies of initial or casual discretionary use usually require confirmation in real-world settings anyway, more so than studies of expert or trained behavior, because of the artificial motivation of the laboratory study participant.

The same goals apply—fewer errors, faster performance, quicker learning, greater memorability, and being enjoyable—but the emphasis differs. For power plant operation, error reduction is critical, performance enhancement is good, and other goals are less important. For telephone order entry takers performance is critical, and testing an interface that could shave a few seconds from a repetitive operation requires a formal experiment. In contrast, consumers often respond to visceral appeal and initial experience. In assessing designs for mass markets, avoiding obvious problems can be more important than striving for an optimal solution. Less rigorous discount usability or cognitive walk-through methods (Nielsen 1989; Lewis et al. 1990) can be enough. Relatively time-consuming qualitative approaches, such as contextual design or persona use (Beyer and Holtzblatt 1998; Pruitt and Adlin 2006), can provide a deeper understanding when context is critical or new circumstances arise.

CHI largely abandoned its roots in scientific theory and engineering, which does not impress researchers from HF&E or theory-oriented IS. The controversial psychological method of verbal reports, developed by Newell and Simon (1972) and foreshadowed by gestalt psychology, was applied to design by Clayton Lewis as "thinking aloud" (Lewis and Mack 1982; Lewis 1983). Perhaps the most widely used CHI method, it led some researchers in other fields to characterize CHI people as wanting to talk about their experiences instead of doing research.

Academic, Linguistic, and Generational Cultures

The academic culture of the sciences is that conferences are venues for work in progress and journals are repositories for polished work. The disciplines of HF&E, IS, Documentation, and Library Science adhere to this practice. In contrast, for U.S. computer science disciplines, conference proceedings are now the final destination of most work. Outside the United States, computer science retains a journal focus, which suggests that a key factor was the decision of ACM to archive conference proceedings (Grudin 2010). Information science draws on researchers from both camps, journals as archival and conferences as archival. Of course, a difference in preferred channel impedes communication. Researchers in journal cultures chafe at CHI's insistence on polish and its high conference rejection rates; CHI researchers are dismayed by the lack of polish at other conferences and are less inclined to read journals.

CHI conferences accept 20%–25% of submissions. With a few exceptions, HF&E and IS conferences accept about 50% or more. In contrast, CHI journals receive fewer submissions and have higher acceptance rates. Many CHI researchers report that journals are not relevant. By my estimate, at most 15% of the work in CHI-sponsored conferences reaches journal publication. In contrast, an IS track organizer for HICSS estimated that 80% of research there progressed to a journal (Jay Nunamaker, opening remarks at HICSS-38, January 2004).

A linguistic divide also set CHI apart. HF&E and IS use the term "operator" and a "user" could be a manager who read printed reports. For CHI, "operator" was demeaning and a "user" was always a hands-on user. In HF&E and IS streams, "task analysis" refers to an organizational decomposition of work, perhaps considering external factors; in CHI, "task analysis" is a cognitive decomposition, such as breaking a text editing move operation into select, cut, select, and paste. In IS "implementation" means organizational deployment, whereas in CHI it is a synonym for development. The terms "system," "application, " and "evaluation" also have different connotations or denotations in the different fields. Significant misunderstandings resulted from failures to appreciate these differences.

Different perspectives and priorities were also reflected in attitudes toward standards. Many HF&E researchers contributed to standards development, believing that standards contribute to efficiency and innovation. A view widespread in the CHI community was that standards inhibit innovation. Both views have elements of truth, and the positions partly converged as Internet and Web standards were tackled. However, the attitudes reflected the different demands of government contracting and commercial software development. Specifying adherence to standards is a useful tool for those preparing requests for proposals, whereas compliance with standards can make it more difficult for a product to differentiate itself.

The generational divide was also a factor. Many CHI researchers who grew up in the 1960s and 1970s did not appreciate the prior generation's orientation toward military, government, and business systems. They were also put off by the lack of gender neutrality in the HF&E and IS "man–machine interaction" literature, which one still occasionally encounters. Only in 1994 did *IJMMS* become *International Journal of Human–Computer Studies*. Such differences affected the enthusiasm for building bridges and exploring literatures.

Competition for resources was another factor. Computers of modest capability were extremely expensive for much of the time span we have considered. CHI was initially largely driven by the healthy tech industry, whereas research in the other fields was more dependent on government funding that waxed and waned. When funding waxed, demand for researchers outstripped supply. HCI prospered during AI winters, starting with Sutherland's use of the TX-2 when AI suffered its first setback and recurring with the emergence of major HCI laboratories during the severe AI winter of the late 1970s. Library schools laboring to create information science programs had to compete with computer science departments that awarded faculty positions to graduates of master's programs when the supply was low.

Greater interdisciplinarity is intellectually seductive. Could we not learn by looking over fences? But a better metaphor might be the big bang. Digital technology is an explosion, streaming matter and energy in every direction, forming worlds that at some later date might discover one another and find ways to communicate, and then again, might not.

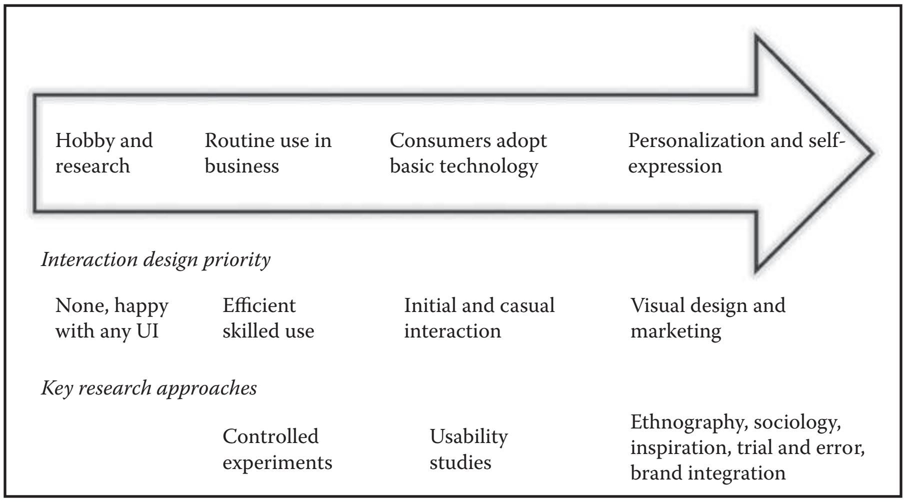
LOOKING FORWARD: TRAJECTORIES

The future of HCI will be dynamic and full of surprises. The supralinear growth of hardware capability confounds efforts at prediction: We rarely experience exponential change and do not reason well about it. In the United States, NSF is tasked with envisioning the future and providing resources for taking us there, yet two major recent HCI initiatives, "Science of Design" and "CreativIT" (focused on creativity), wound down quickly. Nevertheless, extrapolations from observations about the past and present suggest possible developments, providing a prism through which to view other chapters in this handbook and perhaps some guidance in planning a career.

Discretion: Now You See It, Now You Don't

We exercise prerogative when we use digital technology—sometimes. More often when at home, less often at work. Sometimes we have no choice, as when confronted by a telephone answering system. Those who are young and healthy have more choices than those constrained by injury or aging.

Many technologies follow the maturation path shown in Figure 3. Software that was discretionary yesterday is indispensable today. Collaboration forces us to adopt shared conventions. Consider a hypothetical team that has worked together for 20 years. In 1990, members exchanged printed documents. One person still used a typewriter, whereas others used different word processors. One emphasized words by underlining, another by italicizing, and a third by bolding. In 2000, the group decided to exchange digital documents. They had to adopt the same word processor. Choice was curtailed; it was only exercised collectively. Today this team is happy sharing documents in PDF format, so they can again use different word processors. Perhaps tomorrow software will let them personalize their view of a single underlying document, so one person can again use and see in italics what another sees as bold or underlined.



Hobby and research
Routine use in business
Consumers adopt basic technology
Personalization and self-expression
Interaction design priority
None, happy with any UI
Efficient skilled use
Initial and casual interaction
Visual design and marketing
Key research approaches
Controlled experiments
Usability studies
Ethnography, sociology, inspiration, trial and error, brand integration

FIGURE 3 From invention to maturity.

Shackel (1997, p. 981) noted this progression under the heading “From Systems Design to Interface Usability and Back Again.” Early designers focused at the system level; operators had to cope. When the PC merged the roles of operator, output user, and program provider, the focus shifted to the human interface and choice. Then individual users again became components in fully networked organizational systems. Discretion can evaporate when a technology becomes mission-critical, as word processing and e-mail did in the 1990s.

The converse also occurs. Discretion increases when employees can download free software, bring smartphones to work, and demand capabilities they enjoy at home. Managers are less likely to mandate the use of a technology that they use and find burdensome. For example, language-processing systems appealed to military officers, until they themselves became hands-on users:

> Our military users … generally flatly refuse to use any system that requires speech recognition.… Over and over and over again, we were told “If we have to use speech, we will not take it. I don’t even want to waste my time talking to you if it requires speech.…” I have seen generals come out of using, trying to use one of the speech-enabled systems looking really whipped. One really sad puppy, he said “OK, what’s your system like, do I have to use speech?” He looked at me plaintively. And when I said “No,” his face lit up, and he got so happy (Forbus 2003; see also Forbus, Usher, and Chapman [2003]).

In domains where specialized applications become essential and where security concerns curtail openness, discretion can recede. But Moore’s law (broadly construed), competition, and the ease of sharing bits should guarantee a steady flow of experimental technologies with unanticipated and thus initially discretionary uses.

Ubiquitous Computing: Invisible Human–Computer Interaction?

Norman (1988, p. 185) wrote of “the invisible computer of the future.” Like motors, he speculated, computers would be present everywhere and visible nowhere. We interact with clocks, refrigerators, and cars. Each has a motor, but who studies human–motor interaction? Marc Weiser subsequently introduced a similar concept, “ubiquitous computing.” A decade later, at the height of the Y2K crisis and the Internet bubble, computers were more visible than ever. But after a quarter century, while we may always want a large display or two, would anyone call a smartphone or a book reader a computer? The visions of Norman and Weiser may be materializing.

With digital technology embedded everywhere, concern with interaction is everywhere. HCI may become invisible through omnipresence. As interaction with digital technology becomes part of everyone’s research, the three longstanding HCI fields are losing participation.

Human Factors and Ergonomics

David Meister, author of *The History of Human Factors and Ergonomics* (1999), stresses the continuity of HF&E in the face of technology change:

> Outside of a few significant events, like the organization of HFS in 1957 or the publication of Proceedings of the annual meetings in 1972, there are no seminal occurrences … no sharp discontinuities that are memorable. A scientific discipline like HF has only an intellectual history; one would hope to find major paradigm changes in orientation toward our human performance phenomena, but there is none, largely because the emergence of HF did not involve major changes from pre-World War II applied psychology. In an intellectual history, one has to look for major changes in thinking, and I have not been able to discover any in HF (e-mail, September 7, 2004).

Membership in the Computer Systems Technical Group has declined. Technology is heavily stressed in technical groups such as Cognitive Engineering and Decision Making, Communication, Human Performance Modeling, Internet, System Development, and Virtual Environment. Nor do Aging, Medical Systems, or other technical groups avoid “invisible computers.”

Information Systems

While IS was thriving during the Y2K crisis and the Internet bubble, other management disciplines—finance, marketing, operations research, and organizational behavior—became more technically savvy. When the bubble burst and enrollments declined, the IS niche became less well defined. The research issues remain significant, but this cuts two ways. As IT organizations standardize on products and outsource IT functions, business-to-business and web portals for customers get more attention. These give rise to finance and marketing considerations, so HCI functions could be assumed by other management disciplines.

Computer–Human Interaction

This nomadic group started in psychology and then won a seat at the computer science table, which was bestowed grudgingly. Several senior CHI people moved to information schools. Lacking a well-defined academic niche, CHI ties its identity to the SIGCHI organization and the CHI conference. Membership in SIGCHI peaked in 1992 and conference attendance peaked in 2001. As new technologies become widely used, specialized conferences appear, often started by younger researchers. World Wide Web conferences included papers on HCI issues from the outset. HCI is an “invisible” presence in conferences on agents, design, and on computing that is ubiquitous, pervasive, accessible, social, and sustainable. High rejection rates for conference submissions and a new generational divide could accelerate the dispersion of research.

CHI attendance has become more exclusively academic, despite industry’s need for basic research in specific areas.

Apart from education and health, which have broad appeal, and software design and development, CHI remains largely focused on general phenomena and resistant to domain-specific work. This creates additional opportunities for regional and specialized conferences.

Information

Early in the computer era, there were no networks and memory was fantastically expensive. Computers were for computation, not information processing. Today, the situation is reversed: Memory and bandwidth are so plentiful that most computation is in the service of processing and distributing information. And the shift to an emphasis on information, with computation present but less visible, could well accelerate.

Cronin (1995) proposed that information access, in terms of intellectual, physical, social, economic, and spatial/temporal factors, is the focus of the information field. Information is acquired from sensors and human input; it flows over networks including the Web, and is aggregated, organized, and transformed. The routing and management of information within enterprises, as well as the consequences of ever more permeable organizational boundaries, is evolving. Approaches to personal information management are also rapidly changing. It was once centered on shoeboxes of photographs and boxes of old papers. Now most of us face significant online information management decisions, choosing what to keep locally, what to maintain in the cloud, and how to organize it to ensure its future accessibility. The CHI field has over a decade of work on information design and visualization (see Chapter 23 by Stuart Card).

In speculating about the future, Cronin (1995, p. 56) quotes Wersig (1992) who argued that concepts around information might function "like magnets or attractors, sucking the focus-oriented materials out of the disciplines and restructuring them within the information scientific framework." Could this happen? Information schools have hired senior and junior people from many relevant areas. Andrew Dillon, dean of the University of Texas, School of Information, worked at Loughborough with Brian Shackel and Ken Eason. Syracuse, the first extant school of information (since 1974), has faculty with IS training and orientation. CHI faculty have migrated to information schools and departments of several leading universities.

Communication Studies is a discipline to watch. Rooted in humanities and social sciences, it is gradually assuming a quantitative focus. Centered on studies of television and other mass media, the field blossomed in the 1980s and 1990s. Only in the last several years has computer-mediated communication reached the scale of significance of other mass media. HCI is in a position to draw on past work in communication, as communication focuses more on digital media.

The rise of specialized programs—biomedical informatics, social informatics, community informatics, and information and communication technology for development (ICT4D)—works against the consolidation of information studies. Information, like HCI, could become invisible through ubiquity. The annual Information Conference is a barometer. In 2005 and 2006, there was active discussion and disagreement about directions. Should new journals and research conferences be pursued, or should the field stick with the established venues in the various contributing disciplines? In the years since, faculty from different fields worked out pidgin languages with which to communicate with each other. Assistant professors were hired and graduate students enlisted, whose initial jobs and primary identities are with information. Will they creolize the pidgin language?

One can get a sense that the generals may still be arguing over directions, but the troops are starting to march. It is not clear where they will go. The generals, although busy with local campaigns, are reluctant to turn over command. The annual iConference vies with the less international but more established ASIST conference. However this evolves, in the long term, information is likely to be the major player in HCI. Design and information are active foci of HCI today, but the attention to design is compensation for past neglect. Information is being reinvented.

CONCLUSION: THE NEXT GENERATION

Looking back, cyclic patterns and cumulative influences are visible. New waves of hardware enabled different ways to support the same activities. E-mail arrived as an informal communication medium, was embraced by students, regarded with suspicion by organizations, and eventually became more formal and used everywhere. Then texting and instant messaging came along as an informal medium, were embraced by students, regarded with suspicion by organizations, and eventually became used everywhere. Social networking came along. …

Mindful of Edgar Fiedler's admonition that "he who lives by the crystal ball soon learns to eat ground glass," consider this: In the mid-1980s, the mainframe market lost the spotlight. Organizations were buying hundreds of PCs, but these were weak devices with little memory, hard to network. They did not need more mainframes, but what about a massive, parallel supercomputer? Government and industry invested vast sums in high-performance computing only to discover that it was hard to decompose most computational problems into parallel processes whose output could be reassembled. As these expensive and largely ineffective efforts proceeded, PCs slowly got stronger, added some memory, got networked together, and, without vast expenditures and almost unnoticed at first, the Internet and the Web emerged.

Today the PC is losing the spotlight. Organizations buy hundreds of embedded systems, sensors, and effectors, but these are weak devices with little memory, hard to network. Some tasks can be handed off to a second processor, but how far can parallel multicore computers take us? Government and industry are investing large sums in parallel computing. They are rediscovering the difficulties. Sensors and effectors will add processing and memory, harvest energy, and get networked. What will that lead to? The role of the PC may shift, becoming a personal control station where we can monitor vast quantities of information on anything of interest—our health, the state of household appliances, Internet activity, etc.—on large displays, with specific tasks easily moved to portable or distributed devices.

New technologies capture our attention, but of equal importance is the rapid maturation of technologies such as digital video and document repositories, as well as the complex specialization occurring in virtually all domains of application. Different patterns of use emerge in different cultures and different industries. Accessibility and sustainability are wide-open, specialized research and development areas. Tuning technologies for specific settings can bring human factors approaches to the fore; designing for efficient heavy use could revive command-driven interfaces, whether the commands are typed, spoken, or gestural.

Digital technology has inexorably increased the visibility of activity. We see people behaving not as we thought they would or as we think they should. Rules, conventions, policies, regulations, and laws are not consistently followed; sanctions for violating them are not uniformly applied. Privacy and our evolving attitudes toward it are a small piece of this powerful progression. Choosing how to approach these complex and intensifying challenges—Where do we increase enforcement? Should or could we create more nuanced rules? When should we tolerate more deviance?—at the levels of families, organizations, and societies. This will be a perpetual preoccupation as technology exposes the world as it is.

Until some time after it is revoked, Moore's law broadly construed will ensure that digital landscapes provide new forms of interaction to explore and new practices to improve. The first generation of computer researchers, designers, and users grew up without computers. The generation that followed used computers as students, entered workplaces, and changed the way technology was used. Now a generation has grown up with computers, game consoles, and cell phones. They absorbed an aesthetic of technology design and communicate by messaging. They are developing skills at searching, browsing, assessing, and synthesizing information. They use smartphones, acquire multimedia authoring talent, and embrace social networking sites. They have different takes on privacy and multitasking. They are entering workplaces, and everything will be changed once again. However it is defined and wherever it is studied, human–computer interaction will for some time be in its early days.

APPENDIX: PERSONAL OBSERVATIONS

My career from 1973 to 1993 followed a common enough path. I was one of many who worked as a computer programmer, studied cognitive psychology, spent time as an HCI professional in industry, and then moved to academia. I describe personal experiences here not because I am special, but to add texture and a sense of the human impact of some of the developments I have described. My interest in history arose from the feeling of being swept along by invisible forces, sometimes against my intention. My first effort at understanding was titled "The Computer Reaches Out" (Grudin 1990): I saw computers evolving and slowly reaching into the world and changing it in ways that we, their developers, had not foreseen.

1970: A Change in Plans

As a student, I read and believed the *Life* magazine article that forecast computers with superhuman intelligence arriving in several years. I concluded that if we survived a few years, we could count on machines to do all useful work. Human beings should focus on doing what they enjoy. I shifted from physics to mathematics and from politics to literature.

1973: Three Professions

Looking for my first job in 1973, I found three computer job categories in the *Boston Globe* classifieds: (1) operators, (2) programmers, and (3) systems analysts. Not qualified to be a highly paid analyst, I considered low-paid, hands-on operator jobs, but I landed a programming job with Wang Laboratories, which was at the time a small electronics company. For 2 years, I never saw the computer that my programs ran on. I flowcharted on paper and coded on coding sheets that a secretary sent to be punched and verified. A van carried the stack of cards 20 miles to a computer center, and later that day or the next day I got the printout. It might say something like "Error in Line 20," and I would resume work on the program.

1975: A Cadre of Discretionary Hand-On Users

In 1975, Wang acquired a few teletype terminals with access to the WYLBUR line editor, developed at the Stanford Linear Accelerator. Some of us programmers chose to abandon paper and became hands-on computer users.

1983: Chilly Reception for a Paper on Discretion in Use

My first HCI publication, Grudin and MacLean (1984), was written when I was a postdoctoral researcher at the MRC Applied Psychology Unit. Allan and I showed that people sometimes choose a slower interface for aesthetic or other reasons even when they are familiar with a more efficient alternative. A senior colleague asked us not to publish it. He worked on improving expert efficiency through cognitive modeling. A demonstration that greater efficiency could be undesirable would be a distraction, he said: "Sometimes the larger enterprise is more important than a small study."

1984: Encountering Moore's Law, Information Systems, Human Factors, and Design

I returned to Wang, which had become a large minicomputer company, and found that Moore's law had changed the business. More hardware was ordered from catalogs and the reduced cost of memory and other factors had changed programming priorities and skills. I was soon influenced by another cognitive psychologist, Susan Ehrlich, who worked in a marketing research group and later managed the human factors group. She introduced me to the IS literature, which I found difficult to understand. I attended Boston-area chapter meetings of both HFS and SIGCHI. I saw the cultural differences but felt CHI could learn from human factors. In a futile gesture to counter CHI antipathy toward human factors, I began calling myself a human factors engineer. I drove to Cambridge to see the newly released Macintosh. Few software engineers had the visual design skills that I realized would become important, so at work I looked for industrial designers of hardware (boxes) who could be enlisted to support software interface design.

1985: The Graphical User Interface Shock

In the early 1980s, Phil Barnard and I were among the many cognitive psychologists working on command naming. This was an important application in the era of command-line interfaces, but the ambition was to develop a comprehensive theoretical foundation for HCI. The success of the Mac in 1985 curtailed interest in command names. No one would build on our past work—a depressing thought. It also dashed the hope for a comprehensive theoretical foundation for HCI. We had to choose: Am I a cognitive psychologist or a computer professional? Phil remained a psychologist.

1986: Beyond the User: Groups and Organizations

I agreed to join MCC, an industry research consortium. Between jobs I worked on two papers, each addressing a major challenge encountered in product development: (1) From 1984 to 1986, I had worked on several products or features intended to support groups rather than individual users. These had not done well. Why was group support so challenging? (2) It was painfully evident that organizational structures and development processes were badly suited to interactive software development. What could be done about it? These issues formed the basis for much of my subsequent research.

1989: Development Contexts: A Major Differentiator

I spent 2 years at Aarhus University. Within weeks of arriving in a country that had little commercial software development, I saw that differences in the conditions that govern product, in-house, and contract development of interactive software could shape practices and perceptions in CHI, IS, and software engineering. Sorting this out led to my first library research for purely historical purposes (Grudin 1991). Perusing long-forgotten journals and magazines in dusty library corridors felt like wandering through an archaeological site.

1990: Just Words: Terminology Can Matter

I felt a premonition in 1987 when my IS-oriented colleague Susan Ehrlich titled a paper “Successful Implementation of Office Communication Systems.” By “implementation,” she meant introduction into organizations. To me, implementation was a synonym for coding or development. Sure enough, the ACM editor asked her to change the word implementation to adoption (Ehrlich 1987). What she called systems I called applications. Was language, usually an ally, getting in the way?

In 1990, I described the focus of my planned HCI course at Aarhus as “user-interface evaluation.” My new colleagues seemed embarrassed. Weeks later, a book written by one of them was published (Bødker 1990). Its first sentence was a quotation: “Design is where the action is, not evaluation.” Now I was embarrassed. In an in-house development world, with its dogma of getting the design right up front, development projects could take 10 years. Evaluation occurred at the end when only cosmetic changes were possible, and had a negative stigma. In commercial product development, evaluation of the previous version, competitive products, and (ideally) prototypes was integral to design. Evaluation is central to iterative design. It draws on the experimental psychologists’ skillset. We considered it a good thing.

Later in 1990, I participated in a panel on task analysis at a European conference. To my dismay, this IS-oriented group defined task analysis differently than I did. To them, it meant an organizational task analysis: tasks as components in a broad work process. In CHI, it meant a cognitive task analysis: breaking a simple task into components; for example, is “move text” thought of as “select-delete-paste” or as “select-move-place”? Some Europeans felt North American claims to have conducted task analyses were disgraceful, not understanding the context.

Also in 1990, en route to giving a job talk at the University of California Irvine, my first lecture to an IS audience at the University of California Los Angeles Anderson School of Management ended badly when the department head asked a question. It seemed meaningless, so I replied cautiously. He rephrased the question. I rephrased my response. He started again, then stopped and shrugged as if to say, “this fellow is hopeless.” When I saw him a few months later, he was astonished to learn that his Irvine friends were hiring me. Later, I understood the basis of our failure to communicate: We attached different meanings to the word “users.” To me, it meant hands-on computer users. He was asking about IS users who specified database requirements and read reports, but were not hands-on computer users. To me all use was hands-on, so his question had made no sense.

A book could be written about the word “user.” From a CHI perspective, the IS user was “the customer.” Consultants use “client.” In IS, the hands-on user was “the end-user.” In CHI parlance, end-user and user were one and the same—a person who entered data and used the output. The word end-user seemed superfluous or an affectation. Human factors used "operator" which CHI considered demeaning. In software engineering, user typically denoted a tool user, that is, a software engineer.

A final terminology note: the male generic. I avoided submitting to *IJMMS* and turned down an invitation to speak at a "man–machine interaction" event. I was keen on learning from other disciplines, but that was a linguistic bridge I usually avoided crossing. I generally consider words to be a necessary but uninteresting medium for conveying meaning, but such experiences led to an essay on unintended consequences of language (Grudin 1993).

2010: Reflections on Bridging Efforts

I have been a minor participant in efforts to find synergies drawing from CHI and HFS, OIS, IS (in both CSCW and AIS SIGHCI), or Design. None succeeded. I've interviewed others who participated years ago and identified the obstacles touched on in the introduction, many of which I experienced. As a boomer, I experienced generational and cultural divides. Many of my MCC colleagues joined the consortium to avoid Star Wars military projects. We lived through disputes between cognitive psychologists and radical behaviorists. I was among CHI researchers who shifted from journals to conferences as the primary publication venue and from hypothesis-driven experimentation to build-and-assess and qualitative field research.

Some differences fade over time, but many persist. Conference reviewers are often irritated by unfamiliar acronyms used by authors from other fields. Writing a chapter for an IS-oriented book (Palen and Grudin 2002), my coauthor and I wrangled at great length with the editor over terminology.

In researching this article, I reviewed the literature on TAM, the model of white-collar employee perceptions of technology that is heavily cited in IS but never in CHI. I unsuccessfully searched online for TAM references. Only on my third attempt did I see the problem: TAM stands for "Technology Acceptance Model," but I repeatedly typed in "Technology Adoption Model." TAM examined nondiscretionary acceptance, I think in terms of discretionary adoption. Different biases lead to different terminology, and confusion.

2010: Predicting the Future

Detailed forecasts, including mine, rarely look good upon close inspection. But understanding the forces that have shaped the past offers hope of anticipating or reacting quickly to future events. Even more useful may be indications of where effort will be futile. I believe the most common error is to underestimate the impact of hardware changes, and in particular that once effects start to be felt, how rapidly they will escalate. I published some analysis and projection in the November 2006 and January 2007 issues of *ACM Interactions*—check to see how I'm doing. (http://interactions.acm.org/content/archives.php).

Humans in HCI

1 Perceptual-Motor Interaction
Some Implications for Human–Computer Interaction

Timothy N. Welsh, Sanjay Chandrasekharan, Matthew Ray, Heather Neyedli, Romeo Chua, and Daniel J. Weeks

CONTENTS

1.1 PERCEPTUAL-MOTOR INTERACTION: A BEHAVIORAL EMPHASIS

Human–computer interaction is going through a period of rapid evolution. Although mouse, keyboard, and joystick devices will continue to dominate for the immediate future, embodied, gestural, and tangible interfaces—where individuals use their body to directly manipulate information objects—are rapidly changing the computing landscape. Most new laptops and mobile devices now support multitouch, which allows us to use our fingers and gestures to directly manipulate virtual objects on the screen. Hence, as an alternative to pointing and clicking with a mouse, we can now directly pull, push, grab, pinch, squeeze, crush, and throw virtual objects. We can shake our portable music player to change the song we are listening to, or we can turn our mobile devices horizontally to get a wider display screen. Using the Wii Remote, we can now use our body movements to interact with objects in video games and manipulate them. Tangible and augmented interfaces now allow us to interact directly with virtual environments by moving actual objects on a tabletop (Hornecker et al. 2008). In sum, instead of being forced to use dissociated (mouse) and/or arbitrary (keyboard and joystick) sensorimotor mappings to achieve our goals, these new modes of interaction allow for a more direct mapping of our movements on to the work space. The "naturalness" and ease of operation of these interfaces are, in large part, due to the sensory and motor systems' close connection to cognition. Therefore, as these new interfaces become more popular, it is becoming increasingly important to consider the mechanisms that support such interactions.

In our studies of human–computer interaction (HCI) and perceptual-motor interactions in general, we have adopted a number of theoretical and analytical frameworks as part of an integrated approach. Our chapters in earlier editions of this handbook (Chua, Weeks, and Goodman 2003; Welsh et al. 2007) reviewed much of this research and its implications for HCI. The emphasis for these earlier chapters was on using information-processing approaches to understand the translation of perceptual into motor space and the interaction between processes of attention and action planning. Although our research has continued to explore the interplay between the processes of action and attention that we introduced in our chapter in the second edition (Welsh et al. 2007), we are intrigued by the possibilities offered by recently developed tangible interfaces and how theories of embodied cognition and common coding can support and enhance the progress of these systems.

Thus, in the present chapter, we have provided an updated review and expansion of our recent work in the area of action-centered attention and suggest some important implications for the role that action planning plays in the capture of attention and perception. We believe this work has important implications for the design of interaction modes. In the second section, we review the critical features of an alternative theoretical approach to cognition and action that presupposes an in-depth interaction between perception, cognition, and action. This latter theory has shaped much of our more recent work on the development of a tangible and embodied HCI. The critical theme that binds the seemingly diverse lines of work is the role that action planning has in information-processing systems. It is this central consideration that we argue has been lacking over the years and should be an important consideration for the future work.

1.1.1 Human Information Processing and Perceptual-Motor Behavior

The information-processing framework has traditionally provided a major theoretical and empirical platform for many scientists interested in perceptual-motor behavior. The study of perceptual-motor behavior within this framework has inquired into such issues as the information capacity of the motor system (e.g., Fitts 1954), the attentional demands of movements (e.g., Posner and Keele 1969), motor memory (e.g., Adams and Dijkstra 1966), and processes of motor learning (e.g., Adams 1971). The language of information processing (e.g., Broadbent 1958) has provided the vehicle for discussions of mental and computational operations of the cognitive and perceptual-motor system (Posner 1982). Of interest in the study of perceptual-motor behavior is the nature of the cognitive processes that underlie perception and action.

The information-processing approach describes the human as an active processor of information, in terms that are now commonly used to describe complex computing mechanisms. An information-processing analysis describes observed behavior in terms of the encoding of perceptual information, the manner in which internal psychological subsystems utilize the encoded information, and the functional organization of these subsystems. At the heart of the human cognitive system are processes of information transmission, translation, reduction, collation, storage, and retrieval (e.g., Fitts 1964; Marteniuk 1976; Stelmach 1982; Welford 1968). Consistent with a general model of human information processing (e.g., Fitts and Posner 1967), three basic processes have been distinguished historically. For our purposes, we refer to these processes as stimulus identification, response selection, and response programming. Briefly, stimulus identification is associated with processes responsible for the perception of information. Response selection pertains to the translation between stimuli and responses and the selection of a response. Response programming is associated with the organization of the final output (see Proctor and Vu 2003 or the present volume).

A key feature of early models of information processing is the emphasis upon the cognitive activities that precede action (Marteniuk 1976; Stelmach 1982). From this perspective, action is viewed only as the end-result of a complex chain of information-processing activities (Marteniuk 1976). Thus, chronometric measures such as reaction time and movement time, as well as other global outcome measures, are often the predominant dependent measures. However, even a cursory examination of the literature indicates that the time to engage a target has been a primary measure of interest. For example, a classic assessment of perceptual-motor behavior in the context of HCI and input devices was conducted by Card et al. (1978); see also English, Engelhart, and Berman (1967). Employing measures of error and speed, Card et al. (1978) had subjects complete a cursor-positioning task using four different control devices (mouse, joystick, step keys, and text keys). The data revealed the now well-known advantage for the mouse. Of interest is that the speed measure was decomposed into "homing" time, the time that it took to engage the control device and initiate cursor movement, and "positioning" time, the time to complete the cursor movement. Although the mouse was actually the poorest device in terms of the homing time measure, the advantage in positioning time produced the faster overall time. That these researchers sought to glean more information from the time measure acknowledges the importance of the movement itself in perceptual-motor interactions such as these.

The fact that various pointing devices depend on hand movement to control cursory movement has led researchers in HCI to emphasize Fitts's law (Fitts 1954) as a predictive model of time to engage a target. The law predicts pointing (movement) time as a function of the distance to and the width of the target—where, in order to maintain a given level of accuracy, movement time must increase as the distance of the movement increases and/or the width of the target decreases. The impact of Fitts's law is most evident by its inclusion in the battery of tests to evaluate computer pointing devices in ISO 9241-9. We argue that there are a number of important limitations to an exclusive reliance on Fitts's law in this context.

First, although the law predicts movement time, it does so on the basis of distance and target size. Consequently, it does not allow for determining what other factors may influence movement time. Specifically, Fitts's law is often based on a movement to a single target at any given time (although it was originally developed using reciprocal movements between two targets). However, in most HCI and graphical user interface contexts, there is an array of potential targets that can be engaged by an operator. These nontarget, but action-relevant stimuli in the movement environment can have profound and unexpected effects on action planning and execution. For example, Adam et al. (2006) have repeatedly found that the last target in an array enjoys a movement time advantage that is not predicted by Fitts's law. In contrast, distracting nontarget stimuli that capture attention can negatively affect both the temporal and physical characteristics of the movements to the imperative target. We will discuss these negative consequences in greater detail in Section 1.2.1.3.

Second, we suggest that the emphasis on Fitts's law has diverted attention from the fact that cognitive processes involving the selection of a potential target from an array are an important, and time-consuming, information-processing activity that must precede movement to that target. For example, the Hick–Hyman law (Hick 1952; Hyman 1953) predicts the decision time required to select a target response from a set of potential responses—where the amount of time required to choose the correct response increases with the number of possible alternative responses. What is important to understand is that the two laws work independently to determine the total time it takes for an operator to acquire the desired location. In one instance, an operator may choose to complete the decision making and movement components sequentially. Under these conditions, the total time to complete the task will be the sum of the times predicted by the Hick–Hyman and Fitts's laws. Alternatively, an operator may opt to make a general movement that is an approximate average of the possible responses and then select the final target destination while the movement is being completed. Under such conditions, Hoffman and Lim (1997) reported interference between the decision and movement component that was dependent on their respective difficulties (see also Meegan and Tipper 1998).

Finally, although Fitts's law predicts movement time given a set of movement parameters, it does not actually reveal much about the underlying movement itself. Indeed, considerable research effort has been directed toward revealing the movement processes that give rise to Fitts's law. For example, theoretical models of limb control have been forwarded that propose that Fitts's law emerges as a result of multiple submovements (e.g., Crossman and Goodeve 1963/1983), or as a function of both initial movement impulse variability and subsequent corrective processes late in the movement (Meyer et al. 1988). These models highlight the importance of conducting detailed examinations of movements themselves as a necessary complement to chronometric explorations.

For these reasons, HCI situations that involve dynamic perceptual-motor interactions may not be best indexed merely by chronometric methods (cf. Card et al. 1978). Indeed, as HCI moves beyond the simple key press interfaces that are characteristic of early systems to include virtual and augmented reality, teleoperation, gestural and haptic interfaces, among others, the dynamic nature of perceptual-motor interactions are even more evident. Consequently, assessment of the actual movement required to engage such interfaces will be more revealing.

To supplement chronometric explorations of basic perceptual-motor interactions, motor behavior researchers have also advocated a "movement process" approach (Kelso 1982). The argument is that in order to understand the nature of movement organization and control, analyses should also encompass the movement itself, and not just the activities preceding it (e.g., Kelso 1982, 1995; Marteniuk, MacKenzie, and Leavitt 1988). Thus, investigators have examined the kinematics of movements in attempts to further understand the underlying organization involved (e.g., Brooks 1974; Chua and Elliott 1993; Elliott et al. 1991; Kelso, Southard, and Goodman 1979; MacKenzie et al. 1987; Marteniuk et al. 1987). The relevance of this approach will become apparent in later sections.

1.1.2 Sensory Information during the Planning and Control of Action

It almost goes without saying that different types of actions need different types and amounts of information to ensure accurate completion. Theoretical and experimental considerations of this issue, in a manner that is relevant to the field of HCI, have been expanded recently. Before discussing the evidence supporting this view and outlining some potential implications for HCI, we will briefly review the processes involved in the planning and control of action and the types of information used during these processes. Readers interested in gaining a more in-depth understanding of this research should consult a recent book on the topic (Elliott and Khan 2010).

Since the seminal work of Woodworth (1899), it has been generally accepted that goal-directed action consists of two main components: (1) the ballistic or open-loop component that initiates the action toward the goal and (2) the current control or closed-loop component during which movement-produced information is used to facilitate movement accuracy. The initial open-loop component is thought to represent the results of the stages of information processing and initial plan or motor program the individual has developed to complete the goal successfully. The second component of the action begins after the movement has been initiated and directed toward the goal. During this part of the movement, sources of movement-produced information about the current location and trajectory of the effector (feedback) are compared with the predicted or desired location and trajectory to determine any differences between the actual and desired movement pattern (i.e., movement error). These error signals are then used to correct the unfolding movement and achieve the goal.

The main evidence in favor of the notion of planning and control components for goal-directed actions is derived from detailed analyses of the kinematic profiles of aiming actions performed under various stimulus conditions (e.g., Chua and Elliott 1993; Heath 2005; see Khan et al. 2006 for a review).

Although vestibular and proprioceptive information is also necessary for the accurate planning and control of movement, visual information is by far the dominant source and, as such, is the source of information that is most commonly manipulated in these studies. As one would expect, people are more accurate and less variable under conditions in which they have vision of the environment than when they do not. The increase in accuracy is thought to occur, in large part, because the actor has visual information of both the effector and the target to detect and correct errors in the trajectory.

Of greater importance to the present discussion, however, are the results of the in-depth kinematic analysis of the aiming movements. The consistent finding of this research is that the majority of the differences between the movements executed with and without vision appears in the later portions of the movement. Specifically, the initial segments of movements performed both with and without vision are characterized by relatively similar smooth increases and then decreases in velocity (bell-shaped profiles). It is thought that this relative consistency arises because there is a relative consistency in the motor programs that are the basis of these early portions of the movement in both vision and no vision conditions. In contrast to the similarities in the initial parts of the movements, the later portions of the movement performed with continuous visual information of the environment are characterized by a much larger number of sudden decelerations and reaccelerations than movements executed in the absence of visual information. These discontinuities in the kinematic profiles are thought to represent instances in which the actor has used visual information about the effector and the target to detect errors and then formulate and execute corrective submovements. These online corrections increase the accuracy of the movement. In the absence of vision, most errors go undetected leading to smoother deceleration phases (i.e., with fewer corrective submovements) and more end point error.

It is important to note here that not all actions consist of both components. Although each action needs a ballistic component to get the action initiated, actions may be successfully completed in the absence of feedback-based control. There are two common circumstances in which actions are completed without (or with minimal influence from) feedback-based control. The first circumstance in which feedback-based control is not needed is situations in which end point accuracy demands are minimal (e.g., when there is a low index of difficulty, the target is really large and/or close to the effector). Feedback-based corrections might not occur here because the programmed component of the action is accurate enough to achieve the goal. The second circumstance involves situations in which actions are completed in a very short amount of time. Because the feedback loops require time to effectively influence the actions, feedback-based corrections during rapid or ballistic actions are simply not possible. The actor still receives the response-produced information at the end of the movement and can determine whether they have successfully completed the response and can use that information to adjust the next action (i.e., make an offline correction to the action). The information, however, cannot be used online (during the action) to ensure its accurate completion. Thus, for ballistic actions, such as key presses, a continual source of target information during execution will not affect performance because online corrections cannot be made. Successful completion of action in this context is dependent on the accuracy of the motor program. In contrast, for movements with a longer execution time, such as finger- or mouse-based aiming movements, a continual source of information facilitates accurate completion because the information can be used to make online corrections to the unfolding action.

In sum, the critical implication from this discussion of the use of visual information in motor programming and control is that different types of actions require different types and amounts of information. Specifically, because key press responses are completed in a ballistic manner without the use of feedback, the stable sources of information regarding the target location are not needed to ensure accurate completion. In contrast, because aiming movements generally take longer to complete and have higher accuracy demands, a continual and stable source of visual information about the effector and the target is needed for efficient feedback-based corrections and movement accuracy. As will be discussed later, recent findings suggest that the ways in which we perceive and attend to objects in the world is determined, in part, by the to-be-performed response mode. Thus, careful consideration of response mode is necessary when designing work environment to ensure the efficient extraction of the relevant information and use of the system.

1.1.3 Translation, Coding, and Mapping

As outlined in the preceding sections, the dominant models of human information processing (e.g., Fitts and Posner 1967) distinguishes three basic processes: stimulus identification, response selection, and response programming. While stimulus identification and response programming are functions of stimulus and response properties, respectively, response selection is associated with the translation between stimuli and responses (Welford 1968).

Translation is the seat of the human “interface” between perception and action. Moreover, the effectiveness of translation processes at this interface is influenced to a large extent by the relation between perceptual inputs (e.g., stimuli) and motor outputs (e.g., responses). Since the seminal work of Fitts and colleagues (Fitts and Seeger 1953; Fitts and Deninger 1954), it has been repeatedly demonstrated that errors and choice reaction times to stimuli in a spatial array decrease when the stimuli are mapped onto responses in a spatially “compatible” manner. Fitts and Seeger (1953) referred to this finding as stimulus–response (S–R) compatibility and ascribed it to cognitive codes associated with the spatial locations of elements in the stimulus and response arrays. Presumably, it is the degree of coding and recoding required to map the locations of stimulus and response elements that determine the speed and accuracy of translation and thus response selection (e.g., Wallace 1971).

The relevance of studies of S–R compatibility to the domain of human factors engineering is paramount. It is now well understood that the design of an optimal HCI in which effective S–R translation facilitates fast and accurate responses is largely determined by the manner in which stimulus and response arrays are arranged and mapped onto each other (e.g., Bayerl, Millen, and Lewis 1988; Chapanis and Lindenbaum 1959; Proctor and Van Zandt 1994). As a user, we experience the recalibrating of perceptual-motor space when we take hold of the mouse and move it in a fairly random pattern when we interact with a computer for the first time. Presumably, what we are doing here is attempting to calibrate our actual movements to the resulting virtual movements of the cursor on the screen. Such recalibrations require neural networks and resources that are in addition to those typically activated during direct or standard mapping conditions (Snyder, Batista, and Andersen 1998). Thus, for optimal efficiency of functioning, it seems imperative that the system is designed to require as little recalibration as possible. Again, our contribution to the first edition of this handbook reviews our work on the area of S–R translation and the implications of this work for HCI (Chua, Weeks, and, Goodman 2003). We encourage those who are more interested in these issues to read that chapter. For the present chapter, we will instead outline some newer considerations and consequences for contexts in which there is a more direct translation between movements of the user and the effects of these actions in virtual space.

1.2 PERCEPTUAL-MOTOR INTERACTION: ATTENTION AND PERFORMANCE

The vast literature on selective attention and its role in the filtering of target from nontarget information (e.g., Cherry 1953; Treisman 1964a,b, 1986; Deutsch and Deutsch 1963; Treisman and Gelade 1980) has no doubt been informative in the resolution of issues in HCI pertaining to stimulus displays and inputs (e.g., the use of color and sound). However, attention should not be thought of as a unitary function, but rather as a set of information-processing activities that are important for perceptual, cognitive, and motor skills. Indeed, the evolution of HCI into the realm of augmented reality, teleoperation, gestural interfaces, and other areas that highlight the importance of dynamic perceptual-motor interactions, necessitates a greater consideration of the role of attention in the selection and execution of action. Recent developments in the study of how selective attention mediates perception and action and, in turn, how intended actions influences attentional processes, are poised to make just such a contribution to HCI. We will now turn to a review of these developments and some thoughts on their potential relevance to HCI.

1.2.1 Attention

We are all familiar with the concept of "attention" on a phenomenological basis. Even our parents, who likely never formally studied cognition, demonstrated their understanding of the essential characteristics of attention when they directed us to "pay attention" when we were daydreaming or otherwise not doing what was asked. They knew that humans, like computers, have a limited capacity to process information in that we can only receive, interpret, and act upon a fixed amount of information at any given moment. As such, they knew that any additional, nontask processing would disrupt the performance of our goal-task, be it homework, cleaning, or listening to their lecture. But what is "attention"? What does it mean to "pay attention"? What influences the direction of our attention? The answers to these questions are fundamental to understanding how we interact with our environment. Thus, it is paramount for those who are involved in the design of HCI to consider the characteristics of attention and its interactive relationship with action planning.

1.2.1.1 Characteristics of Attention

Attention is the collection of processes that allow us to dedicate our limited information-processing capacity to the purposeful (cognitive) manipulation of a subset of available information. Stated another way, attention is the process through which information enters into working memory and achieves the level of consciousness. There are three important characteristics of attention: (1) attention is selective and allows only a specific subset of information to enter the limited processing system; (2) the focus of attention can be shifted from one source of information to another; and (3) attention can be divided such that, within certain limitations, one may selectively attend to more than one source of information at a time. The well-known "cocktail party" phenomena (Cherry 1953) effectively demonstrates these characteristics.

Picture yourself at the last busy party or poster session you attended where there was any number of conversations continuing simultaneously. You know from your own experience that you are able to filter out other conversations and *selectively* attend to the single conversation in which you are primarily engaged. You also know that there are times when your attention is drawn to a secondary conversation that is continuing nearby. These *shifts* of attention can occur automatically, especially if you hear your name dropped in the second conversation, or voluntarily, especially when your primary conversation is boring. Finally, you know that you are able to *divide* your attention and follow both conversations simultaneously. However, although you are able to keep track of each discussion simultaneously, you will note that your understanding and contributions to your primary conversation diminish as you dedicate more and more of your attentional resources to the secondary conversation. The diminishing performance in your primary conversation is, of course, an indication that the desired amount of information processing has exceeded your limited capacity.

Although the "cocktail party" example outlined here uses auditory stimuli, the ability to select, divide, and shift attentional resources holds for different modalities (e.g., vision, proprioception) and across multiple modalities (e.g., one can shift from auditory stimuli to visual stimuli). Because vision is the dominant modality of information transfer in HCI, we will concentrate our discussion on visual selective attention. It should be noted, however, that there is a growing literature on cross-modal influences on attention, especially visual–auditory system interactions (e.g., Spence et al. 2000), that will be relevant in the near future. For those interested in a broader review of the characteristics of attention are encouraged to read our contribution to the second edition of the handbook (Welsh et al. 2007).

1.2.1.2 Shifts of Attention

Structural analyses of the retinal (photosensitive) surface of the eye have revealed two distinct receiving areas—the fovea and the perifoveal (a.k.a. peripheral) areas. The fovea is a relatively small area (about 2°–3° of visual angle) near the center of the retina, which has the highest concentration of color-sensitive cone cells. It is this high concentration of color-sensitive cells that provides the rich, detailed information that we typically use to identify objects. There are several important consequences of this structural and functional arrangement. First, because of the fovea's pivotal role in object identification and the importance of object identification for the planning of action and many other cognitive processes, visual attention is typically dedicated to the information received by the fovea. Second, because the fovea is such a small portion of the eye, we are unable to derive a detailed representation of the environment from a single fixation. As a result, it is necessary to constantly move information from objects in the environment onto the fovea by rapidly and accurately rotating the eye. These rapid eye movements are known as saccadic eye movements. Because of the tight link between the location of visual attention and saccadic eye movements, these rapid eye movements are referred to as overt shifts of attention.

Although visual attention is typically dedicated to foveal information, it must be remembered that the perifoveal retinal surface also contains color-sensitive cells and, as such, is able to provide details about objects. A *covert* shift of attention refers to any situation in which attention is being dedicated to a nonfoveated area of space. Covert shifts of attention are used when an individual wants or needs to maintain the fovea on a particular object while continuing to scan the remaining environment for other stimuli. Covert shifts of attention also occur immediately before the onset of an overt shift of attention or other type of action (e.g., Shepherd, Findlay, and Hockey 1986). For this reason, people are often able to identify stimuli at the location of covert attention before the acquisition of that location by foveal vision (i.e., overt attention) (Deubel and Schneider 1996).

Both overt and covert shifts of attention can be driven by stimuli in the environment or by the will of the performer. Shifts of attention that are driven by stimuli are known as *exogenous*, or bottom–up, shifts of attention. They are considered to be automatic in nature and thus, for the most part, are outside of cognitive influences. Exogenous shifts of attention are typically caused by a dynamic change in the environment such as the sudden, abrupt appearance (onset) or disappearance (offset) of a stimulus (e.g., Pratt and McAuliffe 2001), a change in the luminance or color of a stimulus (e.g., Folk, Remington, and Johnston 1992; Posner, Nissen, and Ogden 1978; Posner and Cohen 1984), or the abrupt onset of object motion (e.g., Abrams and Chirst 2003; Folk, Remington, and Wright 1994). The effects of exogenous shifts have a relatively rapid onset, but are fairly specific to the location of the dynamic change and are transient, typically reaching their peak influence around 100 ms after the onset of the stimulus (Cheal and Lyon 1991; Müller and Rabbitt 1989). From an evolutionary perspective, it could be suggested that these automatic shifts of attention developed because such dynamic changes would provide important survival information such as the sudden, unexpected appearance of a predator or prey. However, in more modern times, these types of stimuli can be used to quickly draw one's attention to the location of important information.

In contrast, performer-driven, or *endogenous*, shifts of attention are under complete voluntary control. The effects of endogenous shifts of attention take longer to develop, but can be sustained over a much longer period of time (Cheal and Lyon 1991; Müller and Rabbitt 1989). From an HCI perspective, there are advantages and disadvantages to the fact that shifts of attention can be under cognitive control. The main benefit of cognitive control is that shifts of attention can result from a wider variety of stimuli such as symbolic cues like arrows, numbers, or words. In this way, performers can be cued to locations or objects in the scene with more subtle or permanent information than the dynamic changes that are required for exogenous shifts. The main problem with endogenous shifts of attention is that the act of interpreting the cue requires a portion of the limited information-processing capacity and thus can interfere with, or be interfered by, concurrent cognitive activity (Jonides 1981).

Although it was originally believed that top–down processes could not influence exogenous shifts of attention (i.e., that dynamic changes reflexively capture attention regardless of intention), Folk, Remington, and Johnston (1992) demonstrated that this is not always the case. The task in the Folk et al. (1992) study was to identify a stimulus that was presented in one of four possible locations. For some participants, the target stimulus was a single abrupt onset stimulus (the target appeared in one location and nothing appeared in the other three locations), whereas for the remaining participants the target stimulus was a color singleton (a red stimulus that was presented at the same time as white stimuli that appeared in the other three possible locations). One-hundred and fifty milliseconds before the onset of the target, participants received cue information at one of the possible target locations. The cue information was either abrupt onset stimuli at a single location or color singleton information. Across a series of experiments, Folk et al. (1992) found that the cue tended to increase reaction times to the target stimulus when the cue information was presented at a location that was different from where the target subsequently appeared, indicating that attention had initially been exogenously drawn to the cue. Importantly, the cue stimuli only interfered with the identification of the target stimulus when the characteristics of cue stimuli matched the characteristics of the target stimulus (i.e., onset cue-onset target and color cue-color target conditions). When the characteristics of the cue did not match the target stimulus (i.e., onset cue-color target and color cue-onset target conditions), the location of the cue did not influence reaction times. Thus, these results reveal that dynamic changes only capture attention when the performer is searching for a dynamic change stimulus. Stated another way, it seems that "automatic" attentional capture is dependent on the expectations of the performer. Folk et al. suggested that people create an attention set in which they establish their expectations for the characteristics of the target stimulus. Stimuli meeting the established set will automatically capture attention, whereas stimuli that do not meet the established set will not.

Subsequent work on this contingent involuntary capture of attention effect has revealed that this attentional set can only be broadly-tuned in that it is most sensitive for discriminating between so-called static (e.g., color singletons) and dynamic (e.g., abrupt onset singletons) discontinuities. For example, Folk, Remington, and Wright (1994) found that a motion singleton (one object suddenly starting to move) and an offset singleton (one object suddenly disappearing) captured attention when participants were searching for an onset singleton target (see also Gibson and Kelsey 1998). Thus, when key press responses are required to a target that is characterized by a dynamic change in the environment, other dynamic change will fit the attentional set and capture attention. The obvious implication of these results is that the most efficient HCIs will be those for which the designer has considered perceptual expectations of the person controlling the system. As we will discuss in Section 1.2.1.3, however, consideration of the perceptual expectations alone is, at best, incomplete.

1.2.1.3 Action-Centered Attention

The majority of the literature reviewed thus far has involved experiments that investigated attentional processes through tasks that used simple or choice key press actions. Cognitive scientists typically use these arbitrary responses because (1) key press responses are relatively uncomplicated and provide simple measures of performance, namely reaction time and error; and (2) by using a simple response, the researcher assumes that they have isolated the perceptual and attentional processes of interest from additional complex motor programming and control processes. Although there are certainly numerous examples of HCI in which the desired response is an individual key press or series of key presses, there are perhaps as many situations in which more complicated movements are required. Indeed, mouse- and joystick-based interactions are in many ways complicated aiming movements. Further, as HCIs move increasingly into virtual reality, touchscreen, tangible interfaces, and other more complex environments, it will become increasingly important to consider the ways in which attention and motor processes interact. Thus, it will become more critical to determine if the same principles of attention apply when more involved motor responses are required. In addition, some cognitive scientists have suggested that, because human attention systems have developed through evolution to acquire the information required to plan and control complex actions, studying attention under such constrained response conditions may actually provide an incomplete or biased view of attention (Allport 1987, 1993). The tight link between attention and action is apparent when one recognizes that covert shifts of attention occur before saccadic eye movements (Deubel and Schneider 1996) and that overt shifts of attention are tightly coupled to manual aiming movements (Helsen et al. 1998, 2000). Such considerations, in combination with neuroanatomical studies revealing tight links between the attention and motor centers (Rizzolatti, Riggio, and Sheliga 1994), have led to the development of action-centered models of attention (Rizzolatti et al. 1987; Tipper, Howard, and Houghton 1999; Welsh and Elliott 2004a).

1.2.1.3.1 The Relationship between Attentional Capture and Action Coding

Recent research has demonstrated that the behavioral consequences of selecting and executing target-directed actions in the presence of action-relevant nontarget stimuli extend beyond the time taken to prepare and execute the movement (e.g., Meegan and Tipper 1998; Pratt and Abrams 1994). Investigations in our labs and others have revealed that the actual execution of the movement changes in the presence of distractors. For example, there are reports that movements will deviate toward (Welsh, Elliott, and Weeks 1999; Welsh and Elliott 2004a; Welsh et al. 2007; Song and Nakayama 2008; Carr, Phillips, and Meehan 2008; Buetti and Kerzel 2009) or away from (Howard and Tipper 1997; Tipper, Howard, and Jackson 1997; Welsh and Elliott 2004a,b) the nontarget stimulus. For a recent review of the effects of cognitive states on reaching movements, please see Song and Nakayama (2009).

Welsh and Elliott have developed the model of response activation to account for and integrate this research. Consistent with the conclusions of Tipper, Lortie, and Baylis (1992), Welsh and Elliott (2004a) based the model of response activation on the premise that attention and action processes are so tightly linked that the dedication of attention to a particular stimulus automatically initiates response-producing processes that are designed to interact with that stimulus. Responses are activated to attended stimuli regardless of the nature of attentional dedication (i.e., reflexive or voluntary). It is proposed that each time a performer approaches a known scene, a "response set" is established in working memory in which the performer identifies and maintains the characteristics of the expected target stimulus and the characteristics of the expected response to that stimulus. Thus, the response set in the model of response activation is an extension of the attentional set of Folk et al. (1992) in that the response set includes the performer's expectations of the target stimulus as well as preexcited (preprogrammed) and/or preinhibited response codes. Each stimulus that matches the physical characteristics established in the response set captures attention and, as a result, activates an independent response process. Stimuli that do not possess at least some of the expected characteristics do not capture attention and thus do not activate responses. Thus, if only one stimulus in the environment matches the response set, then that response process is completed unopposed and the movement emerges rapidly and in an uncontaminated form. However, under conditions in which more than one stimulus matches the response set, multiple response representations are triggered and subsequently race one another to surpass the threshold level of neural activation required to initiate a response. It is important to note that this is not a "winner-take-all" race where only the characteristics of the winning response influence the characteristics of actual movement alone. Instead, the characteristics of the observed movement are determined by the activation level of each of the competing responses at the moment of movement initiation. In this way, if more than one neural representation is active (or if one is active and one is inhibited) at response initiation, then the emerging response will have characteristics of both responses (or characteristics that are opposite to the inhibited response).

The final relevant element of the model is that the activation level of each response is determined by at least three interactive factors—the salience of the stimulus and associated response, an independent inhibitory process, and the time course of each independent process. The first factor, the salience or action-relevancy of the stimulus, is in fact the summation of a number of separate components including the degree attentional capture (based on the similarity between the actual and anticipated stimulus within the response set), the complexity of the response afforded by the stimulus, and the S–R compatibility. When attentional capture and S–R compatibility are maximized and response complexity is minimized, the salience of an individual response is maximized and the response to that stimulus is activated rapidly.

So, what implications does the model of response activation have for the design of HCI? In short, because the model of response activation provides a fairly comprehensive account of movement organization in complex environments, it could be used as the basis for the design of interfaces that consider the cognitive system as an interactive whole as opposed to separate units of attention and movement organization. One of the more obvious implications is that a designer should consider the time intervals between the presentation of each stimulus in a multiple-stimuli set, as this can have dramatic effects on the performer's ability to quickly respond to each stimulus (e.g., psychological refractory period—Telford 1931; Pashler 1994) and the physical characteristics of each response (Welsh and Elliott 2004a).

1.2.1.3.2 Spatial Coordinates of Attention in Different Action Contexts

Arguably the most influential work in the development of the action-centered models was the article by Tipper et al. (1992). Participants in these studies were presented with nine possible target locations, arranged in a three by three matrix, and were asked to identify the location of a target stimulus appearing at one of these locations while ignoring any nontarget stimuli presented at one of the remaining eight locations. The key innovation of this work was that Tipper and colleagues asked participants to complete a rapid aiming movement to the target location instead of identifying it with a key press. Previous studies of the reference frame of attention using key press responses had revealed that attention can work in retinotopic (e.g., Eriksen and Eriksen 1974), egocentric (e.g., Downing and Pinker 1985; Gawryszewski et al. 1987), and environmental (e.g., Hinton and Parsons 1988) coordinate systems. However, if there is a tight link between attention and action and the requirements of the action modulate, in part, the distribution of attention and attentional capture, then coordinate system used (and subsequent pattern of distractor interference effects observed) during aiming movements should be different from that used during key press responses. This difference in coordinate systems should be observed because the amount and type of information needed to successfully plan and complete aiming movements are different from that needed to successfully complete a key press response (see Section 1.1.2).

Consistent with traditional key press studies, Tipper, Lortie, and Baylis (1992) found that the presence of a distractor increased response times to the target. Although the finding of distractor interference in this selective reaching task was an important contribution to the field in and of itself, the key discovery was that the magnitude of the interference effects caused by a particular distractor location was dependent on the aiming movement being completed. Specifically, it was found that distractors (1) closer to the starting position of the hand (between the start position and the target) cause more interference than distractors farther from the starting position (the proximity-to-hand effect); and, (2) ipsilateral to the moving hand caused more interference than those in the contralateral side of space (the ipsilateral effect). Based on this pattern of interference, Tipper et al. (1992) concluded that attention and action are tightly linked such that the distribution of attention is dependent on the action that was being performed (i.e., attention was distributed in an action-centered coordinate system). Specifically, stimuli that afford actions that are more efficiently executed (i.e., movements of shorter amplitude [Fitts 1954] or into ipsilateral space [Fisk and Goodale 1985]) tend to capture attention to a greater degree (and cause more interference) than distractors that afford less-efficient responses (i.e., movements of longer amplitude or into contralateral space; see also, Tipper, Meegan, and Howard 2002).

Although the study of Tipper et al. (1992) provided critical initial insights into the issue of response efficiency and the action-dependent patterns of interference, additional research has revealed that this pattern of interference is modulated by the characteristics of the environment and the task. For instance, Keulen et al. (2002) have demonstrated that the distance between targets and distractors in the environment alters the attentional frame of reference used during reaching movements. In support of Tipper et al. (1992)

action-centered frame of reference, they found that distractors closer to the start position of the hand caused more interference than distractors beyond the path of the reaching movement (i.e., a proximity-to-hand effect) when there was a large distance (20 mm) between the target and distractor locations. In contrast, when the target and distractor locations were close (5 mm) to each other, a symmetrical pattern of interference was observed in which distractors on either side of the target caused the same amount of interference (i.e., no proximity-to-hand effect was observed). The authors suggested that this shift in the pattern of interference occurred because the planning and control stages of aiming movements require different frames of reference (action-centered and environmental, respectively). These data support the action-centered view in that the patterns interference was even dependent on the stage of action planning and execution. Within the realm of HCI, these data highlight the need for careful consideration of the spatial arrangement of stimuli in the environment because even small changes in the array can alter the efficiency of target engagement.

1.2.1.3.3 The Capture of Attention in Different Action Contexts

As reviewed in Section 1.2.1.3.2, initial investigations into action-centered attention were focused primarily on the influence that the spatial location of distractors with respect to the target had on the planning and execution of action (e.g., Meegan and Tipper 1998; Lyons et al. 1999; Pratt and Abrams 1994; Tipper et al. 1992). In that context, an action-centered framework has offered a useful perspective for the spatial organization of perceptual information presented in an HCI context. However, the reason for engaging a target in an HCI task is because the target symbolically represents an outcome or operation to be achieved. Indeed, this is what defines an icon as a target—target features symbolically carry a meaning that defines it as the appropriate target. Whether by intuition and trial and error, or through consideration of the research on attentional capture (e.g., Folk et al. 1992), programmers have already used a variety of dynamic changes to the stimulus characteristics (e.g., suddenly appearing, blinking, moving, growing, etc.) to draw our attention to certain objects and in the hopes of facilitating target engagement. Although there is little doubt that the dynamic stimuli are, in large part, successful in achieving these goals, recent investigations of how the context of the response influence perception and attention suggest that target engagement may be made more efficient through consideration of the response mode, the requirements of the actions system, and the relationship between the stimulus and the desired response.

As an initial illustration of the tight link between perceptual-motor processes, there is a growing body of evidence revealing how the characteristics of the prepared action influence the processing of certain visual stimuli. For instance, Lindemann and Bekkering (2009; see also Craighero et al. 1999) have shown that the degree of congruency between the action goal and the characteristics of an irrelevant stimulus can facilitate reaction times to initiate the movement. Participants in the study were told to reach out and grasp an X-shaped object as if they were going to turn it clockwise or counterclockwise. They were told in advance which type of movement they would be making and to wait for a "go" signal before initiating the movement that they had prepared. The "go" signal was apparent motion of an object in either a clockwise or counterclockwise direction. It was found that the participants initiated their movements more rapidly when the apparent motion of the "go" signal was congruent with the movement that they had prepared (e.g., a clockwise movement with a clockwise rotating stimulus) than when the apparent motion was incongruent with the prepared movement (e.g., a clockwise movement with a clockwise rotating stimulus). This congruency effect is consistent with other research and demonstrates that prepared movements enhance the perception of characteristics of objects that are related to the to-be-performed movement. For example, the preparation of grasping movements enhances the detection of targets that varied by size, whereas the preparation of pointing movements enhances the detection of targets that varied by luminance (Wykowska, Schubo, and Hommel 2009; see also, Symes et al. 2008).

While the research described in the previous paragraph suggests that perception of specific features is enhanced in an action-specific manner, recent work from our lab suggests that attentional capture is likewise modified by the requirement of the motor system. Specifically, Welsh and Pratt (2008) found that the attentional capture by some dynamic changes is different when key press and aiming responses are required. In this study, participants were asked to identify the location of an onset or offset target stimulus while ignoring a distractor stimulus of the opposite characteristics (i.e., onset targets were paired with offset distractors and vice versa). In separate experiments, participants responded to the target stimulus with a choice key press response or an aiming movement to the target location. Consistent with the findings of Folk et al. (1992) and Folk et al. (1994), interference effects were observed when an offset distractor was presented with an onset target and when an onset distractor was paired with an offset target. When aiming responses were required, however, inference effects were only observed when an onset distractor was presented with an offset target. The offset distractor did not cause an interference effect when participants were aiming to an onset target. Stated another way, the results indicated that an onset distractor slowed responding to an offset target in both key press and aiming tasks. An offset distractor, however, only interfered with task performance when a key press was required.

It was proposed that this action-dependent pattern of interference effects emerged because the action system modified the attentional set, thereby influencing what stimulus features capture attention and those that do not, based on the salience of the stimulus feature for the requirements of the to-be-performed action. Because key press tasks are ballistic in nature, a constant source of stable visual information is not needed to ensure accurate completion. As a result, any dynamic discontinuity is as salient as any other and can capture attention. In contrast, because the accuracy of aiming movements depends on a continual source of stimulus information for feedback-based control, offset and onset stimuli represent the two extreme ends of saliency to the motor system (with onsets at the maximally salient end and offset at the minimally salient end). As a result, offset stimuli have a very low salience to the motor system and are very unlikely to capture attention when an aiming response is required. In contrast, because onset stimuli are highly salient to the motor system, they are very likely to capture attention when aiming responses are required, regardless of the features of the target stimulus. Thus, it seems that the context of the action and the requirements of the motor system to ensure the accurate completion of the response help to shape the attentional set and what does and does not capture attention (see also Higgins and Welsh, submitted; Welsh and Zbinden 2009).

Similar action-specific interference effects to those observed in our lab have been shown across pointing and grasping actions (Bekkering and Neggers 2002; Weir et al. 2003), pointing and verbal responses (Meegan and Tipper 1999), and different types of pointing responses (Meegan and Tipper 1999; Tipper, Meegan, and Howard 2002). In sum, there is growing evidence that traditional conception of the information-processing stream as serial series of events with action only occurring after perception and cognition stages are completed is in need of revision. The research reviewed here suggests that the action system has what would traditionally be considered as an "upstream" effect and plays an important role in shaping perception and attention. From an applied perspective, now that HCI is moving into virtual reality and other types of assisted response devices, it will become increasingly important to consider the required and/or anticipated action when designing HCI environments. Specifically, this work on the spatial layout (e.g., Keulen et al. 2002) and the characteristics of the stimuli (e.g., Welsh and Pratt 2008) highlights the need for the designer to consider the interactions among perception, attention, and motor processing because there are some situations in which the transfer from simple to complex movements is not always straightforward.

1.2.1.4 Summary

Taken into the realm of HCI, it is our position that the interplay between shifts of attention, spatial compatibility, and object recognition will be a central human performance factor as technological developments continue to enhance the "directness" of direct-manipulation systems (cf. Shneiderman 1983, 1992). Specifically, as interactive environments become better abstractions of reality with greater transparency (Rutkowski 1982), the potential influence of these features of human information processing will likely increase. Thus, it is somewhat ironic that the view toward virtual reality, as the solution to the problem of creating the optimal display representation, may bring with it an "unintended consequence" (Tenner 1996). Indeed, the operator in such an HCI environment will be subject to the same constraints that are present in everyday life.

The primary goal of human factors research is to guide technological design in order to optimize perceptual-motor interactions between human operators and the systems they use within the constraints of maximizing efficiency and minimizing errors. Thus, the design of machines, tools, interfaces, and other sorts of devices utilizes knowledge about the characteristics, capabilities, as well as limitations, of the human perceptual-motor system. In computing, the development of input devices such as the mouse and graphical user interfaces was intended to improve human–computer interaction. As technology has continued to advance, the relatively simple mouse and graphical displays have begun to give way to exploration of complex gestural interfaces and virtual environments. This development may perhaps, in part, be a desire to move beyond the "artificial" nature of such devices as the mouse, to ones that provide a better mimic of reality. Why move an arrow on a monitor using a hand-held device to point to a displayed object, when instead, you can "reach" and "interact" with the object? Perhaps such an interface would provide a closer reflection of real-world interactions—and the seeming ease with which we interact with our environments, but also subject to the constraints of the human system. With this in mind, we now turn to an alternative approach to perceptual-motor interactions that we believe may point us in some exciting new directions.

1.3 COMMON CODING ACCOUNTS OF PERCEPTUAL-MOTOR INTERACTIONS

At the same time that the research on action-centered attention and perception is gaining momentum, a new approach to cognition has begun to emerge broadly termed "embodied cognition." This approach argues that, among other things, there is a bidirectional relationship between the body and cognition such that actions are influenced by cognitive operations and cognitive operations are influenced by movements and the body's action state. In many ways, cognition is considered to be a form of action. One of the key mechanisms that is considered to support this two-way connection between the body and cognition is a common representation in the brain that codes both the action plan and the sensory consequences of the action plan (the effects the action will have on the environment). It is this specific common coding mechanism that differentiates this theory from the modified views of the traditional information-processing theories reviewed in Section 1.2.1.3. On a functional level, it is suggested that these common codes connect the perception, execution, and imagination of movements and, as a result, can also help to shape other cognitive processes. Although there is a literature on the connections between action and a variety of cognitive processes, we will focus here on the relevant literature related to the interactions among action, perception, and imagination.

The origins of the common coding approach can be found in the seminal text of William James (1890). The more modern and in-depth development of this idea was first articulated by Prinz (1992) and has been refined and expanded as data accumulate (see, Decety 2002; Hommel et al. 2001; Prinz 2005). Simply put, a central outcome of this common coding mechanism is that perception and action are intimately linked such that the activation of one component automatically activates the coupled component. The planning of an action automatically activates a representation of the sensory consequences of the action and, conversely, perception or imagination of an effect automatically activates a representation of the action(s) that can bring about that effect. As a result, one can activate or simulate an action by conceiving of the desired effects on the environment and the effects of a planned action on the environment can be anticipated with the activation or simulation of the response.

A suggested consequence of this coding is that the motor system is activated when humans perceive and imagine movement-related information. This motor system activation and connection between movement (activation of motor representations), observation of movements (activation of perceptual representations), and imagination of movements (covert activation of motor and perceptual representations), then leads to the preferences and biases of our own movements, which can guide the way we perceive and imagine other movements and actions, and may also influence the way we process representations that embed movements (such as verbs). Consistent with these ideas, recent work has extended this effect to language and concept processing, showing that there is motor activation while imagining words encoding movements, and processing sentences involving movements (Bergen, Chang, and Narayan 2004; Wilson and Gibbs 2007; Holt and Beilock 2006; Barsalou 1999).

A common instance of the embodied resonance and simulation process that may involve the common codes is familiar to cinema goers: while watching an actor moving along a precipice, viewers may move their arms and legs or displace body weight to one side or another, based on what they would like to see the actor doing in the scene. Similar effects are seen in sports fans watching athletes perform and novice video game players interacting with their virtual character. Such "simulation" of others' actions may also underlie our ability to project ourselves into different character roles as well. For instance, this effect may explain why we are emotionally moved by a dramatic film scene: we simulate the characters' movements and emotional expressions using our own body and, as a result, recreate their emotional states.

In implementation terms, common coding can be thought of as an artificial neural network encoding both action and perception elements, where the activation of one type of element automatically activates the other elements (associative priming), similar to connectionist implementations of semantic priming (Cree, McRae, and McNorgan 1999). Imagination of movement, in this view, would be a form of implicit activation of the action network. Recent modeling work has shown how such common coding could arise purely through agent–environment interactions, when agents move from not using any representations (being purely reactive) to a strategy of using stored structures in the world/head. In addition, this model shows that common coding can arise from both evolutionary and within-lifetime learning (Chandrasekharan and Stewart 2007).

Most of the evidence for common coding is derived from behavioral studies in which it is assessed how actions in one medium (e.g., imagination) leads to a difference in reaction time or accuracy in another medium (e.g., execution). The following is a brief review of the experimental evidence for different types of interactions. For the sake of space and relevance to HCI, our review will focus on this behavioral evidence for common coding. It should be noted, however, that this behavioral evidence is supported by neurophysiological experiments, including imaging, transcranial magnetic stimulation (TMS), and patient studies (for a comprehensive review, see Rizzolatti and Craighero 2004; or Brass and Heyes 2005). Finally, for the sake of brevity, we will focus our discussion on the less intuitive and more relevant research on the implications of the common coding system for perception–action and imagination–action relationships. We focus on these relationships because we have used this work as the theoretical basis for a collaborative project to develop a novel tangible interface that we will highlight at the end of the chapter.

1.3.1 Perception–Action Common Coding

If common coding holds and the perception of an action automatically activates the observed action codes in the observer, then two distinct predictions can be made. The first prediction is that the observation and perception of a movement should negatively influence the concurrent performance of a movement when the observed and executed actions are incompatible because different action codes are activated in the motor system through execution and observation. Thus, the codes of observed action should interfere with the codes of the action that is to be executed. This interference effect would be similar to the trajectory deviation effects caused by competing response codes observed in the action-centered attention studies reviewed earlier in the chapter (e.g., Welsh and Elliott 2004a).

In support of the common coding hypothesis, Kilner, Paulignan, and Blakemore (2003; see also Brass, Bekkering, and Prinz 2001) found that there was more variability in the performance of a rhythmic movement pattern when participants observed another individual performing an incompatible versus a compatible rhythmic pattern. Specifically, when participants were performing a rhythmic up-and-down movement pattern with their arms, there was more horizontal deviation in movement pattern when they observed another person performing a horizontal movement pattern than when the observed person performed a vertical movement pattern. Critically, this interference effect did not occur when the participants observed similar compatible and incompatible movement patterns being executed by a robot arm. This contrast in effects of the human and the robot suggests that the activation of the common codes through observation may be sensitive to the characteristics of the observed motion and/or the intentionality the observer is able to attribute to the observed actor.

The second, and probably more relevant, prediction is that the perception of actions should be affected by performance of those actions because recent or extensive execution improves the coding of and familiarity with the perceptual consequences of the action. There are a number of lines of evidence that are consistent with this prediction. One line of evidence is the repeated finding that people are better able to recognize actions after having practiced the action patterns. For example, Casile and Giese (2006) found that people were better able to visually recognize a specific movement pattern faster than other movement sequences after learning the movement pattern. Critically, because participants were blindfolded during the learning of the task, the improvement in *visual* recognition was based on verbal and haptic feedback alone. In a related set of studies, Knoblich, Sebanz, and colleagues (see Knoblich and Sebanz 2006 for a review) have shown that people can accurately identify their own action patterns from those of other people. Presumably, people are very accurate at recognizing their own actions because they have a lifetime of experiencing and building of knowledge of their own action–effect relationships.

In addition to the work on recognition, this effect of learned actions seems to extend to preference judgments. When skilled and novice typists were asked to pick between dyads of letters (such as FV and FJ), the skilled typists preferred dyads that would be typed with less interference (i.e., different fingers), whereas novices showed no preference. Moreover, a motor task performed in parallel to the dyad preference judgments lowered skilled typists' preference, but only when the motor task involved the specific fingers that would be used to type the dyads (Beilock and Holt 2007). This preference effect has been generalized recently by Topolinski and Strack (2009), who showed that the mere exposure effect (MEE; stimuli that are repeatedly encountered are increasingly liked) is dependent on motor simulations. They showed that chewing gum while evaluating stimuli destroyed MEEs for words, but not for visual characters. However, kneading a ball with the hand left both MEEs unaffected. They argued that this effect stems from individuals representing stimuli by covertly simulating the sensorimotor processes that run when the stimuli are perceived or acted on. Chewing disrupts this process, kneading does not. These preference effects have recently been used to explain the strong identification players develop with video game characters (Chandrasekharan et al. 2010).

1.3.2 Imagination–Action Common Coding

We believe the most straightforward and convincing demonstration of the involvement of the motor system in imagination, at least in the imagination of actions, is the repeated finding that the time to mentally execute actions closely corresponds to the time it takes to actually perform them (Decety 2002; Jeannerod 2006; Young, Pratt, and Chau 2009). However, it has also been shown that responses beyond voluntary control (such as heart and respiratory rates) are activated by imagining actions to an extent proportional to that of actually performing the action (Decety 2002). In sum, these data suggest that imagination of these actions involves the activation of response codes, with these response codes running offline and generating many of the same physiological effects that would be generated during execution, although to a diminished degree. The connections between the motor system and imagination extend beyond the simulation of motor tasks to other cognitive activities (e.g., Hegarty 2004; Martin and Schwartz 2005; Nersessian 2002, 2008). We will center our discussion, however, on mental rotation.

The main prediction of this work is that, if cognitive processes such as imagination and mental rotation engage the common coding system, then these cognitive processes should be affected by concurrent action execution and vice versa. To test the prediction that action planning and execution influences cognition, Wohlschlager (2001; see also Wexler, Kosslyn, and Berthoz 1998) asked participants to mentally rotate an object while they were planning an action or actually moving their hands or feet in a direction that was compatible or incompatible with the direction of the mental rotation. Consistent with predictions based on the notion of common coding, performance on the mental rotation suffered when the direction of action was incompatible with the direction of mental rotation and performance improved when the direction of action was compatible with the mental rotation.

Although the involvement of our action system in cognition may facilitate efficient processing, the limitations of our motor system may likewise limit or hinder cognitive functioning. For example, it has recently been shown that people with writer's cramp (a focal hand dystonia characterized by constant contractions of the muscles of the hand and forearm that limit hand use) take more time to complete certain mental rotation tasks than their peers without neurological disorders. Interestingly, the difficulties in mental rotation seem to be specific to images of the affected limb (i.e., rotating pictures of hands). The time it took people with focal hand dystonia to rotate pictures of nonbody parts (e.g., houses and cars) were not different from their peers without dystonia (Fiorio, Tinazzi, and Agiloti 2006). Likewise, Kosslyn (1994) reports that participants need more time to perform mental rotations that are physically awkward. These data suggest that common coding may restrict or limit our ability to imagine novel actions and movements. Thus, although our action system may be engaged to facilitate certain cognitive processes, its role is limited by our action repertoire.

1.3.3 Summary

Through this review, we have attempted to concisely summarize the critical features of common coding theories and the evidence that supports these views. Although this area is, in many ways, in its infancy, there is a clear growing body of evidence supporting a common code system linking execution, perception, and imagination of movement and that this system can be accessed to support a wide variety of cognitive processes. The vast majority of the research in this area has been directed to testing and expanding the theoretical aspects of common coding. We believe, however, that there is tremendous potential for the principles outlined in common coding theory to shape and enhance HCI. In fact, this theoretical approach has recently been used to derive novel embodied interaction designs. We will describe this development and some potential applications in the second half of the following section.

1.4 PERCEPTUAL-MOTOR INTERACTION IN APPLIED TASKS: A FEW EXAMPLES

As we mentioned at the outset of this chapter, the evolution of computers and computer-related technology has brought us to the point at which the manner with which we interact with such systems has become a research area in itself. Current research in motor behavior and experimental psychology pertaining to attention, perception, action, and spatial cognition is poised to make significant contributions to the area of HCI. In addition to the continued development of a knowledge base of fundamental information pertaining to the perceptual-motor capabilities of the human user, these contributions will include new theoretical and analytical frameworks that can guide the study of HCI in various settings. In this final section, we highlight just a few specific examples of HCI situations that offer a potential arena for the application of the basic research that we have outlined in this chapter.

1.4.1 Attention Cueing for Military Target Detection

Combat identification of friends and enemies is essential for mission effectiveness and the prevention of friendly fire. The software that projects images to the operator's displays, including images from unmanned aerial vehicles and on head mounted displays (HMDs), can cue attention to possible target locations. In each situation, the user is required to navigate and engage targets in the real world, while attempting to perform a detection and identification on the interactive display. The use of this assistive software creates a dual task in which the operator must divide his or her attention between the separate tasks in order to complete the job successfully. Although the identification cues can provide great opportunities to facilitate the detection of critical information, they could also decrease performance by creating distracting clutter on the display (Yeh and Wickens 2001a,b). These effects are magnified as the cue reliability decreases and, in the case where the task can be performed easily without the cue, it has been shown that imperfect cues may hinder performance (Maltz and Shinar 2003). In this context, an error of commission (i.e., the cue indicates a nontarget) has much greater behavioral consequences than an error of omissions (i.e., the technology fails to cue a target) (Maltz and Shinar 2003). Thus, it is imperative that the cue stimuli involved in the secondary identification task be carefully designed to ensure the efficient processing of this information to allow as much of the attentional resources as possible to be available for the real-world tasks of target engagement.

An HMD can assist with target detection because it overlays critical cue information over the actual environment, reducing the scanning time required to sample and attend both the display and the environment. An HMD also allows for cueing in *x* and *y* coordinates and the use of *conformal imagery* in which cues or information is presented in a world-referenced frame rather than a screen-referenced frame eliminating the need for the user to transfer between reference frames (Yeh, Wickens and Seagull 1999). Users are also better at recovering from cueing errors using an HMD (Yeh et al. 2003). However, HMDs are especially susceptible to the detrimental effects of clutter as the user is expected to attend concurrently to information both on the display and in the environment.

The majority of studies find that cueing assists the user in detecting the target more quickly and accurately (e.g., Maltz and Shinar 2003); however, there is often a cost for detecting uncued targets (e.g., Yeh et al. 2003) and an increase in false alarms (Yeh and Wickens 2001a,b). The cost may result from "attentional tunnelling" where the participants fail to direct their attention to areas outside of the cue. The tunnelling may result from the user creating an attention set (Folk et al. 1992; Folk et al. 1994) for specific cue features. This attentional set may increase the chances of these salient cue stimuli capturing attention, but at the same time reduce the chances that stimuli not in the set (i.e., uncued targets) capture attention. Overall, cueing can assist the user in directing attention in difficult detection tasks as long as the cue is sufficiently reliable and does not induce clutter into the visual scene.

1.4.2 Deriving Novel Interaction Designs from Common Coding

Although there are clear implications for the research outlined above for the design of stimuli in virtual environments, we also believe that the principles of perceptual-cognitive-motor interactions outlined above should shape and enhance the interface devices that are used to translate our action goals into virtual environments. In fact, two of us (Timothy N. Welsh and Sanjay Chandrasekharan) have been involved in the recent development of a novel interaction device (see Mazalek et al. 2010). The goal of the research was to develop a device that more effectively mapped the actions of the user to the movements of the avatar. The rationale for this goal being that, by translating the user's own actions onto the avatar, there will be a shorter recalibration period, and the user can more easily relate to the avatar and respond more efficiently in the virtual environment. An additional, yet to be tested, potential consequence of this more direct relationship between user and avatar, is that once the user has identified with the avatar's movements, it is possible that the user can then learn from the avatar if it moves in a novel action pattern that is physically consistent with the movements of the user. Thus, a more direct translation from user to avatar might not only facilitate performance in virtual environments, but it might also assist in the learning and development of the user.

The development of this device is rooted in the common coding theory (e.g., Prinz 1997). A particularly informative set of findings are that individuals recognize their own actions more accurately than the action patterns of other people, even when all that is available is a very information-poor rendition such as point-light displays (see Knoblich and Sebanz 2006, for a review). This own-action advantage is thought to arise because the observer's motor system is involved in the perception process. Because the motor system of the observer is trained to their own actions and the sensory consequences of those actions, it is thought that viewing their own actions more efficiently activates their motor system and the tightly linked common perceptual codes. This more efficient activation of the common codes then allows the individuals to identify their own actions more accurately than those of other people. Extending these findings to HCI, we reasoned that a user would identify more closely with a virtual character in a virtual environment if that virtual character encodes the player's own actions as opposed to movement primitives common to all, or at least a subset of, characters.

Based on this experimental and theoretical work, a control interface was developed to more directly map the user's own actions onto a virtual character in a real-time virtual environment. The device that was developed was a wearable, jointed puppet whose limbs are attached to the limbs of the user so that the limbs of the puppet move along with the hands, legs, and neck of the user. Potentiometers are located at the joints so that the changes in joint angle of the puppet can be transferred to a virtual character (Mazalek et al. 2010). As an initial testing of the puppet system, we recently examined if the same "own-action" advantage (people can recognize their own movements better than others, Knoblich and Sebanz 2006) was present when their movements were represented by a virtual character. Consistent with previous work, we have found that individuals were able to identify abstract representations (point-light displays) of their own actions when the representations were created by affixing small lights to actor's actual body (see Mazalek et al. 2009) and when a player's movements are transferred to an avatar using the puppet (Mazalek et al. 2010). The advantages persist even when the point-light walkers were presented in altered body sizes (Mazalek et al. 2009). Thus, we feel confident that the movements of an individual can be effectively transferred to virtual characters through the puppet device and that people may be able to identify with (embody) these characters when this transfer of movement patterns is successful.

Although our initial development and testing of the device seems positive, the interface continues to evolve. As the interface improves, our view to the possible applications of this system, beyond real-time interaction, expands. For example, we are opening a second line of research in which we are trying to exploit the link between action, cognition, and imagination. Extending the results from the research reviewed above and the theoretical relationship between action, cognition, and imagination, we hypothesized that novel movements executed by the embodied avatar may improve imagination of novel movements, thus improving players' ability to execute creative cognitive processes such as mental rotation. To facilitate this learning effect, however, the "embodied" virtual characters (characters encoding the player's own actions) would need to execute movements on screen that are impossible for the actual user to perform. Further, the user will lose some control of the embodied avatar when the avatar executes novel movements, such as back-flips (as this would require the user also doing back-flips). Thus, the puppet-controlled avatar will need to retain the movement patterns of the user while executing these physically impossible movements. This is an interesting application challenge, where we need to maintain a fine line between control and no-control, with self-recognition elements of the former situation retained/continued into the latter situation.

As an initial attempt to solve this issue, we have developed a game in which the cameras around the avatar rotate slowly, giving the impression of the avatar rotating in space. Objects then appear close to the avatar, and the user's task is to touch these objects using the puppet interface. Our preliminary results reveal that playing this game using the puppet leads to improved performance on the game and a mental rotation task compared with playing the game using standard game interfaces, such as keyboards and game controllers. These and other experimental applications are still under development. While we are hopeful that the puppet device will achieve all our aims, we feel that, regardless of the outcome, this entire line of research is a powerful example of how theoretical considerations of perceptual-cognitive-motor interactions can be used to inform HCI development and, likewise, this technological development can lead to new methods for testing and enhancing the theory on which the technology was based. For a wider discussion of how common coding theory can help in deriving novel interaction modes, see Chandrasekharan et al. (2010).

1.5 SUMMARY

The field of HCI offers a rich environment for the study of perceptual-motor interactions. The design of effective human–computer interfaces has been, and continues to be, a significant challenge that demands an appreciation of the entire human perceptual-motor system. The information-processing approach has provided a dominant theoretical and empirical framework for the study of perceptual-motor behavior in general, and for consideration of issues in HCI and human factors in particular. Texts in the area of human factors and HCI (including the present volume) are united in their inclusion of chapters or sections that pertain to the topic of human information processing. Moreover, the design of effective interfaces reflects our knowledge of the perceptual (e.g., visual displays, use of sound, graphics), cognitive (e.g., conceptual models, desktop metaphors), and motoric constraints (e.g., physical design of input devices, ergonomic keyboards) of the human perceptual-motor system.

Technological advances have undoubtedly served to improve the HCI experience. For example, we have progressed beyond the use of computer punch cards and command-line interfaces to more complex tools such as graphical user interfaces, speech recognition, and tangible control systems. As HCI has become not only more effective, but by the same token more elaborate, the importance of the interaction between the various perceptual, cognitive, and motor constraints of the human system has come to the forefront. In our previous chapters, we presented overviews of some topics of research in action-centered attention and in S–R compatibility in perceptual-motor interactions that we believed were relevant to HCI. In the present chapter, we have added an overview of common coding theories of cognition. We believe that the relevance of the research and theoretical considerations discussed in this chapter for HCI cannot be underestimated. Clearly, considerable research will be necessary to evaluate the applicability of both of these potentially relevant lines of investigation to specific HCI design problems. Nevertheless, the experimental work to date leads us to conclude that the motor system is not simply responsible for outputting the results of perceptual and cognitive processing, but in fact has a critical and active role in shaping perception and cognition. For this reason, an effective interface must be sensitive to the perceptual and action expectations of the user, the specific action associated with a particular response location, the action relationship between that response and those around it, and the degree of translation required to map the perceptual-motor workspaces.

2 Human Information Processing
An Overview for Human–Computer Interaction

Robert W. Proctor and Kim-Phuong L. Vu

CONTENTS

> It is natural for an applied psychology of human-computer interaction to be based theoretically on information-processing psychology.
>
> **—Card, Moran, and Newell (1983)**

Human–computer interaction (HCI) is fundamentally an information-processing task. When interacting with a computer or any technological device, a user has specific goals and subgoals in his or her mind. For example, smartphone users initiate the interaction by turning on or activating the device and selecting the appropriate commands needed to accomplish their desired goal. Given that the smartphone can do more than just make calls, the commands may activate applications designed to allow specific types of tasks such as playing games, e-mailing, navigating with GPS, or web surfing to be performed. The resulting output, typically displayed on the phone's screen, must provide adequate information for the user to complete the next step, or the user must enter another command to obtain the desired output. The sequence of interactions to accomplish the goals may be long and complex, and several alternative sequences, differing in efficiency, may be used to achieve these goals. During the interaction, the user is required to identify displayed information, select responses based on the displayed information, and execute those responses by entering commands. The user must search the displayed information and attend to the appropriate aspects of it. She or he must also recall the commands and the resulting consequences of those commands for different programs, remember information specific to the task that is being performed, and make decisions and solve problems during the process. For the interaction between the device and user to be efficient, the interface must be designed in accordance with the user's information-processing capabilities.

2.1 HUMAN INFORMATION-PROCESSING APPROACH

The rise of the human information-processing approach in psychology is closely coupled with the growth of the fields of cognitive psychology, human factors, and human engineering (see Proctor and Vu 2010). Although research that can be classified as falling within these fields has been conducted since the last half of the nineteenth century, their formalization dates back to World War II (see Hoffman and Defenbacher 1992). As part of the war efforts, experimental psychologists worked along with engineers on applications associated with using the sophisticated equipment being developed. As a consequence, the psychologists were exposed not only to applied problems but also to the techniques and views being developed in areas such as communications engineering (see Roscoe 2011). Many of the concepts from engineering, for instance, the notion of transmission of information through a limited capacity communications channel, were seen as applicable to analyses of human performance.

The human information-processing approach is based on the idea that human performance, from displayed information to response, is a function of several processing stages. The nature of these stages, how they are arranged, and the factors that influence how quickly and accurately a particular stage operates, can be discovered through appropriate research methods. It is often said that the central metaphor of the information-processing approach is that a human is like a computer (e.g., Lachman, Lachman, and Butterfield 1979). However, even more fundamental than the computer metaphor is the assumption that the human is a complex system that can be analyzed in terms of subsystems and their interrelation. This point is evident in the work of researchers on attention and performance, such as Paul Fitts (1951) and Donald Broadbent (1958), who were among the first to adopt the information-processing approach in the 1950s.

The systems perspective underlies not only human information processing but also human factors and HCI, providing a direct link between the basic and applied fields (Proctor and Van Zandt 2008). Human factors, in general, and HCI in particular, begin with the fundamental assumption that a human–machine system can be decomposed into machine and human subsystems, each of which can be analyzed further. The human information-processing approach provides the concepts, methods, and theories for analyzing the processes involved in the human subsystem. Posner (1986) stated, “Indeed, much of the impetus for the development of this kind of empirical study stem from the desire to integrate description of the human with overall systems” (p. V-6). Young, Clegg, and Smith (2004) emphasized that the most basic distinction among three processing stages (perception, cognition, and action), as captured in a block diagram model of human information processing, is important even for understanding the dynamic interactions of an operator with a vehicle for purposes of computer-aided augmented cognition. They note,

> “This block diagram model of the human is important because it not only models the flow of information and commands between the vehicle and the human, it also enables access to the internal state of the human at various parts of the process. This allows the modeling of what a cognitive measurement system might have access to (internal to the human), and how that measurement might then be used as part of a closed-loop human-machine interface system” (pp. 261–262).

In the first half of the twentieth century, the behaviorist approach predominated in psychology, particularly in the United States. Within this approach, many sophisticated theories of learning and behavior were developed that differed in various details (Bower and Hilgard 1981). However, the research and theories of the behaviorist approach tended to minimize the role of cognitive processes and were of limited value to the applied problems encountered in World War II. The information-processing approach was adopted because it provided a way to examine topics of basic and applied concern such as attention that were relatively neglected during the behaviorist period. It continues to be the main approach in psychology, although contributions have been made from other approaches.

Within HCI, human information-processing analyses are used in two ways. First, empirical studies evaluate the information-processing requirements of various tasks in which humans use computers. Second, computational models are developed with the intent to characterize human information processing when interacting with computers and to predict human performance with alternative interfaces. In this chapter, we survey methods used to study human information processing and summarize the major findings and the theoretical frameworks developed to explain them. We also tie the methods, findings, and theories to HCI issues to illustrate their use.

2.2 INFORMATION-PROCESSING METHODS

Any theoretical approach makes certain presuppositions and tends to favor some methods and techniques over others. Information-processing researchers have used behavioral and, to an ever-increasing extent, psychophysiological and neuroimaging measures, with an emphasis on chronometric (time-based) methods. There also has been a reliance on flow models that are often quantified through computer simulation or mathematical modeling.

2.2.1 Signal Detection Methods and Theory

One of the most useful methods for studying human information processing is that of signal detection (Macmillan and Creelman 2005). In a signal detection task, some event is classified as a signal, and the subject’s task is to detect whether the signal is present. Trials on which it is not present are called noise trials. The proportion of trials on which the signal is correctly identified as present is called the hit rate, and the proportion of trials on which the signal is incorrectly identified as present is called the false alarm rate. By using the hit and false alarm rates, whether the effect of a variable is on detectability or response bias can be evaluated.

Signal detection theory is often used as the basis for analyzing data from such tasks. This theory assumes that the response on each trial is a function of two discrete operations, encoding and decision. On a trial, the subject samples the information presented and decides whether this information is sufficient to warrant a *signal present* response. The sample of information is assumed to provide a value along a continuum of evidence states regarding the likelihood that the signal was present. The noise trials form a probability distribution of states, as do the signal trials. The decision that must be made on each trial can be characterized as whether the event is from the signal or noise distribution. The subject is presumed to adopt a criterion value of evidence above which he or she responds *signal present* and below which he or she responds *signal absent*.

In the simplest form, the distributions are assumed to be normal and equal variance. In this case, a measure of detectability, d', can be derived, as well as a measure of response bias, C (for criterion; Macmillan and Creelman 2005). The d' measure represents the difference in the means for the signal and noise distributions in standard deviation units and is found by converting the hit rate and false alarm rate to standard normal scores and obtaining the difference. A value of 0 indicates no detectability, whereas a value of 3.0 or greater indicates close to perfect detectability. The C measure is calculated by summing the standardized values of the hit and false alarm rates, and dividing by two. A value of 0 for C indicates no response bias. Positive values indicate a bias toward *signal absent* responses, and negative values indicate a bias toward *signal present* responses, with the absolute value indicating the magnitude of the bias. This measure reflects the observer's overall willingness to say *signal present*, regardless of whether it actually is present. There are numerous alternative measures of detectability and bias based on different assumptions and theories, and many task variations to which they can be applied (see Macmillan and Creelman 2005).

Signal detection analyses have been particularly useful because they can be applied to any task that can be depicted in terms of binary discriminations. For example, the proportion of words in a memory task correctly classified as old can be treated as a hit rate, and the proportion of new lures classified as old can be treated as a false alarm rate (e.g., Rotello and Macmillan 2006). In cases such as these, the resulting analysis helps researchers determine whether variables are affecting detectability of an item as old or response bias.

An area of research in which signal detection methods have been widely used is that of vigilance (Parasuraman and Davies 1977). In a typical vigilance task, a display is monitored for certain changes in it (e.g., the occurrence of an infrequent stimulus). Vigilance tasks are common in the military, but many aspects also can be found in computer-related tasks such as monitoring computer network operations (Percival and Noonan 1987). A customary finding for vigilance tasks is the vigilance decrement, in which the hit rate decreases as time on the task increases. The classic example of this vigilance decrement is that, during World War II, British radar observers detected fewer of the enemy's radar signals after 30 minutes in a radar observation shift (Mackworth 1948). Parasuraman and Davies concluded that, for many situations, the primary cause of the vigilance decrement is an increasingly strict response criterion. That is, the false alarm rate as well as the hit rate decreases as a function of time on task.

Parasuraman and Davies (1977) also provided evidence that detectability decreases across the vigil when the task requires comparison of each event to a standard held in memory and the event rate is high. Findings indicate that this decrease in detectability is a consequence of the high demand on cognitive resources imposed by such tasks. Although vigilance tasks were previously thought to be undemanding, evidence has shown that maintaining a vigil in many situations requires considerable mental effort (Warm, Parasuraman, and Matthews 2008). Our point here is that signal detection theory has played a prominent role in this research on vigilance, helping to dissociate changes in performance associated with mental demands (decreased detectability) from those due to lapses of attention (response criteria).

2.2.2 Chronometric Methods

Chronometric methods, for which time is a factor, have been the most widely used for studying human information processing. Indeed, Lachman, Lachman, and Butterfield (1979) portrayed reaction time (RT) as the main dependent measure of the information-processing approach. Although many other measures are used, RT still predominates in part because of its sensitivity and in part because of the sophisticated techniques that have been developed for analyzing RT data.

A technique called the subtractive method, introduced by Donders (1868/1969) in the 1860s, was revived in the 1950s and 1960s. This method provides a way to estimate the duration of a particular processing stage. The assumption of the subtractive method is that a series of discrete processing stages intervene between stimulus presentation and response execution. Through selection of pairs of tasks that differ by a single stage, the RT for the easier task can be subtracted from that for the more difficult task to yield the time for the additional process. Donders used three tasks hypothesized to differ with respect to stimulus identification and response selection, respectively, and estimated the time for each stage. Recently, Van de Laar et al. (2010) applied similar logic to situations in which on some trials a participant receives a "stop" signal during the reaction process, indicating that the response is to be stopped. They estimated the durations of the stop-signal identification process and a response-mapping process to be 34 and 20 ms, respectively.

The subtractive method has been used to estimate the durations of a variety of other processes, including rates of mental rotation (approximately 12–20 ms per degree of rotation; Shepard and Metzler 1971) and memory search (approximately 40 ms per item; Sternberg 1969). An application of the subtractive method to HCI would be, for example, to compare the time to find a target link on two web pages that are identical except for the number of links displayed, and to attribute the extra time to the additional visual search required for the more complex web page.

The subtractive method is only applicable when discrete, serial processing stages can be assumed. Also, the processing for the two tasks being compared must be the same except for the additional process that differentiates them. This requires an assumption of pure insertion, which is that the additional process for the more complex of two tasks can be inserted without affecting the processes held in common by the tasks. However, this assumption often is not justified.

Sternberg (1969) developed the additive factors method to allow determination of the processes involved in performing a task. The additive factors method avoids the problem of pure insertion because the crucial data are whether two variables affect RT for the same task in an additive or interactive manner. Sternberg assumed, as did Donders, that information processing occurs in a sequence of discrete stages, each of which produces a constant output that serves as input to the next stage in the sequence. With these assumptions, he showed that two variables that affect different stages should have additive effects on RT. In contrast, two variables that affect the same stage should have interactive effects on RT. Sternberg performed detailed analyses of memory search tasks in which a person holds a set of letters or digits in memory and responds to a target stimulus by indicating whether it is in the memory set. Based on the patterns of additive and interactive effects that he observed, Sternberg concluded that the processing in such tasks involves four stages: target identification, memory search, response selection, and response execution. Grobelny, Karwowski, and Drury (2005) provide an application of additive factors logic to usability of graphical icons in the design of HCI interfaces. Mode of icon array (menu or dialog box), number of icons, and difficulty of movement had additive effects on response times, implying that these variables affect different processing stages.

Both the subtractive and additive factors methods have been challenged on several grounds (Pachella 1974). First, the assumption of discrete serial stages with constant output is difficult to justify in many situations. Second, both methods rely on analyses of RT, without consideration of error rates. This can be problematic because performance is typically not error free, and, as described in Section 2.2.3, speed can be traded for accuracy. Despite these limitations, the methods have proved to be robust and useful (Sanders 1998). For example, Salthouse (2005) notes that the process analysis approach used in contemporary research into aging effects on cognitive abilities “has used a variety of analytical methods such as subtraction, additive factors … to partition the variance in the target variable into theoretically distinct processes” (p. 288).

2.2.3 Speed–Accuracy Methods

The function relating response speed to accuracy is called the speed–accuracy trade-off (Pachella 1974). The function, illustrated in Figure 2.1, shows that very fast responses can be performed with chance accuracy, and accuracy will increase as responding slows down. Of importance is the fact that when accuracy is high, as in most RT studies, a small increase in errors can result in a large decrease in RT. With respect to text entry on computing devices, MacKenzie and Soukoreff (2002) state, “Clearly, both speed and accuracy must be measured and analyzed…. Participants can enter text more quickly if they are willing to sacrifice accuracy” (pp. 159–160).

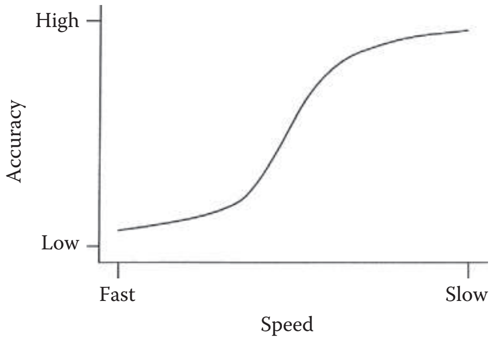

FIGURE 2.1 Speed-accuracy operating characteristic curve. Faster responding occurs at the cost of lower accuracy.

In speed–accuracy trade-off studies, the speed–accuracy criterion is varied between blocks of trials or among subjects by using different instructions regarding the relative importance of speed versus accuracy, varying payoffs such that speed or accuracy is weighted more heavily, or imposing different response deadlines (Wickelgren 1977). These studies have the potential to be more informative than RT studies because they can provide information about whether variables affect the intercept (time at which accuracy exceeds chance), asymptote (the maximal accuracy), and rate of ascension from the intercept to the asymptote, each of which may reflect different processes. For example, Boldini, Russo, and Avons (2004) obtained evidence favoring dual-process models of recognition memory over single-process models by varying the delay between a visually presented test word and a signal to respond. Recognition accuracy benefited from a modality match at study and test (better performance when the study words were also visual rather than auditory) at short response-signal delays, but it benefited from deep processing during study (judging pleasantness) over shallow processing (repeating aloud each word) at long response-signal delays. Boldini et al. interpreted these results as consistent with the view that recognition judgments are based on a fast familiarity process or a slower recollection process.

In tasks requiring search of complex visual displays, a speed emphasis may influence more than just the criterion for emitting a response. McCarley (2009) had young adults perform a simulated baggage-screening task under instructions that emphasized speed or accuracy of responding. With speed emphasis, the participants made fewer eye fixations of shorter duration than under accuracy emphasis. Reduction in accuracy was a consequence mainly of failure to fixate the target of the search rather than a failure to respond to targets that were fixated. This study illustrates how a speed–accuracy trade-off manipulation can be of value in applied contexts.

Because the speed–accuracy criterion is manipulated in addition to any other variables of interest, much more data must be collected in a speed–accuracy study than in a typical RT study. Consequently, use of speed–accuracy methods has been restricted to situations in which the speed–accuracy relation is of major concern or of apparent significant value, rather than being widely adopted as the method of choice.

2.2.4 Psychophysiological and Neuroimaging Methods

In the past decade, psychophysiological and neuroimaging methods have been used increasingly to evaluate implications of information-processing models and to relate the models to brain processes. This area of research is called *cognitive neuroscience* (Ward 2010). Such methods can provide details regarding the nature of processing by examining physiological activity as a task is being performed. The most widely used psychophysiological method involves measurement of electroencephalograms (EEGs), which are recordings of changes in brain activity as a function of time as measured from electrodes placed on the scalp (Rugg and Coles 1995). Different frequency bands of EEG rhythms can be distinguished that can be related to subjective states and the processes underlying task performance.

One application of EEGs to HCI in recent years has been the development of brain–computer interfaces that allow a person to control technological devices through the use of brain signals. Such interfaces are of value for motor-disabled persons who are not able to communicate through traditional data-entry devices. Changes in EEGs that arise from different types of mental processing can be coded into distinct computer commands, and people can be trained to use their thoughts to control the computer's interface (e.g., Kauhanen et al. 2007). This mode of HCI opens up possibilities for disabled persons to interact with their environment and communicate with other people.

Of most concern for information-processing research are event-related potentials (ERPs), which are the changes in brain activity that are elicited by an event such as stimulus presentation or response initiation. ERPs are obtained by averaging across many trials of a task to remove background EEG noise and are thought to reflect postsynaptic potentials in the brain. There are several features of the ERP that represent different aspects of processing. These features are labeled according to their polarity, positive (P) or negative (N), and their sequence or latency. The first positive (P1) and negative (N1) components are associated with early perceptual processes. They are called exogenous components because they occur in close temporal proximity to the stimulus event and have a stable latency with respect to it. Later components reflect cognitive processes and are called endogenous because they are a function of the task demands and have a more variable latency than the exogenous components. One such component that has been studied extensively is the P3 (or, P300), which represents postperceptual processes. When an occasional target stimulus is interspersed in a stream of standards, the P3 is observed in response to targets, but not to standards. By comparing the effects of task manipulations on various ERP components such as P3, their onset latencies, and their scalp distributions, relatively detailed inferences about the cognitive processes can be made.

An early application of P3 analysis to HCI is a study by Trimmel and Huber (1998). In their study, subjects performed three HCI tasks (text editing, programming, and playing the game *Tetris*) for 7 minutes each. They also performed comparable paper/pencil tasks in three other conditions. The P3 was measured after each experimental task by having subjects monitor a stream of high- and low-pitched tones, keeping count of each separately. The P3 varied as a function of type of task, as well as medium (computer vs. paper/pencil). The amplitude of the P3 was smaller following the HCI tasks than following the paper/pencil tasks, suggesting that the HCI tasks caused more fatigue or depletion of cognitive resources than the paper/pencil task. The P3 latency was shorter after the programming task than after the others, which the authors interpreted as an aftereffect of highly focused attention.

Another measure that has been used in studies of human information processing is the lateralized readiness potential (LRP; Eimer 1998). The LRP can be recorded in choice-reaction tasks that require a response with the left or right hand. It is a measure of differential activation of the lateral motor areas of the visual cortex that occurs shortly before and during execution of a response. The asymmetric activation favors the motor area contralateral to the hand making the response, because this is the area that controls the hand. The LRP has been obtained in situations in which no overt response is ever executed, allowing it to be used as an index of covert, partial response activation. The LRP is thus a measure of the difference in activity from the two sides of the brain that can be used as an indicator of covert reaction tendencies, to determine whether a response has been prepared even when it is not actually executed. It can also be used to determine whether the effects of a variable are before or subsequent to response preparation.

Electrophysiological measurements do not have the spatial resolution needed to provide precise information about the brain structures that produce the recorded activity, although advances in the technology are producing continual improvements in this regard. Much work has been done recently, though, on neuroimaging methods that provide better spatial resolution. These include positron-emission tomography, functional magnetic resonance imaging (fMRI), and transcranial Doppler sonography, which measure changes in blood flow associated with neuronal activity in different regions of the brain (Huettel, Song, and McCarthy 2004). Traditionally, these methods have poorer temporal resolution than the electrophysiological methods, but with the introduction of more sophisticated techniques, the gap in temporal resolution has been greatly reduced.

In an imaging study, often both control and experimental tasks are performed, and the functional neuroanatomy of the cognitive processes is derived by subtracting the image during the control task from that during the experimental task. This subtractive method of neuroimaging analysis has the same limitations as that for reaction-time analysis (Sartori and Umiltà 2000). Stevenson, Kim, and James (2009) provided evidence that an additive factors analysis of fMRI data, in which interactive vs. additive effects of different independent variables are compared, "provides a method for investigating multisensory interactions that goes beyond what can be achieved with more established metric-based, subtraction-type methods" (p. 183).

Application of cognitive neuroscience to human factors and HCI has been advocated under the heading of neuroergonomics (e.g., Lees et al. 2010). According to Parasuraman (2003), "Neuroergonomics focuses on investigations of the neural bases of mental functions and physical performance in relation to technology, work, leisure, transportation, health care and other settings in the real world" (p. 5). Neuroergonomics has the goal of using knowledge of the relation between brain function and human performance to design interfaces and computerized systems that are sensitive to brain function with the intent of increasing the efficiency and safety of human–machine systems.

2.3 INFORMATION-PROCESSING MODELS

It is common to assume that the processing between stimuli and responses consists of a series of discrete stages for which the output for one stage serves as the input for the next, as Donders and Sternberg assumed. This assumption is made for the Model Human Processor (Card, Moran, and Newell 1983) and the Executive-Process Interactive Control (EPIC; Meyer and Kieras 1997) architectures, among others, both of which have been applied to HCI. However, models can be developed that allow for successive processing stages to operate concurrently. McClelland's (1979) cascade model, in which partial information at one subprocess, or stage, is transferred to the next, is of this type. Each stage is continuously active, and its output is a continuous value that is always available to the next stage. The final stage results in selection of which of the possible alternative responses to execute. Many parallel distributed processing, or neural network, models are of a continuous nature.

According to J. Miller (1988), models of human information processing can be classified as discrete or continuous along three dimensions: representation, transformation, and transmission. Representation refers to whether the input and output codes for the processing stage are continuous or discrete. Transformation refers to whether the operation performed by the processing stage (e.g., spatial transformation) is continuous or discrete. Transmission is classified as discrete if the processing of successive stages does not overlap temporally. The discrete stage model proposed by Sternberg (1969) has discrete representation and transmission, whereas the cascade model proposed by McClelland (1979) has continuous representation, transmission, and transformation. Models can be intermediate to these two extremes. For example, Miller's (1988) asynchronous discrete coding model assumes that most stimuli are composed of features, and these features are identified separately. Discrete processing occurs for feature identification, but once a feature is identified, this information can be passed to response selection while the other features are still being identified.

Sequential sampling models are able to account for both RT and accuracy, and consequently, the trade-off between them (Ratcliff and Smith 2004; Van Zandt, Colonius, and Proctor 2000). Such models are dynamic models of signal detection, in which decisions are based on a series of samples from the probability distributions rather than a single sample. Each sample is classified as favoring one alternative or another, and this information is fed into a decision mechanism in which gradual accumulation of the information occurs until a response threshold is reached, at which time that response is made. As Busemeyer and Diederich (2010) note, "Dynamic models of signal detection have proven to be very effective for simultaneously analyzing choice probability and the response time distributions for signal detection tasks" (p. 89).

Various types of the dynamic models have been developed and applied to an array of experimental tasks. In such models, factors that influence the quality of information processing (the detectability or discriminability) have their effects on the rate at which the information accumulates. In contrast, factors that bias speed versus accuracy or factors that produce biases toward particular responses have their effects on the response thresholds.

Sequential sampling can be incorporated into more complete cognitive architectures to model speed and accuracy. These architectures specify properties of various processing stages and stores, such as memory and decision processes, and provide a means for developing specific models to simulate performance of a range of tasks. One widely used architecture of this type is Adaptive Control of Thought—Rational (Anderson et al. 2004), which has been used to model, for example, improvements in performance and retention with practice (practice and retention [Anderson, Fincham, and Douglass 1999] and the choices in decision-making tasks [Gonzalez, Lerch, and Lebiere 2003]).

2.4 INFORMATION PROCESSING IN CHOICE-REACTION TASKS

In a typical choice-reaction task in which each stimulus is assigned to a unique response, it is customary to distinguish between three stages of processing: stimulus identification, response selection, and response execution (Proctor and Van Zandt 2008). The stimulus-identification stage involves processes that are entirely dependent on stimulus properties. The response-selection stage concerns those processes involved in determining which response to make to each stimulus. Response execution refers to programming and execution

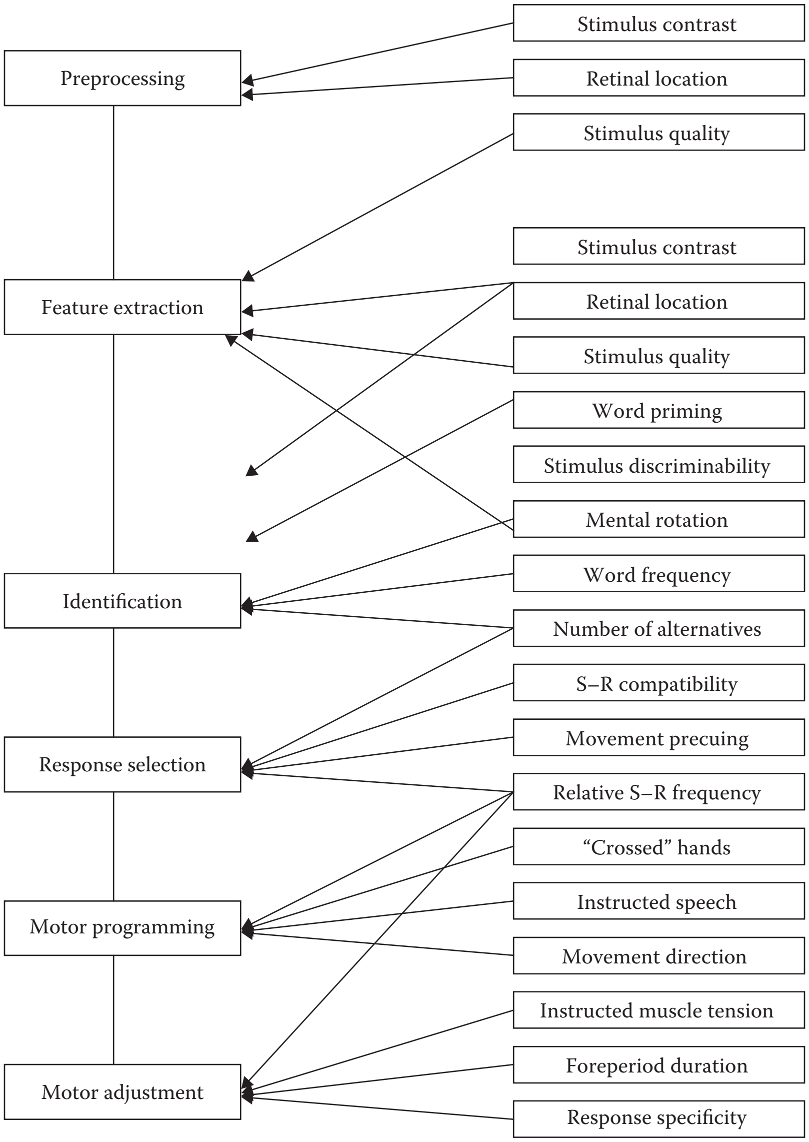

FIGURE 2.2 Information-processing stages and variables that affect them, based on Sanders' (1998) taxonomy. (From Sanders, A. F., *Elements of Human Performance*, Erlbaum, Mahwah, New Jersey, 1998. With permission.)

of motor responses. Based on additive factors logic, Sanders (1998) decomposed the stimulus-identification stage into three subcategories and the response-execution stage into two subcategories, resulting in six stages (see Figure 2.2).

2.4.1 Stimulus Identification

The preprocessing stage of stimulus identification refers to peripheral sensory processes involved in the conduction of the sensory signal along the afferent pathways to the sensory projection areas of the cerebral cortex. These processes are affected by variables such as stimulus contrast and retinal location. As stimulus contrast, or intensity, decreases, RT increases. For example, Miles and Proctor (2009) had participants make left and right keypress responses to the nonspatial or spatial feature of centrally presented location words. The discriminability of the spatial feature of the word, or of both the spatial and nonspatial features, was manipulated. When the spatial feature of the word was task-irrelevant, decreasing the discriminability of this feature reduced the typical benefit for correspondence of the word meaning with the key press response to the relevant stimulus feature. This correspondence benefit was restored when the discriminability of both the task-relevant and task-irrelevant features were reduced together, slowing the processing of both the relevant and irrelevant information. These results suggest that reduction of discriminability slows processing of the perceptual information but does not alter the response-selection processes that operate on that information.

Feature extraction involves lower-level perceptual processing based in area V1 (the visual cortex) and other early visual cortical areas. Stimulus discriminability, word priming, and stimulus quality affect the feature extraction process. For example, manipulations of stimulus quality such as superimposing a grid slow RT, presumably by creating difficulty for the extraction of features. Identification itself is influenced by word frequency and mental rotation. The latter refers to that when a stimulus is rotated from the upright position, the time it takes to identify the stimulus increases as an approximately linear function of angular deviation from upright (Shepard and Metzler 1971; see also Section 2.2.2). This increase in identification time is presumed to reflect a normalization process by which the image is mentally rotated in a continuous manner to the upright position.

2.4.2 Response Selection

Response selection refers to those processes involved in determining what response to make to a particular stimulus. It is affected by the number of alternatives, stimulus–response compatibility, and precuing (providing advance information about a forthcoming event). RT increases as a logarithmic function of the number of stimulus–response alternatives (Hick 1952; Hyman 1953). This relation is known as the Hick–Hyman law, which for *N* equally likely alternatives is as follows:

$$\mathrm{RT} = a + b \log_2 N \tag{2.1}$$

where *a* is the base processing time, and *b* is the amount that RT increases with increases in *N*. The slope of the Hick–Hyman function is influenced by many factors. For example, the slope decreases as subjects become practiced at a task (Teichner and Krebs 1974). Usher, Olami, and McLelland (2002) provided evidence from fits of a sequential sampling model that the Hick–Hyman law is due to subjects' adjusting their response criteria upward as the number of alternatives increases, in an attempt to maintain a constant high level of accuracy.

One variable that influences the slope of the Hick–Hyman function is stimulus–response compatibility, which has considerable impact on response-selection efficiency (see Proctor and Vu 2006, for a review of compatibility principles). Compatibility effects are differences in speed and accuracy of responding as a function of how natural, or compatible, the relation between stimuli and responses is. Two types of compatibility effects can be distinguished (Kornblum, Hasbroucq, and Osman 1990). For one type, certain sets of stimuli are more compatible with certain sets of responses than with others. For example, the combinations of verbal–vocal and spatial–manual sets yield better performance than the combinations of verbal–manual and spatial–vocal sets (Wang and Proctor 1996). For the other type, within a specific stimulus–response set, some mappings of individual stimuli to responses produce better performance than others. If one stimulus has the meaning "left" and the other "right," performance is better if the left stimulus is mapped to the left response and the right stimulus to the right response, for all stimulus and response modes.

Fitts and Seeger (1953) and Fitts and Deininger (1954) demonstrated both types of compatibility effects for spatially arranged display and response panels. However, compatibility effects occur for a much wider variety of other stimulus–response sets. According to Kornblum, Hasbroucq, and Osman (1990), dimensional overlap (similarity) between the stimulus and response sets is the critical factor. When the sets have dimensional overlap, a stimulus will activate its corresponding response automatically. If this response is correct (compatible mapping), responding will be facilitated, but if it is not correct (incompatible mapping), responding will be inhibited. A second factor contributing to the advantage for the compatible mapping is that intentional translation of the stimulus into a response will occur quicker when the mapping is compatible than when it is not. Most contemporary models of stimulus–response compatibility include both automatic and intentional response-selection routes (Hommel and Prinz 1997), although they differ regarding the exact conditions under which each plays a role and the way in which they interact.

One reason why automatic activation is considered to contribute to compatibility effects is that such effects occur when irrelevant stimulus information overlaps with the response set (Lu and Proctor 1995). The Stroop color-naming effect, for which an incongruent color word produces interference in naming a relevant stimulus color, is most well-known example. An irrelevant stimulus location also produces interference when it is incongruent with the location of a key press to a relevant stimulus dimension, a phenomenon known as the Simon effect (Simon 1990). Psychophysiological studies in which the LRP has been measured have provided evidence that the Simon effect is due, at least in part, to activation of the response corresponding to stimulus location (Melara et al. 2008).

For completely unrelated stimulus and response sets that are structured, performance is better when structural correspondence is maintained (Reeve and Proctor 1990). For instance, when stimuli and responses are ordered (e.g., a row of four stimulus locations and a row of four response locations), RT is faster when the stimulus–response mapping can be characterized by a rule (e.g., press the key at the mirror opposite location) than when the mapping is random (Duncan 1977). Spatial compatibility effects also occur when display and response elements refer to orthogonal spatial dimensions (Proctor and Cho 2006). However, stimulus–response compatibility effects sometimes do not occur under conditions in which one would expect them to. For example, when compatible and incompatible mappings are mixed within a single block, the typical compatibility effect is eliminated (Shaffer 1965; Vu and Proctor 2004). Moreover, the same display and response elements can be coded along multiple dimensions in certain situations (e.g., vertical position vs. horizontal position). The relative importance of maintaining compatibility on each dimension is a function of how salient the dimensions are made by the task environment (Rubichi et al. 2006).

Stimulus–response compatibility effects occur for older adults as well as younger adults, with older adults typically showing larger compatibility effects that cannot be attributed entirely to general slowing (Proctor, Vu, and Pick 2005). Although older adults show a greater cost of incompatibility than do younger adults, evidence indicates that the processing of information proceeds in a similar, though slower, manner (Vu and Proctor 2008). Because the older adults' response times increase disproportionally as a function of uncertainty, they benefit more from a precue that either indicates which of two tasks will be performed or reduces the number of possible stimulus and response alternatives (Vu and Proctor 2008). Implications of these findings for HCI are that older adults' performance will suffer more from incompatibility in designs, but this cost can be minimized by design strategies that limit the amount of information that must be processed.

Responses often produce effects in the environment, as, for example, when flipping a switch turns on a light. Studies have shown that speed of response selection is also influenced by such response-effect compatibility. Kunde (2001) had participants respond to the color of a single stimulus centered on a display screen by pressing one of four response keys, arranged in a row, with the index and middle fingers of the hands. Pressing a key filled in one box in a row of four outline boxes located above the response keys. Performance was faster when the mapping of keys to the filled-in boxes was spatially compatible than when it was incompatible. That response time is influenced by compatibility of a response with the effect that it produces implies that actions are selected and performed in anticipation of their consequences.

Because situations in which compatibility effects will influence performance are not always obvious, interface designers may make poor decisions if they rely only on their intuitions. Payne (1995), Vu and Proctor (2003), and Tlauka (2004) showed that naïve subjects can predict basic compatibility effects such as that performance will be better with a mapping that is spatially compatible than with one that is not. However, they do not accurately predict many other compatibility effects that occur such as the benefit of maintaining a consistent stimulus–response mapping rule. One encouraging finding is that estimates of relative compatibility can be improved by a small amount of experience performing with the different stimulus–response mappings (Vu and Proctor 2003). Designers need to be aware of the potential problems created by various types of incompatibility between display and response elements because their influences are not always obvious. A designer can get a better feel for the relative compatibility of alternative arrangements by performing tasks that use them. However, after the designer selects a few arrangements that would seem to yield good performance, more thorough usability testing of the remaining arrangements on groups of users needs to be performed.

2.4.3 Response Execution

Motor programming refers to specification of the physical response that is to be made. This process is affected by variables such as relative stimulus–response frequency and movement direction. One factor that influences this stage is movement complexity. The longer the sequence of movements that is to be made upon occurrence of a stimulus in a choice-reaction task, the longer the RT to initiate the sequence (Sternberg et al. 1978). This effect is thought to be due to the time required to load the movement sequence into a buffer before initiating the movements. Time to initiate the movement sequence decreases with practice, and fMRI evidence suggests that this decrease in RT involves distinct neural systems that support visuomotor learning of finger sequences and spatial learning of the locations of the finger movements on a keypad (Parsons, Harrington, and Rao 2005).

One of the most widely known relations attributed to response execution is Fitts's law, which describes the time to make aimed movements to a target location (Fitts 1954). This law, as originally specified by Fitts, is as follows:

$$\text{Movement Time} = a + b \log_2(2D / W) \qquad (2.2)$$

where a and b are constants, D is distance to the target, and W is target width. However, there are slightly different versions of the law. According to Fitts's law, movement time is a direct function of distance and an inverse function of target width. Fitts's law has been found to provide an accurate description of movement time in many situations, although alternatives have been proposed for certain situations. One factor that contributes to the increase in movement time as the index of difficulty increases is the need to make a corrective submovement based on feedback in order to hit the target location (Meyer et al. 1988).

The importance of Fitts's law for HCI is illustrated by the fact that the December 2004 issue of the *International Journal of Human-Computer Studies* was devoted to the fiftieth anniversary of Fitts's original study. In the preface to the issue, the editors, Guiard and Beudouin-Lafon (2004), state, "What has come to be known as Fitts's law has proven highly applicable in Human–Computer Interaction (HCI), making it possible to predict reliably the minimum time for a person in a pointing task to reach a specified target" (p. 747). Several illustrations of this point follow.

One implication of the law for interface design is that the slope of the function, b, may vary across different control devices, in which case, movement times will be faster for the devices that yield lower slopes. Card, English, and Burr (1978) conducted a study that evaluated how efficient text keys, step keys, a mouse, and a joystick are at a text-selection task, in which users selected text by positioning the cursor on the desired area and pressing a button or key. They showed that the mouse was the most efficient device for this task: Positioning time for the mouse and joystick could be accounted for by Fitts's law, with the slope of the function being less steep for the mouse; positioning time with the keys was proportional to the number of key strokes that had to be executed.

Another implication of Fitts's law is that any reduction in the index of difficulty should decrease the time for movements. Walker, Smelcer, and Nilsen (1991) evaluated movement time and accuracy of menu selection for the mouse. Their results showed that reducing the distance to be traveled (which reduces the index of difficulty) by placing the initial cursor in the middle of the menu, rather than the top, improved movement time. Placing a border around the menu item in which a click would still activate that item, and increasing the width of the border as the travel distance increases, also improved performance. The reduction in movement time by use of borders is predicted by Fitts's law because borders increase the size of the target area. McGuffin and Balakrishnan (2005) showed that a similar reduction in movement time can be accomplished by expanding the target size while the movement is taking place.

Gillan et al. (1992) noted that designers must be cautious when applying Fitts's law to HCI because factors other than distance and target size play a role when using a mouse. Specifically, they proposed that the critical factors in pointing and dragging are different than those in pointing and clicking (which was the main task in Card, English, and Burr [1978] study). Gillan et al. showed that, for a text-selection task, both point–click and point–drag movement times can be accounted for by Fitts's law. For point–click sequences, the diagonal distance across the text object, rather than the horizontal distance, provided the best fit for pointing time. For point–drag, the vertical distance of the text provided the best fit. The reason why the horizontal distance is irrelevant is that the cursor must be positioned at the beginning of the string for the point–drag sequence. Thus, task requirements should be considered before applying Fitts's law to the interface design.

Motor adjustment deals with the transition from a central motor program to peripheral motor activity. Studies of motor adjustment have focused on the influence of foreperiod duration on motor preparation. In a typical study, a neutral warning signal is presented at various intervals before the onset of the imperative stimulus. Bertelson (1967) varied the duration of the warning foreperiod and found that RT reached a minimum at a foreperiod of 150 ms and then increased slightly at 200- and 300-ms foreperiods. However, error rate increased to a maximum at the 150-ms foreperiod and decreased slightly at the longer foreperiods. This relatively typical pattern suggests that it takes time to attain a state of high motor preparation, and that this state reflects an increased readiness to respond quickly at the expense of accuracy.

2.5 MEMORY IN INFORMATION PROCESSING

Memory refers to explicit recollection of information in the absence of the original stimulus and to persisting effects of that information on information processing that may be implicit. Memory may involve recall of an immediately preceding event or one many years in the past, knowledge derived from everyday life experiences and education, or procedures learned to accomplish complex perceptual-motor tasks. Memory can be classified into several categories. Episodic memory refers to memory for a specific event such as going to the movie last night, whereas semantic memory refers to general knowledge such as what a movie is. Declarative memory is verbalizable knowledge, and procedural memory is knowledge that can be expressed nonverbally. In other words, declarative memory is knowing that something is the case, whereas procedural memory is knowing how to do something. For example, telling your friend your new phone number involves declarative memory, whereas riding a bicycle involves procedural knowledge. A memory test is regarded as explicit if a person is asked to judge whether a specific item or event has occurred before in a particular context; the test is implicit if the person is to make a judgment, such as whether a string of letters is a word or nonword, that can be made without reference to earlier "priming" events. In this section, we focus primarily on explicit episodic memory.

Three types of memory systems are customarily distinguished: sensory stores, short-term memory (STM; or working memory), and long-term memory (LTM). Sensory stores, which we will not discuss in detail, refer to brief modality-specific persistence of a sensory stimulus from which information can be retrieved for 1 or 2 seconds (see Nairne 2003). STM and LTM are the main categories by which investigations of episodic memory are classified, and as the terms imply, the distinction is based primarily on duration. The dominant view is that these are distinct systems that operate according to different principles, but there has been debate over whether the processes involved in these two types of memories are the same or different. An fMRI study by Talmi et al. (2005) found that recognition of early items in the list was accompanied by activation of areas in the brain associated with LTM, whereas recognition of recent items did not, supporting a distinction between STM and LTM stores.

2.5.1 Short-Term (Working) Memory

STM refers to representations that are currently being used or have recently been used and last for a short duration. A distinguishing characteristic is that STM is of limited capacity. This point was emphasized in Miller's (1956) classic article, "The Magical Number Seven Plus or Minus Two," in which he indicated that capacity is not simply a function of the number of items, but rather the number of "chunks." For example, "i, b, m" are three letters, but most people can combine them to form one meaningful chunk of "IBM." Subsequent evidence indicates that the capacity of STM for verbal material is less than originally estimated by Miller, being three chunks when covert rehearsal is prevented (Chen and Cowan 2009). As a consequence of chunking, memory span is similar for strings of unrelated letters and strings of meaningful acronyms or words. Researchers refer to the number of items that can be recalled correctly, in order, as memory span. When rehearsal is not prevented, the memory span for words varies as a function of word length: The number of words that can be retained decreases as word length increases (Baddeley, Thomson, and Buchanan 1975). Evidence has indicated that the capacity is the number of syllables that can be said in about 2 seconds (Schweickert and Boruf 1986).

As most people are aware from personal experience, if distracted by another activity, information in STM can be forgotten quickly. With respect to HCI, Oulasvirta and Saariluoma (2004) note that diversion of attention from the current task to a competing task is a common occurrence, for example, when an unrequested pop-up dialog box requiring an action appears on the screen. Laboratory experiments have shown that recall of a string of letters that is within the memory span decreases to close to chance levels over a retention interval of 18 seconds when rehearsal is prevented by an unrelated distractor task (Brown 1958; Peterson and Peterson 1959). This short-term forgetting was thought initially to be a consequence of decay of the memory trace due to prevention of rehearsal. However, Keppel and Underwood (1962) showed that proactive interference from items on previous lists is a significant contributor to forgetting. They found no forgetting at long retention intervals when only the first list in a series was examined, with the amount of forgetting being much larger for the second and third lists as proactive interference built up. Consistent with this interpretation, "release" from proactive inhibition, that is, improved recall, occurs when the category of the to-be-remembered items on the current list differs from that of previous lists (Wickens 1970).

As the complexity of an HCI task increases, one consequence is to overload STM. Jacko and Ward (1996) varied four different determinants of task complexity (multiple paths, multiple outcomes, conflicting interdependence among paths, or uncertain or probabilistic linkages) in a task requiring use of a hierarchical menu to acquire specified information. When one determinant was present, performance was slowed by approximately 50%, and when two determinants were present in combination, performance was slowed further. That is, as the number of complexity determinants in the interface increased, performance decreased. Jacko and Ward attributed the decrease in performance for all four determinants to the increased STM load they imposed.

The best-known model of STM is Baddeley and Hitch's (1974) working memory model, which partitions STM into three main parts: central executive, phonological loop, and visuospatial sketchpad. The central executive is closely tied to the focus of attention. It is involved in computational processing, as in performing mental arithmetic, as well as in controlling and coordinating the actions of the phonological loop and visuospatial sketchpad. The phonological loop is composed of a phonological store that is responsible for storage of the to-be-remembered items, and an articulatory control process that is responsible for recoding verbal items into a phonological form and rehearsal of those items. The items stored in the phonological store decay over a short interval and can be refreshed through rehearsal from the articulatory control process. The visuospatial sketchpad retains information regarding visual and spatial information, and it is involved in mental imagery.

The working memory model has been successful in explaining several phenomena of STM (Baddeley 2000; 2003). However, the model cannot explain why memory span for visually presented material is only slightly reduced when subjects engage in concurrent articulatory suppression (such as saying the words "the" aloud repeatedly). Articulatory suppression should monopolize the phonological loop, preventing any visual items from entering it. To account for such findings, Baddeley revised the working memory model to include an episodic buffer (see Figure 2.3). The buffer is a limited capacity temporary store that can integrate information from the phonological loop, visuospatial sketchpad, and LTM. By attending to a given source of information in the episodic buffer, the central executive can create new cognitive representations that might be useful in problem solving.

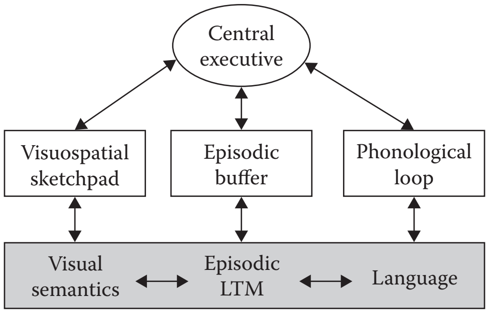

FIGURE 2.3 Baddeley's (2000) revised working memory model. (Reprinted from *Trends in Cogn Sci*, 4, Baddeley, A. D., The episodic buffer: A new component of working memory? 421, Copyright 2000, with permission from Elsevier.)

2.5.2 Long-Term Memory

LTM refers to representations that can be remembered for durations longer than can be attributed to STM. LTM can involve information presented minutes ago or years ago. Initially, it was thought that the probability of an item being encoded into LTM was a direct function of the amount of time that it was in STM, or how much it was rehearsed. However, Craik and Watkins (1973) showed that rehearsal in itself is not sufficient, but rather that deep-level processing of the meaning of the material is the important factor in transferring items to LTM. They presented subjects with a list of words and instructed them that when the experimenter stopped the presentation, they were to recall the last word starting with the letter "a." The number of other words between instances of "a" words was varied with the idea that the amount of time a word was rehearsed would depend on the number of words before the next "a" word. At the end of the session, subjects were given a surprise test in which they were to recall all "a" words. There was no effect of number of intervening words on recall, suggesting that although subjects rehearsed the words longer, their recall did not improve because the words were not processed deeply.

Craik and Watkins' (1973) results are consistent with the levels of processing framework proposed by Craik and Lockhart (1972). According to this view, encoding proceeds in a series of analyses, from shallow perceptual features to deeper, semantic levels. The deeper the level of processing, the more strongly the item is encoded in memory. A key study supporting the levels of processing view is that of Hyde and Jenkins (1973). In their study, groups of subjects were presented a list of words for which they engaged in shallow processing (e.g., deciding whether each word contained a capital letter) or deep processing of it (e.g., identifying whether each word was a verb or a noun). Subjects were not told in advance that they would be asked to recall the words, but were given a surprise recall test at the end of the session. Results showed that the deep processing group recalled more words than the shallow processing group. Of direct relevance to HCI, Oulasvirta, Kärkkäinen, and Laarni (2005) found that participants who viewed the content area of a web page had no better memory for the material than that guessed by a control group who had never seen the page, because the participants' task was to locate links on the page and not to process the content information.

Another well-known principle for LTM is encoding specificity, which states that the probability that a retrieval cue results in recollection of an earlier event is an increasing function of the match between the features encoded initially and those provided by the retrieval cue (Surprenant and Neath 2009). An implication of this principle is that memory will be context dependent. Godden and Baddeley (1975) demonstrated a context-dependent memory effect by having divers learn a list of words on land or under water, and recall the words on land or under water. Recall was higher for the group who learned on land when the test took place on land than under water, and vice versa for the group who learned under water. A related principle is that of transfer appropriate processing (Morris, Bransford, and Franks 1977). Morris et al. showed that deep-level semantic judgments during study produced better performance than shallow rhyme judgments on a standard recognition memory test. However, when the memory test required decisions about whether the test words rhymed with studied words, the rhyme judgments led to better performance than the semantic judgments. Brain imaging evidence consistent with transfer appropriate processing was obtained by Park and Rugg (2008), who found that word and picture stimuli on a recognition memory test produced greater activity in brain regions associated with those stimulus modes when the original study stimuli were also presented in the same mode. Healy, Wohldman, and Bourne (2005) have proposed that encoding specificity and transfer appropriate processing can be incorporated within the single principle of procedural reinstatement: Retention will be evident to the extent that the procedures engaged in during study or training are reinstated at the retention test.

Research has confirmed that the levels of processing framework must accommodate the effects of the retention context, as captured by the above principles, to explain the effects of processing performed during encoding. Although levels-of-processing has a strong effect on accuracy of explicit recall and recognition, Jacoby and Dallas (1981) found no effect on an implicit memory test. Later studies have shown a robust effect of levels-of-processing on implicit tests similar to that obtained for recall and recognition if the test is based on conceptual cues, rather than perceptual cues (Lee 2008).

2.5.3 Other Factors Affecting Retrieval of Earlier Events

Memory researchers have studied many factors that influence long-term retention. Not surprisingly, episodic memory improves with repetition of items or events. Also, massed repetition (repeating the same item in a row) is less effective than spaced repetition (repeating the same item with one or more intervening items). This benefit for spaced repetition, called the spacing effect or lag effect, is often attributed to two main factors. First, study time for the same items appearing in succession is less than study time for the same items appearing further apart. Second, when the items are studied over a longer period of time, there is an opportunity for the items to be associated with different cues that can aid recall later. The spacing or lag effect is widespread and occurs for both recall and recognition (Hintzman 1974). Bahrick and Hall (2005) noted that a similar spacing benefit is found for learning lists of items when practice sessions, each with test and learning phases, are separated by several days. They presented evidence that a large part of the spacing benefit in this case arises from individuals determining which study strategies are more effective at promoting long-term retention and then using those strategies more.

Another widely studied phenomenon is the generation effect, in which recall is better when subjects have to generate the to-be-remembered words rather than just studying the words as they are presented (Slamecka and Graf 1978). In a generation effect experiment, subjects are divided into two groups: read and generate. Each group receives a series of words, with each word spelled out completely for the read group and missing letters for the generate group. An example is as follows:

Read group: CAT; ELEPHANT; GRAPE; CAKE
Generate group: C _ T; E_E_H _ NT; G _ APE; CAK_

The typical results show that subjects in the generate group can recall more words than those in the read group. One application of the generation effect to HCI is that when a computer user needs a password for an account, the system should allow the user to generate the password rather than providing him or her with one because the user would be more likely to recall the generated password. The common method of proactive password generation, in which users are asked to generate a password that meets certain restrictions (e.g., contain an uppercase letter, a lowercase letter, a digit, etc.), is intended to result in more memorable and secure passwords (see, e.g., Vu et al. 2007).

Events that precede or follow an event of interest can interfere with recall of that event. The former is referred to as proactive interference, and was discussed in the section on STM, and the latter is referred to as retroactive interference. One area of research in which retroactive interference is of central concern is that of eyewitness testimony. Loftus and Palmer (1974) showed that subsequent events could distort a person's memory of an event that the person witnessed. Subjects were shown a sequence of events depicting a car accident. Subsequently, they were asked the question, "How fast were the cars going when they _____ each other." When the verb "contacted" was used, subjects estimated the speed to be 32 mph, and only one-tenth of them reported seeing broken glass. However, when the verb "smashed" was used, the estimated speed increased to 41 mph, and almost one-third of the subjects reported seeing broken glass. Demonstrations like these indicate not only that retroactive interference can cause forgetting of events, but that it also can cause the memory of events to be changed. More recent research has shown that completely false memories can be implanted (see Roediger and McDermott 1995).

Mnemonic techniques can also be used to improve recall. The basic idea behind mnemonics is to connect the to-be-remembered material with an established organizational structure that can be easily accessible later on. Two widely used mnemonic techniques are the pegword method (Wood and Pratt 1987) and the method of loci (Verhaeghen and Marcoen 1996). In the pegword method, a familiar rhyme provides the organizational structure. A visual image is formed between each pegword in the rhyme and the associated target item. At recall, the rhyme is generated, and the associated items come to mind. For the method of loci, locations from a well-known place, such as your house, are associated with the to-be-remembered items. Although specific mnemonic techniques are limited in their usefulness, the basic ideas behind them (utilizing imagery, forming meaningful associations, and using consistent encoding and retrieval strategies) are of broad value for improving memory performance.

Vu et al. (2007) examined the effectiveness of a "first-letter" mnemonic technique to help users relate individual characters of a password to a structured sentence in order to aid recall at a later time. In one condition, Vu et al. had users generate a sentence and take the first letter of each word in the sentence to form a password; in another condition, users generated a sentence that also included a number and special character embedded into the sentence and resulting password. Passwords generated using the first-letter technique were more memorable when users did not have to embed a digit and special character into the sentence, but were more secure (i.e., more resistant to cracking) when the sentence and resulting password included the digit and special character. Thus, when it comes to memory and security of computer passwords, there seems to be a trade-off between memorability and security.

Two additional factors have shown recently to benefit retrieval from memory. The first is repeated testing of items (Karpicke and Roediger 2008). The retrieval practice engendered by testing seems to be far more beneficial than additional studying of the items. The second is the relation of the to-be-remembered items to adaptive function (Nairne and Pandeirad 2010). Several studies have found evidence that survival-related words are retained better than ones that are not related to that adaptive function. From results like these, Nairne and Pandeirada have concluded, "to maximize retention in basic and applied settings it is useful to develop encoding techniques that are congruent with the natural design of memory systems" (p. 381).

2.6 ATTENTION IN INFORMATION PROCESSING

Attention is increased awareness directed at a particular event or action to select it for increased processing. This processing may result in enhanced understanding of the event, improved performance of an action, or better memory for the event. Attention allows us to filter out unnecessary information so that we can focus on a particular aspect that is relevant to our goals. Several significant information-processing models of attention have been proposed.

2.6.1 Models of Attention

In an influential study, Cherry (1953) presented different messages to each ear through headphones. Subjects were to repeat aloud one of the two messages while ignoring the other. When subsequently asked questions about the two messages, subjects were able to accurately describe the message to which they were attending but could not describe anything except physical characteristics, such as gender of the speaker, about the unattended message.

To account for such findings, Broadbent (1958) developed the filter theory, which assumes that the nervous system acts as a single-channel processor. According to filter theory, information is received in a preattentive temporary store and then is selectively filtered, based on physical features such as spatial location, to allow only one input to access the channel. Broadbent's filter theory implies that the meaning of unattended messages is not identified, but later studies showed that the unattended message could be processed beyond the physical level, in at least some cases (Treisman 1964).

To accommodate the finding that meaning of an unattended message can influence performance, Treisman (1964) reformulated filter theory into what is called the filter-attenuation theory. According to attenuation theory, early selection by filtering still precedes stimulus identification, but the filter only attenuates the information on unattended channels. This attenuated signal may be sufficient to allow identification if the stimulus is one with a low-identification threshold, such as a person's name or an expected event. Deutsch and Deutsch (1963) proposed that unattended stimuli are always identified and the bottleneck occurs in later processing, a view called late-selection theory. The difference between attenuation theory and late-selection theory is that the latter assumes that meaning is fully analyzed, whereas the former does not.

Lavie et al. (2004) have proposed a load theory of attention, which they claim "resolves the long-standing early versus late selection debate" (p. 339). Specifically, the load theory includes two selective attention mechanisms, a perceptual selection mechanism and a cognitive control mechanism. When perceptual load is high (i.e., great demands are placed on the perceptual system), the perceptual mechanism excludes irrelevant stimuli from being processed. When memory load is high, it is not possible to suppress irrelevant information at a cognitive level. In support of load theory, Lavie et al. showed that interference from distracting stimuli is reduced under conditions of high perceptual load but increased under conditions of high working memory load.

In divided attention tasks, a person must attend to multiple sources of information simultaneously. Kahneman (1973) proposed a unitary resource model that views attention as a single resource that can be divided up among different tasks in different amounts, based on task demands and voluntary allocation strategies. Unitary resource models provided the impetus for dual-task methodologies, such as performance operating characteristics, and mental workload analyses that are used widely in HCI (Eberts 1994). The expectation is that multiple tasks should produce interference when their resource demands exceed the supply that is available.

Many studies have shown that it is easier to perform two tasks together when they use different stimulus or response modalities than when they use the same modalities. Performance is also better when one task is verbal and the other visuospatial than when they are the same type. These result patterns provide the basis for multiple resource models of attention such as that of Wickens (1984). According to multiple resource models, different attentional resources exist for different sensory-motor modalities and coding domains. Multiple resource theory captures the fact that multiple-task performance typically is better when the tasks use different input–output modes than when they use the same modes. However, it is often criticized as being too flexible because new resources can be proposed arbitrarily to fit any finding of specificity of interference (Navon 1984).

A widely used metaphor for visual attention is that of a spotlight that is presumed to direct attention to everything in its field (Posner and Cohen 1984). Direction of attention is not necessarily the same as the direction of gaze because the attentional spotlight can be directed independently of fixation. Studies show that when a location is cued as likely to contain a target stimulus, but then a probe stimulus is presented at another location, a spatial gradient surrounds the attended location such that items nearer to the focus of attention are processed more efficiently than those farther away from it (Yantis 2000). The movement of the attentional spotlight to a location can be triggered by two types of cues: exogenous and endogenous. An exogenous cue is an external event such as the abrupt onset of a stimulus at a peripheral location that involuntarily draws the attentional spotlight to its location. Exogenous cues produce rapid performance benefits, which dissipate quickly, for stimuli presented at the cued location. This is followed by a period in which performance is worse for stimuli at the cued location than for ones presented at the uncued location, a phenomenon called inhibition of return (Posner and Cohen 1984). An endogenous cue is typically a symbol such as a central arrowhead that must be identified before a voluntary shift in attention to the designated location can be made. The performance benefits for endogenous cues take longer to develop and are sustained for a longer period of time when the cues are relevant, indicating that their benefits are due to conscious control of the attentional spotlight (Klein and Shore 2000).

Attentional focus is needed to detect change, and once attention is allocated to the processing of an event, there is a period in which it cannot be allocated to the processing of another event. Change blindness is the inability to detect sometimes large changes in a visual display or scene (Simons and Ambinder 2005). It has been demonstrated in the flicker task, in which one scene alternates with another and the presence versus absence of a distinctive feature such as an aircraft engine or building is not detected. Change blindness also occurs in natural settings when attention is diverted momentarily. A closely related phenomenon is that of the attentional blink (Martens and Wyble 2010). In this paradigm, there is rapid presentation of a sequence of displays of visual stimuli. When a target stimulus is detected in one display, the probability of detecting a second target stimulus presented within the next several displays is reduced dramatically. Martens and Wyble attribute the attentional blink to a deficit in consolidation of the second target into a conceptual working-memory representation due to processing capacity being devoted to consolidation of the first target and being unavailable for processing of the second. They note that this limitation may be linked to a mechanism of attentional control.

In a visual search task, subjects are to detect whether a target is present among distractors. Treisman and Gelade (1980) developed feature integration theory to explain the results from visual search studies. When the target is distinguished from the distractors by a basic feature such as color (feature search), RT and error rate often show little increase as the number of distractors increases. However, when two or more features must be combined to distinguish the target from distractors (conjunctive search), RT and error rate typically increase sharply as the number of distractors increases. To account for these results, feature integration theory assumes that basic features of stimuli are encoded into feature maps in parallel across the visual field at a preattentive stage. Feature search can be based on this preattentive stage because a “target-present” response requires only detection of the feature. The second stage involves focusing attention on a specific location and combining features that occupy the location into objects. Attention is required for conjunctive search because responses cannot be based on detection of a single feature. According to feature integration theory, performance in conjunctive search tasks decreases as the number of distractors increases because attention must be moved sequentially across the search field until a target is detected or all items present have been searched. Feature integration theory served to generate a large amount of research on visual search that showed, as typically the case, that the situation is not as simple as depicted by the theory. This has resulted in modifications of the theory, as well as alternative theories. For example, Wolfe’s (2007) Guided Search Theory maintains the distinction between an initial stage of feature maps and a second stage of attentional binding, but assumes that the second stage is guided by the initial feature analysis.

In HCI, a common visual search task involves locating menu items. When users know exactly what option to search for, identity matching can be used, in which users search the display for the menu name that they want to find. Perlman (1984) suggested that when identity search is used, the menu options should be displayed in alphabetical order to facilitate search. When users do not know where an option is included within a main list of menus, inclusion matching is used.

The users must decide within which group the specific option would be categorized and then search the list of items for that group. With inclusion matching, search times may be longer for items that can be classified in more than one of the main groupings or when the items are less well-known examples of a main grouping (Somberg and Picardi 1983). Equivalence search occurs when the users know what option to select, but does not know how that option is labeled. McDonald, Stone, and Liebelt (1983) showed that alphabetical and categorical organizations yield shorter search times than randomized organization for equivalence search. Search can also be affected by the breadth versus depth of the menu design. Lee and MacGregor (1985) showed that deep hierarchies are preferred over broad ones. However, more recently, Tullis, Tranquada, and Siegel (2011) suggested that, for complex or ambiguous situations, there is a benefit for broad menu designs because they facilitate comparison between categories. The main point is that when structuring menus, designers must consider the type of search in which the user would most likely be engaged.

The role of attention in response selection has been investigated extensively using the psychological refractory period (PRP) paradigm (Pashler 1998). In the PRP paradigm, a pair of choice-reaction tasks must be performed, and the stimulus onset asynchrony (SOA) of the second stimulus is presented at different intervals. RT for Task 2 is slowed at short SOAs, and this phenomenon is called the PRP effect. The experimental results have been interpreted with what is called locus of slack logic (Schweickert 1978), which is an extension of additive factors logic to dual-task performance. The basic idea is that if a Task 2 variable has its effect prior to a bottleneck, that variable will have an underadditive interaction with SOA. This underadditivity occurs because, at short SOAs, the slack period during which postbottleneck processing cannot begin can be used for continued processing for the more difficult condition. If a Task 2 variable has its effect after the bottleneck, the effect will be additive with SOA.

The most widely accepted account of the PRP effect is the response-selection bottleneck model (Pashler 1998). The primary evidence for this model is that perceptual variables typically have underadditive interactions with SOA, implying that their effects are before the bottleneck. In contrast, postperceptual variables typically have additive effects with SOA, implying that their effects are after the bottleneck. There has been dispute as to whether there is also a bottleneck at the later stage of response initiation (De Jong 1993), whether the response-selection bottleneck is better characterized as a parallel processor of limited capacity that divides resources among to-be-performed tasks (Tombu and Jolicœur 2005), and whether the apparent response-selection bottleneck is structural or simply a strategy adopted by subjects to comply with task instructions (Meyer and Kieras 1997). This latter approach is consistent with an emphasis on the executive functions of attention in the coordination and control of cognitive processes (Monsell and Driver 2000).

2.6.2 Automaticity and Practice

Attention demands are high when a person first performs a new task. However, these demands decrease and performance improves as the task is practiced. Because the quality of performance and attentional requirements change substantially as a function of practice, it is customary to describe performance as progressing from an initial cognitively demanding phase to a phase in which processing is automatic (Anderson 1982; Fitts and Posner 1967).

With the largest benefits occurring early in practice, the time to perform virtually any task from choice RT to solving geometry problems decreases with practice. Newell and Rosenbloom (1981) proposed a power function to describe the changes in RT with practice:

$$\mathrm{RT} = BN^{-\alpha} \tag{2.3}$$

where N is the number of practice trials, B is RT on the first trial, and α is the learning rate. Although the power function has become widely accepted as a law that describes the changes in RT, Heathcote, Brown, and Mewhort (2000) indicated that it does not fit the functions for individual performers adequately. They showed that exponential functions provided better fits than power functions to 40 individual data sets, and proposed a new exponential law of practice. The defining characteristic of the exponential function is that the relative learning rate is a constant at all levels of practice, whereas, for the power function, the relative learning rate is a hyperbolically decreasing function of practice trials.

2.7 PROBLEM SOLVING AND DECISION MAKING

Beginning with the work of Newell and Simon (1972), it has been customary to analyze problem solving in terms of a problem space. The problem space consists of the following: (1) an initial state, (2) a goal state that is to be achieved, (3) operators for transforming the problem from the initial state to the goal state in a sequence of steps, and (4) constraints on application of the operators that must be satisfied. The problem-solving process itself is conceived of as a search for a path that connects the initial and goal states.

Because the size of a problem space increases exponentially with the complexity of the problem, most problem spaces are well beyond the capacity of STM. Consequently, for problem solving to be effective, search must be constrained to a limited number of possible solutions. A common way to constrain search is through the use of heuristics. For example, people often use a means-ends heuristic for which at each step, an operator is chosen that will move the current state closer to the goal state (Atwood and Polson 1976). Such heuristics are called weak methods because they do not require much knowledge about the exact problem domain. Strong methods, such as those used by experts, rely on prior domain-specific knowledge and do not require much search because they are based on established principles applicable only to certain tasks.

The problem space must be an appropriate representation of the problem, if the problem is to be solved. One important method for obtaining an appropriate problem space is to use analogy or metaphor. Analogy enables a shift from a problem space that is inadequate to one that may allow the goal state to be reached. There are several steps in using analogies (Holland et al. 1986), including detecting similarity between source and target problems, and mapping the corresponding elements of the problems. Humans are good at mapping the problems, but poor at detecting that one problem is an analog of another. An implication for HCI is that potential analogs should be provided to users for situations in which they are confronted by novel problems.

The concept of mental model, which is closely related to that of the problem space, has become widely used in recent years (see Payne, this volume). The general idea of mental models with respect to HCI is that as the user interacts with the computer, she or he receives feedback from the system that allows him/her to develop a representation of how the system is functioning for a given task. The mental model incorporates the goals of the user, the actions taken to complete the goals, and expectations of the system's output in response to the actions. A designer can increase the usability of an interface by using metaphors that allow transfer of an appropriate mental model (e.g., the desktop metaphor), designing the interface to be consistent with other interfaces with which the user is familiar (e.g., the standard web interface), and conveying the system's functions to the user in a clear and accurate manner. Feedback to the user is perhaps the most effective way to communicate information to the user and can be used to guide the user's mental model about the system.

Humans often have to make choices for situations in which the outcome depends on events that are outside of their control. According to expected utility theory, a normative theory of decision making under uncertainty, the decision maker should determine the expected utility of a choice by multiplying the subjective utility of each outcome by the outcome's probability and summing the resulting values (Hastie and Dawes 2010). The expected utility should be computed for each choice, and the optimal decision is the choice with the highest expected utility. It should be clear from this description that for all but the simplest of problems, a human decision maker cannot operate in this manner. To do so would require attending to multiple cues that exceed attentional capacity, accurate estimates of probabilities of various events, and maintenance of, and operation on, large amounts of information that exceeds STM capacity.

Research of Kahneman and Tversky (2000) and others has shown that what people do when the outcome associated with a choice is uncertain is to rely heavily on decision-making heuristics. These heuristics include representativeness, availability, and anchoring. The representativeness heuristic is that the probability of an instance being a member of a particular category is judged on the basis of how representative the instance is of the category. The major limitation of the representativeness heuristic is that it ignores base rate probabilities for the respective categories. The availability heuristic involves determining the probability of an event based on the ease with which instances of the event can be retrieved. The limitation is that availability is affected not only by relative frequency but also by other factors. The anchoring heuristic involves making a judgment regarding probabilities of alternative states based on initial information, and then adjusting these probabilities from this initial "anchor" as additional information is received. The limitation of anchoring is that the initial judgment can produce a bias for the probabilities. Although heuristics are useful, they may not always lead to the most favorable decision. Consequently, designers need to make sure that the choice desired for the user in a particular situation is one that is consistent with the user's heuristic biases.

2.8 SUMMARY AND CONCLUSION

The methods, theories, and models in human information processing are currently well developed. The knowledge in this area, of which we are only able to describe at a surface level in this chapter, is relevant to a wide range of concerns in HCI, from visual display design to representation and communication of knowledge. For HCI to be effective, the interaction must be made compatible with the human information-processing capabilities. Cognitive architectures that incorporate many of the facts about human information processing have been developed that can be applied to HCI. The Model Human Processor of Card, Moran, and Newell (1983) is the most widely known, but other more recent architectures, including the adaptive control of thought model of Anderson and colleagues (Anderson, Matessa, and Lebiere 1997), the State, Operator, and Result (SOAR) Model of Newell and colleagues (Howes and Young 1997), and the EPIC Model of Kieras and Meyer (1997) have considerable utility for the field, as demonstrated in Chapter 5 of this volume.

The human information-processing approach emphasizes laboratory research in which fundamental cognitive processes and principles thought to be of broad generalizability are established. Although this approach has been highly successful in many respects, some researchers think that more emphasis should be placed on real-world behavior in natural environments. Alternative approaches to perception, cognition, and action with such emphasis include the following. The ecological approach associated with Gibson (1979) places emphasis on analyzing the perceptual information that is available in the optic array and the dynamics of this information as the individual interacts with the environment. The cybernetic view, that cognition emerges as a consequence of motor control over sensory feedback, stresses self-regulated control of perception and cognition (Smith and Henning 2005). The situated cognition approach focuses on the need to understand behavior in specific contexts in which, for example, a computer application will be used (Kiekel and Cooke 2011). A recently popular approach is that of embodied cognition, according to which knowledge is acquired and processed through interactions of the body with the environment (e.g., Sherman, Gangi, and White 2010). One common feature of these alternative accounts is an emphasis on the relation among perception, cognition, and action. We agree that, in certain areas of information-processing research, action has been viewed as a final stage that does not influence the prior stages of perception and cognition. However, in other areas, such as that of human performance, action has been emphasized since the earliest applications of the information-processing approach (Fitts and Posner 1967; since 1975, one division of the *Journal of Experimental Psychology* has been subtitled *Human Perception and Performance*). From our perspective, information-processing analyses and models will continue to be useful tools for understanding and predicting human behavior both in general and in HCI in particular.

3 Mental Models in Human–Computer Interaction

Stephen J. Payne

CONTENTS

The plan for this chapter is as follows. It begins by reviewing and discussing the term "mental models" as it has been used in the literature on human–computer interaction (HCI), and in the neighboring disciplines of cognitive psychology where it was first coined. There is little consensus on what exactly is and is not a mental model, and yet it is too widely used for any posthoc attempt at a narrower definition to somehow cleanse the field. In consequence, I characterize several layers of theoretical commitment that the term may embrace, following an earlier discussion (Payne 2003). To illustrate the argument, several classic and more recent studies from the HCI literature will be reviewed, with pointers to others. This first part of the chapter is based on material published in Payne (2003).

In cognitive psychology, mental models have major currency in two sub-disciplines—text comprehension and reasoning, although in the former they more often currently go by the name "situation models." Discussion in the latter focuses on quite refined theoretical disputes that currently have little relevance for HCI. The work on text comprehension, however, is germane. With the advent of the web, the comprehension of text of various kinds has become a dominant mode of HCI, with important design issues for websites, digital libraries, and so on. Interaction with text is in some ways a paradigm for interaction with information. With these points in mind, the concept of mental models in text comprehension will be discussed, with a particular eye to the issues that HCI accentuates, such as understanding multiple texts.

Two of the major practical questions raised by mental models are (1) How are they acquired? and (2) How can their acquisition be supported by instruction? The third section of this chapter will discuss two angles on these questions in HCI: first, the use of interactive computation and multimedia as an instructional method; second, the important tension between exploration and instruction, first systematically discussed in the HCI literature by Carroll's (1990) work on minimalism.

Finally, the paper will review some recent work on the importance of mental models for understanding aspects of collaborative teamwork. This area suggests that a relatively expansive view of human knowledge representations may be necessary for progress in HCI.

Throughout the chapter, a particular approach is taken to review: to choose one or two key studies and report them in some detail. I hope that this will allow some of the empirical methodologies and the rich variation in these to be conveyed. The chosen studies will be accompanied by some further references to the literature, but there are too many subtopics reviewed to aim for completeness.

3.1 WHAT IS A MENTAL MODEL?

The user's mental model of the device is one of the more widely discussed theoretical constructs in HCI. Alongside wide-ranging research literature, even commercial style guides have appealed to mental models for guidance (i.e., Mayhew 1992; Tognazzini 1992; Apple Human Interface Guidelines Apple Computer Inc. 1987).

Yet a casual inspection of the HCI literature reveals that mental models are used to label many different aspects of users' knowledge about the systems they use. Nevertheless, I propose that even this simple core construct—what users know and believe about the systems they use—is worth highlighting and promoting. It is more distinctive than it might first seem, especially in comparison with other cognitive-science approaches. Further, beyond the core idea there is a progression of stronger theoretical commitments that have been mobilized by the mental models label, each of which speaks to important issues in HCI research, if not yet in practice.

The fundamental idea is that the *contents* of people's knowledge, including their theories and beliefs, can be an important explanatory concept for understanding users' behavior in relation to systems. This idea may seem obvious and straightforward, but in fact it suggests research questions that go against the grain of most contemporary cognitive psychology, which has concerned itself much more with the general limits of the human-information-processing system, such as the constraints on attention, retrieval, and processing. Thus, cognitive psychology tends to focus on the *structure* of the mind, rather than its contents. (The major exception to the rule that cognitive psychology has been obsessed with architecture over content is the work on expertise, and even here, recent work has focused on explanations of extreme performance in terms of general independent variables such as "motivated practice," i.e., Ericsson, Krampe, and Tesch-Romer [1993], rather than epistemological analysis.)

Refocusing attention on mental content about particular domains is what made mental models a popular idea in the early 1980s, such as the papers in Gentner and Stevens (1983). For example, work on naïve physics (i.e., McCloskey 1983) attempts to explain people's reasoning about the physical world, not in terms of working memory limits or particular representations, but in terms of their beliefs about the world, such as the nature of their theories of mechanics or electricity, for example. This focus on people's knowledge, theories, and beliefs about particular domains transfers naturally to questions in HCI, where practical interest may focus on how users conceive the workings of a particular device, how their beliefs shape their interactive behavior, and what lessons may be drawn for design.

In this mold, consider a very simple study of my own (Payne 1991). Students were interviewed about ATMs. Following Collins and Gentner (1987) among others, "what if" questions were posed to uncover student's theories about the design and function of ATMs. For example, students were asked whether machines sometimes took longer to process their interactions; what information was stored on the plastic card; and what would happen if they "typed ahead" without waiting for the next machine prompt.

The interviews uncovered a wide variety in students' beliefs about the design of ATMs. For example, some assumed that the plastic card was written to as well as read from during transactions, and thus could encode the current balance of their account. Others assumed that the only information on the card was the user's personal identification number, allowing the machine to check the identity of the user (as it turns out, both these beliefs are incorrect). A conclusion from this simple observation is that users of machines are eager to form explanatory models and will readily go beyond available data to infer models that are consistent with their experiences. (One might wonder whether such explanations were not merely ad hoc, prompted during the interview: in fact some were, but explicit linguistic cues—such as "I've always thought"—strongly suggested that many were not.)

Another observation concerning students' "models" of ATMs was that they were fragmentary, perhaps more fragmentary than the term "model" might ordinarily connote: they were collections of beliefs about parts of the system, processes, or behaviors, rather than unified models of the whole design. Students would happily recruit an analogy to explain one part of the machine's operation that bore no relation to the rest of the system. This fragmentary character of mental models of complex systems may be an important aspect (see i.e., Norman 1983), allowing partial understandings to be maintained. One implication is that users' mental models of single processes or operations might be a worthwhile topic for study and practical intervention (in design or instruction).

One widely held belief about a particular process affected the students' behavior as users. Almost all respondents believed that it was not possible to type ahead during machine pauses. At the time the study was conducted this was true for some, but not all, designs in use. Consequently, in some cases transactions were presumably being needlessly slowed because of an aspect of users' mental models.

A more recent study of a similar kind is an investigation of users' models of the navigation facilities provided by Internet browsers (Cockburn and Jones 1996). Internet browsers, like Internet Explorer, maintain history lists of recently visited pages, providing direct access to these pages without needing to enter the URL or follow a hyperlink. The "back" and "forward" buttons provide a very frequently used mechanism for browsing history lists, but do users have good mental models for how they work? Cockburn and Jones (1996) showed that many do not.

The history list of visited pages can be thought of as a stack: a simple last-in-first-out data structure to which elements can be added (pushed) or taken out (popped) only from the top (consider a stack of trays in a canteen). When a new web page is visited by following a hyperlink, or by entering a URL, its address is pushed onto the top of the stack. This is true even if the page is already in the history list, so that the history list may contain more than one copy of the same page. However, when a page is visited by using the Back button (or, at least typically, by choosing from the history list), the page is not pushed onto the stack. So, what happens when the currently displayed page is not at the top of the stack (because it has been visited via the history list) and a new link is followed (or a new URL entered)? The answer is that all the pages in the history list that were above the current page are popped from the stack, and the newly visited page is pushed onto the stack in their place. For this reason the history list does *not* represent a complete record, or time-line of visited pages, and not all pages in the current browsing episode can be backed-up to. In Cockburn and Jones' study, few users appreciated this aspect of the device.

This then, has been the major thrust of work on mental models in HCI: what do people know and believe to be true about the way the systems they interact with are structured? How do their beliefs affect their behavior? In this literature a "mental model" is little more than a pointer to the relevant parts of the user's knowledge, yet this is not to deny its usefulness. One approach that it has engendered is a typology of knowledge—making groupings and distinctions about types of knowledge that are relevant in certain circumstances. It is in exactly this way that a literature on "shared mental models" as an explanatory concept in teamwork has been developed. This topic is perhaps the most rapidly growing area of mental models research in HCI and will be reviewed in the final section of this chapter.

However, as argued at length in Payne (2003), there are approaches to mental models in HCI that go beyond a concern with user knowledge and beliefs to ask more nuanced theoretical questions. The first of these is to investigate the form of mental models by inspecting the processes through which mental models might have their effects on behavior.

A powerful idea here is that mental models of machines provide a problem space that allows more elaborate encoding of remembered methods, and in which novice or expert problem solvers can search for new methods to achieve tasks.

The classic example of this approach is the work of Halasz and Moran (1983) on Reverse Polish Notation (RPN) calculators. RPN is a post-fix notation for arithmetic, so that to express 3 + 4, one would write 3 4 +. RPN does away with the need for parentheses to disambiguate composed operations. For example (1 + 2) * 3 can be expressed 1 2 + 3 * with no ambiguity. RPN calculators need a key to act as a separator between operands, which is conventionally labeled ENTER, but they do not need an = key, as the current total can be computed and displayed whenever an operator is entered.

Halasz and Moran taught one group of students how to use an RPN calculator using instructions, like a more elaborate version of the introduction above, which simply described the appropriate syntax for arithmetic expressions. A second group of subjects was instructed, using a diagram, about the stack model that underlies RPN calculation. Briefly, when a number is keyed in, it is "pushed" on top of a stack-data structure (and the top slot is displayed). The ENTER key copies the contents of the top slot down to the next slot. Any binary arithmetic operation is always performed on the contents of the top two slots and leads to the result being in the top slot, with the contents of slots 3 and below moving up the stack.

Halasz and Moran discovered that the stack-model instructions made no difference to participants' ability to solve routine arithmetic tasks: the syntactic "method-based" instructions sufficed to allow participants to transform the tasks into RPN notation. However, for more creative problems (such as calculating (6 + 4) and (6 + 3) and (6 + 2) and only keying the number 6 once) the stack group was substantially better. Verbal protocols showed that these subjects reasoned about such problems by mentally stepping through the transformations to the stack at each keystroke.

This kind of reasoning, stepping through a sequence of states in some mental model of a machine, is often called "mental simulation" in the mental models literature, and the kind of model that allows simulation is often called a "surrogate" (Young 1983; Carroll and Olson 1988). From a practical standpoint, the key property of this kind of reasoning is that it results in behavior that is richer and more flexible than the mere rote following of learned methods. The idea that the same method may be encoded more richly, so that it is more flexible and less prone to forgetting will be returned to later in the chapter when a theory of mental models of interactive artifacts is considered, and when ideas about instruction for mental models are reviewed.

A second example of mental models providing a problem space elaboration of rote methods comes in the work of Kieras and Bovair (1984). This research was similar to that of Halasz and Moran (1983) in that it compared the learning performance of two groups: (1) one instructed with rote procedures, (2) the other additionally with a diagrammatic model of the device on which the procedures were enacted. In this case, the device was a simple control panel, in which each rote procedure specified a sequence of button-pushes and knob-positions leading to a sequence of light-illuminations. The model was a circuit diagram showing the connections between power-source switches and display-lights.

Kieras and Bovair (1984) found that the participants instructed with the model learned the procedures faster, retained the procedures more accurately, executed the procedures faster, and could simplify inefficient procedures that contained redundant switch settings. They argued that this was because the model (circuit diagram) explained the contingencies in the rote-action sequences (i.e., if a switch is set to MA, so that the main accumulator circuit is selected, then the FM, fire main, button must be used).

A related theoretical idea is that mental models are a special kind of representation, sometimes called an *analog* representation: one that shares the structure of the world it represents. This was taken as the definitional property of mental models by the modern originator of the term, the British psychologist Kenneth Craik (1943). It is this intuition that encourages the use of terms like "mental simulation"—the intuition that a mental model is like a physical model, approximating the structure of what it represents, just as a model train incorporates (aspects of) the physical structure of a train.

The idea that mental models are analog in this sense is a definitional property in the work on reasoning and comprehension by Johnson-Laird (Johnson-Laird 1983, 1989; this will be further discussed in Section 3.2, concerning representations of text) and also in the theory of Holland et al. (1986) and Moray (1999). However, there are different nuances to the claim, which must be considered. And, in addition, there is a vexed question to be asked; namely, what is the explanatory or predictive force of a commitment to analog representational form? Is there any reason for HCI researchers to pay attention to theoretical questions at this level?

Certainly, this is the view of Moray (1999) who is concerned with mental models of complex dynamic systems, such as industrial plants. He proposes that models of such systems are structure-sharing *homomorphisms* rather than isomorphisms, that is, they are many to one rather than one-to-one mappings of objects, properties, and relations. (In this he follows Holland et al. 1986.)

Homomorphic models of dynamic systems may not share structure with the system at the level of static relations, but only at the level of state-changes. Thus, such models have the character of state-transition diagrams, making the empirical consequences of structure sharing somewhat unclear, because any problem space can be represented in this way.

In my view, a clearer view of the explanatory force of analog mental models can be derived by carefully considering the ideas of computational and informational equivalence first introduced by Simon (1978).

It is obviously possible to have two or more distinct representations of the same information. Call such representations "informationally equivalent" if all the information in one is inferable from the other, and vice versa. Two informationally equivalent representations may or may not additionally be "computationally equivalent," meaning that the cost structure of accessing and processing the information is equivalent in both cases, or, as Larkin and Simon (1987) put it: "information given explicitly in the one can also be drawn easily and quickly from the information given explicitly in the other, and vice versa." As Larkin and Simon point out, "easily" and "quickly" are not precise terms, and so this definition of computational equivalence is inherently somewhat vague; nevertheless it points to empirical consequences of a representation (together with the processes that operate upon it) that depend on form, and therefore go beyond mere informational content.

In Payne (2003), I propose adopting *task-relative* versions of the concepts of informational and computational equivalence. Thus, representations are informationally equivalent, *with respect to a set of tasks*, if they allow the same tasks to be performed (i.e. contain the requisite information for those tasks). The representations are, additionally, computationally equivalent with respect to the tasks they allow to be performed, if the *relative difficulty* of the tasks is the same, whichever representation is being used. (Note that according to these definitions, two representations might be computationally equivalent with regard to a subset of the tasks they support but not with regard to the total set, so that in Larkin and Simon's sense they would merely be informationally equivalent. The task-relative versions of the constructs thus allow more finely graded comparisons between representations.)

This idea can express what is behaviorally important about the idea of analog models, or structure-sharing mental representations of a state of affairs of a dynamic system. An analog representation is computationally equivalent (with respect to some tasks) to external perception and manipulation of the state of affairs it represents.

Bibby and Payne (1993, 1996) exploited this distinction between computational and informational equivalence in the domain of HCI, using a computer simulation of a device derived from that studied by Kieras and Bovair (1984). The device was a multiroute circuit, in which setting switches into one of several configurations would make a laser fire; various indicator lights showed which components of the circuit were receiving power. What concerned Bibby and Payne (1993) was the idea of computational equivalence between a mental model and a diagram of the device, rather than the device itself.

Bibby and Payne asked participants to repeatedly perform two types of tasks: a switch task, in which all but one switch was already in position to make a laser fire (the participant had to key the final switch) and a fault task, in which the pattern of indicator lights was such that one of the components must be broken (the participant had to key the name of the broken component).

Participants were instructed about the device with either a table, which showed the conditions under which each indicator light would be illuminated, or with procedures, sequences of switch positions enabling the laser to be fired. Both instructions were sufficient for both switch and fault tasks; they were informationally equivalent with respect to those tasks. However, the table made the fault task easier than the switch task, whereas the procedures made the switch task easier.

During practice, when participants consulted the instructions, this pattern of relative difficulty was confirmed by a crossover interaction in response times. Furthermore, when the instructions were removed from the participants, so that they had to rely on their mental representation of the device, the crossover interaction persevered, demonstrating that the mental representations were computationally equivalent to the external instructions.

In subsequent experiments, Bibby and Payne (1996) demonstrated that this pattern persevered even after considerable interaction with the device that might have been expected to provide an opportunity to overcome the representational constraints of the initial instruction. The crossover interaction eventually disappeared only after extended practice on the particular fault-and-switch task (80 examples of each: perhaps because of asymptotic performance having been reached). At this point, Bibby and Payne introduced two similar but new types of tasks designed so that once again, the table favored one task whereas procedures favored the other. (However, the device instructions were *not* re-presented.) At this point the crossover re-appeared, demonstrating that participants were consulting their instructionally derived mental model of the device, and that this was still in a form computationally equivalent to the original external representation of the instructions.

Practically, this research shows that the exact form of instructions may exert long-lasting effects on the strategies that are used to perform tasks, so that designers of such instructions must be sensitive not only to their informational content but also to their computational properties. In this light, they also suggest that one instructional representation of a device is very unlikely to be an optimal vehicle for supporting all user tasks: it may well be better to provide different representations of the same information, each tailored to particular tasks. In this sense, perhaps instructions should mirror and exploit the natural tendency, noted above, for users to form fragmentary mental models, with different fragments for different purposes.

In terms of theory, Bibby and Payne's findings lend support to the suggestion developed above that mental models of a device that are formed from instructions may be computationally equivalent to the external representations of the device. This idea gives a rather new reading, and one with more ready empirical consequences to the theoretically strong position that mental models are essentially analog, homomorphic representations.

3.2 MENTAL MODELS OF TEXT AND OTHER ARTIFACTS

The psychological literature on text comprehension has been transformed by the idea of a situation model, first put forward as part of a general theory of text comprehension by van Dijk and Kintsch (1983), and developed over the years by Kintsch (1998) and followers. The central idea of the general theory is that readers construct mental representations of what they read at several different levels. First, they encode the surface form of the text: the words and syntax. Second, they go beyond this to a representation of the propositional content of the text. Finally, they go beyond the propositional context of the text itself to represent what the text is about, incorporating their world knowledge to construct a situation model or mental model of the described situation.

(Under this view, it is the content that distinguishes a situation model from a text base, rather than a representational format. However, some researchers, notably Johnson-Laird (1983), and followers have pursued the idea of mental models derived from text as analog representations of the described situation. Thus, in text comprehension, there is a version of the issue discussed in part one.)

It is instructive to consider some of the evidence for situation models, and what important issues in text comprehension the theory of situation models allows us to address.

A classic early study was conducted by Bransford, Barclay, and Franks (1972). They asked participants to read simple sentences such as,

> Three turtles rested beside/on a floating log, and a fish swam beneath them.

(The slash indicates that some subjects read the sentence with the word "beside." and others read the same sentence with the word "on.")

In a later recognition test, interest centered on how likely readers were to falsely accept minor rewordings of the original sentences. In the above case, the foil sentence was

> Three turtles rested beside/on a floating log, and a fish swam beneath it.

The key finding was that people who had read the "on" versions of the sentences were much more likely to accept the changed version of the sentence, despite the fact that at the level of the sentences the difference between original and foil sentences in the two conditions is identical, limited in each case to the last word of the sentence. The reason for false recognition in one case is because, in this case, but not when "on" is replaced by "beside," the original and foil sentences describe the same situation.

A related series of experiments was reported by Fletcher and Chrysler (1990). In a series of carefully controlled experiments, they varied the overlap between sentences in a recognition test and sentences from 10 different texts read by the participants. Each text described a state of affairs (i.e., the relative cost of antiques) consistent with a linear ordering among a set of five objects. They found that participants were influenced by overlap between sentences at study and test corresponding to the three levels of discourse representation proposed by van Dijk and Kintsch (1983): surface form, text base, and situation model. Recognition performance was best when distracter items were inconsistent with all three levels of representation. Recognition was above chance when distracters violated merely the surface form of the original sentences (i.e. substituting rug for carpet). It improved further when propositional information from the text base, but not the linear ordering of the situation, was violated. Recognition was best of all when the distracters were inconsistent with the situation described by the text. This suggests that some aspects of the structure of the situation (in this case a set of linear orderings) were retained.

Next, consider work by Radvansky and Zacks (Radvansky and Zacks 1991; Radvansky, Spieler, and Zacks 1993). In these experiments, participants read sentences such as, "The cola machine is in the hotel," each of which specified the location of an object. In one condition sentences shared a common object (i.e. cola machine) but different locations. In a second condition, different objects share a common location (i.e. the city hall). Later in the experiment participants were given a speeded-recognition test. Radvansky and Zacks found a significant fan effect for the common object condition; times to verify sentences increased as the number of different locations rose. For the common location sentences no significant fan effect emerged. This was interpreted as evidence that participants formed mental models around the common location (a representation of such a location containing all the specified objects) and retrieval from long-term memory (LTM) was organized around these mental models. It is impossible, or much harder, to form such a representation of the same object in multiple locations.

What all these studies, and many like them, reveal is that when understanding text, readers spontaneously construct a mental representation that goes beyond the text itself and what it means, and use inferences to construct a richer model of what the text is about—a situation model.

Beyond these refined and clever, but undeniably rather narrow experimental contexts, the construct of situation models has been put to work to illuminate some practical issues concerning text comprehension, and exactly this issue will be returned to later, where we will see how it can inform attempts to understand instructional strategies for engendering useful mental models.

There are two principal ways in which the literature on text comprehension is relevant to HCI. First, it provides support for the idea that a mental model is a representation of what a representational artifact represents. The layered model of text comprehension previously outlined can be generalized to the claim that the user of any representational artifact must construct a representation of the artifact itself, and of what the artifact represents, and of the mapping between the two (how the artifact represents). This is the basis of the Yoked State Space (YSS) hypothesis (Payne, Squibb, and Howes 1990).

If a reader's goal is just to understand a text, as it was in the experiments just reviewed, then the text-representation can be discarded once a model has been constructed. However, there are many tasks of text *use,* in which it is necessary to maintain a representation of the text, alongside a mental model of the meaning of the text. Consider, for example, the tasks of writing and editing, or of searching for particular content in a text. In such tasks, it is necessary to keep in mind the relation between the surface form of the text—wording, spatial layout, and so on—and its meaning. Text is a representational artifact, and to *use* it in this sense one needs a mental representation of the structure of the text, and of the "situation" described by the text and of the mapping between the two.

According to the YSS hypothesis (Payne, Squibb, and Howes 1990), this requirement is general to all representational artifacts, including computer systems. To use such artifacts requires some representation of the domain of application of the artifact—the concepts the artifact allows you to represent and process. The user's goals are states in this domain, which is therefore called the goal space. However, states in the goal space cannot be manipulated directly. Instead, the user interacts with the artifact, and therefore needs knowledge of the artifact, and of the operations that allow states of the artifact to be transformed. Call this problem space the device space. In order to solve problems in the goal space by searching in the device space, the user must know how the device space represents the goal space. In this sense the two spaces need to be yoked. The minimal device space for a certain set of tasks must be capable of representing all the states in the corresponding goal space. More elaborate device spaces may incorporate device states that do not directly represent goal states, but which allow more efficient performance of tasks, just as the stack model of an RPN calculator allows an elaboration of methods for simple arithmetic.

The work of Halasz and Moran (1983) can readily be assimilated into the YSS framework. The no-model condition was provided with enough information to translate algebraic expressions into their Reverse Polish equivalent. However, in this understanding of RP expressions, the ENTER key was given merely an operational account, serving simply as a separator of operands, and did not transform the device state. The stack model, however, provides a figurative account of the ENTER key.

This discussion illustrates a practical lesson for the design of interfaces and instructions. In the case of the copy buffer and the calculator stack, the standard interface does not allow the appropriate device space readily to be induced, so that conceptual instructions must fill the gap. The obvious alternative, which has been developed to some extent in both cases, is to redesign the user interface so as to make the appropriate device space visible. These examples suggest a simple heuristic for the provision of conceptual instructions that may help overcome the considerable controversy over whether or not such instructions (as opposed to simple procedural instructions) are useful. According to this heuristic, conceptual instructions will be useful if they support construction of a YSS that the user would otherwise have difficulty inducing (Payne, Howes, and Hill 1992).

A more direct way in which text comprehension research is relevant to HCI is that so much HCI is reading text. Beyond the standard issues, the widespread availability of electronic texts raises some new concerns that have not yet seen much work, yet are perhaps the most directly relevant to HCI design. Two issues stand out: (1) the usability of documents that incorporate multiple media alongside text, and (2) the exploitation by readers of multiple texts on the same topic.

How are multimedia "texts" that incorporate graphics comprehended? There is only a small literature on this within the mainstream field of text comprehension, but this literature exploits the idea of a mental model.

Glenberg and Langston (1992) argued that the widespread idea that diagrams can assist the comprehension of technical text had, at the time, been little tested or understood and that mental models were an important explanatory construct. In their analysis, diagrams are useful in concert with texts precisely because they assist the construction of mental models. This idea has been pursued in a very active program of work on multimedia instruction by Mayer and colleagues, which will be reviewed in the next section.

What about when the multiple sources of information are not presented as part of a single text, but rather independently, covering overlapping ground, so that the reader has to perform all the integration and mapping? This is the issue of multiple texts, and it has become commonplace in the age of the Internet. It is now rarely the case that a student struggles to find relevant source documents on a topic. Instead, students are typically faced with an overabundance of relevant materials and must somehow allocate their time across them, and integrate the knowledge they derive from different sources.

Perfetti (1997) has suggested that learning from multiple texts is one of the most important new challenges for text researchers. Research has shown, for example, that integrating information across multiple texts is a skill that does not come readily but can be acquired and taught (Stahl et al. 1996; Rouet et al. 1997).

The YSS theory raises important issues here. As previously noted, everyday reading of text can be seen as engendering a progression of mental representations moving from the surface form through the propositional content to a situation model. When reading, earlier representations can be discarded as later ones are formed, but for other tasks of text use, the reader needs to maintain a representation of the form of the multitext, and map this form onto the content. Payne and Reader (in press) refer to such a representation as a structure map.

The usefulness of a structure map becomes even more apparent when multiple texts are considered. In this case, structure maps could play a role in encoding *source* information, which might be important not only for locating information, but also for integrating diverse and potentially contradictory information and for making judgments of trust or confidence in the information. Source information might additionally encode temporal properties of information sources, and thus be useful for memory updating—revising knowledge in the light of new information, making distinctions between current and superseded propositions.

The widespread availability of the web not only means that multiple texts are more widely encountered, but also encourages a situation where multiple texts are read in an interleaved fashion, in a single sitting, or at least temporally close, raising the importance of the above challenges, and meaning that recency in autobiographical memory is unlikely to accomplish source identification, so further stressing the importance of a structure map.

Payne and Reader (in press) studied readers' ability to search for specific ideas in multiple texts that they had just read. They found evidence that readers spontaneously constructed structure maps, as just described, in that they showed some memory of which documents contained which ideas, even when they did not expect to need such knowledge when reading the texts.

3.3 INSTRUCTIONS FOR MENTAL MODELS

3.3.1 Multimedia Instruction

If mental models are important for operating devices, how should they best be taught? We have seen that models are constructed automatically by readers of text, but can modern computational media, such as animations, be used to improve the acquisition of mental models from instructional texts, just as Glenberg and Langston (1992) suggested in the case of simple diagrams? Just such a question has been addressed in a long-standing program of work by Richard Mayer and colleagues, which will be reviewed in this section.

Mayer and Moreno (2002) present a cognitive theory of multimedia learning, which builds on three main ideas:

1. From dual coding theory the authors suppose that humans have separate visual and verbal information processing systems (Clark and Paivio 1991; Paivio 1986)
2. From cognitive load theory the authors assume that the processing capacity of both the visual and the verbal memory system is strictly limited (Baddeley 1992; Chandler and Sweller 1991) and that cognitive load during instruction can interfere with learning
3. From constructivist learning theory the authors take the idea that meaningful learning requires learners actively to select relevan``t information, to structure it into coherent representations, and make connections with other relevant knowledge (Mayer 1996, 1999a)

This latter process, of building coherent representations that connect information from different modalities with pre-existing knowledge, bears clear relation to Johnson-Laird's construct of mental models, and indeed Mayer and colleagues use the term in this context. In the case of the physical systems that many of their studies have addressed, mental models may take the form of cause-effect chains. According to Mayer and Moreno (2002) a key design principle for instructional materials is that they should maximize the opportunity for these model-construction processes to be completed.

Mayer and colleagues have conducted a large number of experiments comparing learning from multimedia source materials with learning from components of these materials (words, pictures, etc.) successively or in other kinds of combination. Based on this research, Mayer (1999b) and Mayer and Moreno (2002) have identified some principles of instructional design that foster multimedia learning.

The *multiple presentation principle* states that explanations in words and pictures will be more effective than explanations that use only words (Mayer and Moreno 2002, p. 107). When words only are presented, learners may find it difficult to construct an appropriate mental image, and this difficulty may block effective learning. Mayer and Anderson (1991; Experiment 2b) compared four treatment groups: (1) words with pictures, (2) words only, (3) pictures only, and (4) control, on tests of creative problem solving involving reasoning how a bicycle pump works. Results demonstrated that participants in the words with pictures group generated a greater number of creative problem solutions than did participants in the other groups. Interestingly, animation without narration was equivalent to no instruction at all. Other studies have offered support for the general idea that learners will acquire richer knowledge from narration and animation than from narration alone (Mayer and Anderson 1991, Experiment 2a; Mayer and Anderson 1992, Experiments 1 and 2).

The *contiguity principle* is the claim that simultaneous as opposed to successive presentation of visual and verbal materials is preferred (Mayer and Moreno 2002), because this will enable learners to build referential connections more readily (Mayer and Sims 1994). Mayer and Anderson (1991, Experiments 1 and 2) studied a computer-based animation of how a bicycle pump works. They compared a version that presented words with pictures against the same content presenting words before pictures, and tested acquisition with tests of creative problem solving. Those in the words-with-pictures group generated about 50% more solutions to the test problems than did subjects in the words-before-pictures group.

The *individual differences principle* predicts that factors such as prior knowledge or spatial ability will influence transfer of learning from multimedia materials, moderating the effects of other principles (Mayer 1999c). With regard to domain specific knowledge, Mayer proposed that experienced learners may suffer little decrease in problem solving transfer when receiving narration and animation successively because their background knowledge will allow a mental model to be constructed from the words alone, then linked to the visual information. Low-experience learners, on the other hand, will have no means to over-ride the effects underlying the contiguity principle, and their problem solving transfer will suffer (Mayer and Sims 1994). In support of this suggestion, experimental work by Mayer and Gallini (1990) demonstrated across three studies that the synchronization of words and pictures served to improve transfer for low- but not high-experience learners.

The *chunking principle* refers to a situation in which visual and verbal information must be presented successively, or alternately (against the contiguity principle). It states that learners will demonstrate better learning when such alternation takes place in short rather than long segments. The reasoning is straightforward, given the assumptions of the framework: working memory may become overloaded by having to hold large chunks before connections can be formed (Mayer 1999b). An experiment by Mayer and Moreno (1998) investigated this chunking principle using explanations of how lightning storms develop. The ability to solve novel, transfer problems about lightning exhibited by a 'large chunk' group (who received all the visual information before or after all the verbal information) was compared with that of a 'small chunk' group (alternating presentations of a short portion of visual followed by a short portion of narration). The gain in performance of the small chunk group over the large chunk group was circa 100% (Mayer and Moreno 1998).

The debt of Mayer's work to Sweller's program of research on Cognitive Load Theory is obvious. Mayer's design principles reflect the premise that students will learn more deeply when their visual and/or verbal memories are not overloaded. Students are better able to make sense of information when they receive both verbal and visual representations rather than only verbal; when they can hold relevant visual and verbal representations in working memory at the same time; when they have domain specific knowledge and/or high spatial ability; and when they receive small bits of information at a time from each mode of presentation.

Despite incredibly positive research results, at this stage Mayer's work should be viewed with a little caution. Almost all of the experiments utilize very short instructional presentations, with some of the animations lasting only 30 seconds. Subjects are then required to answer problem-solving questions that seem ambiguous, requiring students to be fairly creative in order to generate solutions. Mayer's work also typically neglects to include any tests of long-term retention. It may conceivably be falling into the instructional trap of maximizing performance during learning at the expense of longer-term performance. This issue is the focus of the next section.

3.3.2 Theory of Learning by Not Doing

Mayer's theory of multimedia instruction adheres to the common assumption that the optimal design of instructional material involves minimizing the cognitive burden on the learner due to the limits of the working memory.

Yet minimizing the mental effort of learners is not necessarily or always a good instructional strategy. According to Schmidt and Bjork (1992), instructional conditions that achieve the training goals of generalizability and long-term retention are not necessarily those that maximize performance during the acquisition phase.

They argue that the goal of instruction and training in real-world settings should first be to support a level of performance in the long term, and second to support the capability to transfer that training to novel-tasks environments. Methodologically, in order to measure a genuine *learning effect,* some form of long-term assessment of retention must take place; skill acquisition is not a reliable indicator of learning.

Schmidt and Bjork (1992) discussed three situations in which introducing difficulties for the learner can enhance long-term learning. First, studies that vary the scheduling of tasks during practice were reported. Random practice is more difficult than blocked schedules of practice, as a given task is never practiced on the successive trial. Using a complex motor task involving picking up a tennis ball and using it to knock over a particular set of barriers, Shea and Morgan (1979) reported a clear advantage for subjects who practiced under blocked conditions (subsets of barriers to knock), in terms of performance during practice. However, the amount of learning as demonstrated by the retention phase favored the random condition. Similar results have been reported by Baddeley and Longman (1978), Lee and Magill (1983), and (with verbal tasks) Landauer and Bjork (1978).

Schmidt and Bjork offer an explanation for this paradigm, in which retrieval practice may play a key role. They suggest that there may be a benefit, in terms of long-term retention, for activities that actually cause forgetting of the information to be recalled, forcing the learner to practice retrieving this information (Bjork and Allen 1970).

Experiments that vary the feedback the learner receives have demonstrated a similar phenomenon. A study by Schmidt et al. (1989) demonstrated that delaying the feedback that subjects received during motor tasks interfered with performance. However, on a delayed-retention test, those who had received the feedback least often demonstrated the most effective performance. This seems to contradict the established opinion that feedback is vital for effective learning. Schmidt and Bjork (1992) suggested that frequent feedback may actually serve to block information-processing activities that are important during the skill-acquisition phase.

A final area reviewed by Schmidt and Bjork concerns the introduction of variability during practice, such as when practicing tossing a beanbag at a target at a particular distance. Practicing at variable distances is more effective than practicing at a fixed distance (Kerr and Booth 1978).

Does the Schmidt and Bjork approach extend to HCI tasks, and in particular to instruction for mental models?

One impressive example of an instructional effect in the Schimdt and Bjork (1992) paradigm is informed by the idea of mental models or situation models derived from text, as discussed in Section 3.2 of this chapter. Informed by the distinction between a text base and a situation model, work by McNamara et al. (1996) has shown how expository text can be designed to introduce difficulties for readers in exactly the productive manner advocated by the Schmidt and Bjork conception of training. These authors created two versions of target texts, one more coherent than the other (one experiment used a text about traits of mammals, a second used a text about heart disease). Coherence cues were provided by linking clauses with appropriate connectives and by inserting topic headings. The level of readers' background knowledge on the topic of the text was also assessed with a pretest. After reading a text, participants were given tests of the text base (free recall of the text propositions and specific factual questions about the contents of the text) and tests of the situation model (problem-solving-based questions, questions requiring inferences from the text, and a concept-sorting task).

McNamara et al. (1996) reported that for measures that tested the text base, the high coherence texts produced better performance. However, for situation-model measures, test performance for high-knowledge readers was better when they read the low-coherence text. McNamara et al. argued that limiting the coherence of a text forced readers to engage in compensatory processing to infer unstated relations in the text. This compensatory processing supported a deeper understanding of the text, in that the information in the text became more integrated with background knowledge. Thus, for high-knowledge readers, the texts that were more difficult to read improved the situation model by encouraging more transfer-appropriate processing. Low-knowledge readers were, presumably, unable to achieve the compensatory inferences, and therefore did better with more coherent texts. Because the text base does not incorporate background knowledge, it was not enhanced by any compensatory processing. (This finding is related to the work of Mayer and Sims [1994] reviewed above.)

One very successful practical approach to the design of instructions for interactive devices which is well known in the HCI community, is perhaps quite strongly related to this more theoretically oriented work. The concept of a "minimal manual" was outlined by Carroll (1990). It sought to minimize the extent to which instructional materials obstruct learning. Crucially, a well-designed Minimal Manual does not necessarily optimize the speed at which users can perform procedures as they read. Carroll's manuals avoided explicit descriptions that encouraged rapid but mindless rote performance. Instead, the emphasis was on active learning whereby learners were encouraged to generate their own solutions to meaningful tasks. This process was facilitated in part by reducing the amount of text provided and including information about error recovery.

O'Hara and Payne (1998, 1999) argued that learning from a problem-solving experience might be enhanced to the extent that problem solvers planned their moves through the problem space. Many puzzles with an interactive user interface, and indeed many user interfaces to commercial systems, encourage a one-step-at-a-time approach to problem solving, in which a move is chosen from the currently available set. This may be quick and relatively effortless, yet lead to little learning and inefficient solutions. For example, in an HCI task, participants had to copy names and addresses from a database to a set of letters. Each item category from the database had to be copied to several letters, so that the most obvious and perhaps least effortful strategy of preparing letters one at a time was inefficient in terms of database access. O'Hara and Payne's manipulation was to increase the cost of making each move (in the copying experiment by adding a system lock-out time). This resulted in more planning, more think-time per move, meaning slower solutions in the first instance, but more efficient behavior in the long term, and the discovery of strategies that required fewer database accesses and fewer user inputs.

Recent work by Duggan and Payne (2001) combined several of the insights in the work just reviewed to explore acquisition of interactive procedures during instruction following. Good procedural instructions for interactive devices must satisfy two criteria. First, they must support performance. Like all procedural instructions they should effectively communicate the procedure they describe, so as to allow users who don't know the procedure to enact it successfully and efficiently. Second, they must support learning. In common with instructions for all procedures that will be used repeatedly, they should facilitate subsequent memory for the procedure, so that it might later be performed without consulting the instructions.

How might procedural instructions be designed so as to follow the Schmidt and Bjork paradigm and provide transfer-appropriate practice opportunities for the learner? Of course, not all manipulations that introduce difficulties during learning are beneficial for the learner. Simply making the instructions unclear is unlikely to be effective. However, much this idea may have informed the design of some commercial user manuals. The criterion that quality instructions must communicate the procedure that they describe cannot be ignored.

The work of Diehl and Mills (1995) further illustrated the relevance of the theory of text comprehension to the design of instruction for interactive procedures. They argued that in the case of procedural instructions the distinction between situation model and text base maps directly onto a distinction between memory for the procedure (as tested by later task performance) and memory for the instructions themselves.

Texts describing how to complete a task using a device (setting an alarm clock or constructing a child's toy) were provided. While reading a text, participants were required to either perform the task (read and do), or do nothing (read only). (In addition, Diehl and Mills studied some intermediate conditions, such as read and watch experimenter. These conditions produced intermediate results and are not relevant to the current argument.) The effect of these training methods was then examined by asking participants to recall the text and then complete the task.

Diehl and Mills reported that the increased exposure to the device in the read-and-do condition resulted in improved task performance times relative to the read-only condition. However, text recall was better in the read-only condition, supporting the conceptual separation of text base and situation model.

Inspired by this work, Duggan and Payne (2001) introduced a particular technique to exploit the principle of Schmidt and Bjork (1992) and the methods of McNamara and colleagues (1996). Like the manipulations of Diehl and Mills (1995), their innovation centered not on the design of the instructions per se, but rather on the way the instructions are read and used. Diehl and Mills' reported advantage for reading and doing over reading alone has no real practical implication, as it is difficult to imagine anyone advocating isolated reading as a preferred method. However, Duggan and Payne suggested that the way learners manage the interleaving of reading and doing will affect their later retention, and thus offers an important lever for improving instruction.

Many procedural instructions have a natural step-wise structure, and in these cases it is possible to execute the procedure while reading with minimal load on memory. Learners can read a single step, and then execute it before reading the next step. Such an approach is low in effort (and therefore attractive to the learner), but also low in transfer-appropriate practice and therefore, one would argue on the basis of the reviewed work, poor at encouraging retention. If learners could instead be prompted to read several procedural steps before enacting them, performance would be made more effortful, but learning might benefit. Readers would be encouraged to integrate the information across the chunk of procedural steps, and the increased memory load would provide transfer-appropriate practice.

Duggan and Payne (2001) developed this idea as follows. First, by implementing an online help system in the context of experimental tasks (programming a VCR) they forced participants into either a step-wise or a chunk-based strategy for interleaving reading and acting. These experiments demonstrated that reading by chunks did tax performance during training, but improved learning, in particular retention of the procedure. Next, they developed a more subtle, indirect manipulation of chunking. By adding a simple cost to the access of online instructions (c.f., O'Hara and Payne 1998), they encouraged readers to chunk steps so as to minimize the number of times the instructions were accessed. Just as with enforced chunking, this led to improved retention of the procedures.

3.4 SHARED MENTAL MODELS

In the last 10 years or so there has been a rapid surge of interest in the concept of shared mental models in the domain of teamwork and collaboration. The use of mental models in this literature, to date, is somewhat inexact, with little theoretical force, except to denote a concern with what the team members know, believe, and want. As the name suggests, shared mental models refers to the overlap in individuals' knowledge and beliefs.

The central thesis and motive force of the literature is that team performance will improve when team members share relevant knowledge and beliefs about their situation, task, equipment, and team. Different investigations and different authors have stressed different aspects of knowledge, and indeed proposed different partitions into knowledge domains. (And recently, as we shall see, some investigators have questioned the extent to which overlapping knowledge is a good thing. There are some situations in which explicit distribution or division of knowledge may serve the team goals better.)

At first glance, the idea that teams need to agree about or share important knowledge seems intuitively plain. Models of communication (i.e., Clark 1992) stress the construction of a common ground of assumptions about each partner's background and intentions. The idea of shared mental models develops this idea in a plausible practical direction.

A recent study by Mathieu et al. (2000) was one of the most compelling demonstrations of the basic phenomenon under investigation, as well as being centered on an HCI paradigm. For these reasons, this study will be described and used as a framework to introduce the space of theoretical and empirical choices that characterize the mainstream of the shared mental models literature.

Mathieu et al. (2000) considered team members' mental models as comprising knowledge of four separate domains: (1) technology (essentially the mental models described in part one of this chapter); (2) job or task; (3) team interaction (such as roles, communication channels and information flow), and (4) other teammates' knowledge and attitudes. Knowledge of the last three types would rarely be called a mental model outside this literature, and so straight away we can see a broader and more practical orientation than in individually oriented mental models literatures.

For the purposes of operationalization, the authors suggested that these four categories of knowledge may be treated as two: task related and team related. This binary distinction mirrors a distinction that has been made in terms of team behaviors and communications, which have been considered in terms of a task track and a teamwork track (McIntyre and Salas 1995).

Mathieu and colleagues studied dyads using a PC-based flight simulator. One member of each dyad was assigned to the joystick to control aircraft position. The other was assigned to keyboard, speed, weapon systems, and information gathering. Both members could fire weapons. The experimental procedure incorporated a training phase, including the task and basics of teamwork, and then the flying of six missions, divided into three equally difficult blocks of two, each mission lasting around 10 minutes. Performance on a mission was scored in terms of survival, route following, and shooting enemy planes. Team processes were scored by two independent raters viewing videotapes to assign scores, for example, how well the dyad communicated with each other.

Mental models were measured after each pair of missions. At each measurement point, each individual's task or team mental model was elicited by the completion of a relatedness matrix (one for task, one for team), in which the team member rated the degree to which each pair from a set of dimensions was related. For the task model there were eight dimensions, including diving versus climbing; banking or turning; and choosing airspeed. For the team model there were seven dimensions, including amount of information and roles and team spirit.

Thus, at each measurement point, participants had to assign numbers between –4 (negatively related, a high degree of one requires a low degree of the other) and +4 (positively related, a high degree of one requires a high degree of the other) to each pair of dimensions in each domain. For example, they had to rate the relatedness of diving versus climbing to choosing airspeed, and the relatedness of roles to team spirit. For each team at each time for each model-type a convergence index was calculated by computing a correlation co-efficient (QAP correlation) between the two matrices. The co-efficient could vary from –1 (complete disagreement) to +1 (completely shared mental models).

The main findings of this investigation were as follows. Contrary to hypothesis, convergence of mental models did not increase over time; rather it was stable across missions 1 to 3. This runs counter to a major and plausible assumption of the shared mental models program, which is that agreement between team members should increase with extent of communication and collaboration.

Nevertheless, convergence of both task and team models predicted the quality of team process and the quality of performance. Further, the relationship between convergence and performance was fully mediated by quality of team process.

The most natural interpretation of these findings is that team process is supported by shared mental models. In turn, good team processes lead to good performance. According to its authors, this study provided the first clear empirical support for the oft-supposed positive relationship between shared mental models and team effectiveness (Mathieu et al. 2000, p. 280).

As well as being paradigmatic in illustrating the key ideas in the shared mental models literature, this study has several aspects that highlight the range of approaches and the controversy in the field.

First, it is worth considering what particular properties of the task and teams may have contributed to the positive relation between shared mental models and team process and performance. Compared with most situations in which coordination and collaboration are of prime interest, including most situations addressed by CSCW researchers, the teams studied by Matheiu et al. were minimal (two members) and the tasks were very short term and relatively circumscribed. Beyond these obvious remarks, I would add that the division of labor in the task was very "close," and the workers' performance was extremely interdependent. Of course, interdependence is the signature of collaborative tasks; nevertheless, a situation in which one person controls airspeed and another controls altitude may make this interdependence more immediate than is the norm.

It is also possible that the relatively circumscribed nature of the task and collaboration contributed to the failure of this study to find evidence for the sharing of mental models increasing across the duration of collaboration.

As just mentioned, although the literature contains many proposals that shared mental models will positively influence process and performance, there has been much less empirical evidence. Another study of particular relevance to HCI is concerned with the workings of software development teams.

Software development is an ideal scenario for the study of team coordination for several reasons. First, much modern software development is quintessentially team based (Crowston and Kammerer 1998; Curtis, Krasner, and Iscoe 1998; Kraut and Streeter 1995), and relies heavily on the complex coordinations of team members. Secondly, this effort is often geographically dispersed, further stressing collaboration and putting an emphasis on communications technologies. Finally, software development takes place in technologically advanced settings with technologically savvy participants, so that it provides something of a test bed for collaboration and communication technologies.

One study of complex geographically distributed software teams has been reported that partially supports the findings of the Mathieu et al. (2000) study and provided complementary evidence for positive effects of shared mental models on team performance. Espinosa et al. (2002) reported a multimethod investigation of software teams in two divisions of a multinational telecommunications company. The most relevant aspect of their study was a survey of 97 engineers engaged in team projects of various sizes ranging from 2 to 7. Team coordination and shared mental models (SMM) were both measured by simple survey items, followed by posthoc correlational analysis to uncover the relation between shared mental models and team process. As in the Mathieu et al. (2000) study, shared mental models were considered in two categories: task and team. A positive relation between team SMM and coordination was discovered, but the effect of task SMM was not significant.

It is worth being clear about the positive relation and how it was computed. Team SMM was computed for each team by assessing the correlations between each team member's responses to the team SMM survey items. This index was entered as an independent variable in a multiple regression to predict average reported levels of team coordination. It is, of course, hard to infer any causal relation from such correlational analyses, and one might also wonder about the validity of purely questionnaire-based measures of some of the constructs, yet nevertheless the study is highly suggestive that SMM can have a positive influence in group-work situations far removed from pairs of students interactive with a flight simulator. Additionally, Espinosa et al. (2002) reported an interview study in which respondents confirmed their own belief that SMM contributed positively to project communications and outcomes.

Nevertheless, Espinosa et al. (2002) failed to find any relation between task SMM and team process. It seems to me that, in view of the survey methodology, this would have been the more compelling evidence in favor of the SMM construct. It seems less surprising and perhaps less interesting that there should be a correlation between participants' survey responses concerning how well they communicated on their team, and, for example, their agreement about which teammates had high knowledge about the project.

Levesque, Wilson, and Wholey (2001) reported a different study of software development teams, using ad hoc student-project groupings to study whether sharing of Team SMM increased over time. They only measured Team SMM, using Likert scale items on which participants signaled amount of agreement or disagreement with statements like, “Most of our team’s communication is about technical issues,” “Voicing disagreement on this team is risky,” or “Lines of authority on this team are clear.” Team SMM was measured by computing correlations among team members of these responses after 1, 2, and 3 months of working on a joint project.

Levesque, Wilson, and Wholey (2001) found that, contrary to their hypothesis, team SMM decreased over time. They argue that this is because projects were managed by a division of labor that required much initial collaboration but meant that later activity was more individual.

There are surely many teamwork situations in which role differentiation is critical for success, and this observation suggested that the most straightforward interpretation of shared mental models is overly simple. Indeed, even in teams that continue to meet, communicate, and collaborate, it may be that role differentiation means that task mental models should not so much be “shared” as “distributed” to allow for effective team performance. (Studies of intimate couples have explored a similar process of specialization of memory functions, under the name “transactive memory,” i.e., Wegner 1987, 1995).

When roles are differentiated, it is no longer important that task knowledge is shared, but rather that individuals’ knowledge about who knows what is accurate. Thus, one would expect team SMMs to support communication and collaboration even in teams with highly differentiated roles. This may explain the previously reviewed findings. In the Mathieu et al. study, the team members’ technical roles remained tightly interdependent, so that both task and team models had to be shared for successful performance. In the Espinosa et al. (2002) study, the technical roles may have been differentiated but the level of communication remained high, so that team SMM affected performance but task SMM did not. In the Levesque et al. study, the teams divided their labor to the extent that communication and collaboration ceased to be necessary (apart, perhaps for some final pooling of results). In this case, we would predict that neither task nor team SMMs would affect performance once the division of labor had been accomplished. No data on performance were reported, but team models became less shared over the course of the projects.

Although there has been quite a sudden flurry of interest in shared mental models, this brief review makes clear that much empirical and conceptual work remains to be done. Of particular relevance to this chapter is the question of what exactly is meant by a mental model in this context.

To date throughout the field, mental models have been considered as semantic knowledge, using traditional associative networks as a representation. Thus, mental models have typically been tapped using simple likert scales or direct questions about the relations (i.e. similarity) between constructs, analyzed with multidimensional techniques such as pathfinder (for a review of measurement techniques in this field, see Mohammed, Kilmoski, and Rentsch 2000). Because interest has focused on the extent to which knowledge and beliefs are common among team members, these approaches have been useful, allowing quantitative measures of similarity and difference. Nevertheless, compared with the literature on individual mental models, they tend to reduce participants’ understanding to mere associations, and yet the thrust of the individual work shows that this may not be appropriate, because the particular conceptualizations of the domain, the analogies drawn, the computational as well as informational relations between internal and external representations, and so on can have real effects on performance. It seems that an important path of development may be to adopt this more refined cognitive orientation and investigate the impact of shared models—as opposed to shared networks of facts and associations—on collaboration.

4 Task Loading and Stress in Human–Computer Interaction

Theoretical Frameworks and Mitigation Strategies

James L. Szalma, Gabriella M. Hancock, and Peter A. Hancock

CONTENTS

Individuals whose professional lives revolve around human–computer interaction (HCI) might well ask themselves why they should even glance at a chapter on stress. It is evident that many computer systems have to support people operating in stressful circumstances and, of course, there are important design issues concerning how to present information in these very demanding circumstances. However, one can legitimately question whether such issues are of any interest to those operating in mainstream HCI. Indeed, if these were the only issues we would most probably agree and recommend the reader to pass on quickly to something of much more evident relevance. However, we hope to persuade the reader that the various aspects of stress research and its application to HCI are not limited to such concerns alone. Indeed, we hope to convince the reader that stress, in its critical form of task loading, is central to all HCIs. To achieve this goal, we first present a perspective that puts stress front and center in the HCI realm. Traditionally, stress has been considered to result from exposure to some adverse environmental circumstances such as excessive heat, cold, noise, or vibration (Hancock, Ross, and Szalma 2007; Conway, Szalma, and Hancock 2007). Its effects manifest themselves primarily in relation with physiological responses most perturbed by the stress at hand. However, Hancock and Warm (1989) observed that stress effects are virtually all mediated through the brain; but for the cortex such effects are almost always of secondary concern since the brain is primarily involved with the goals of ongoing behavior or more simply with dealing with the current task at hand (see Hancock 2010). Therefore, we want to change the orientation of concern here so that stress is not just a result of external interference but rather the primary source of stress comes from the *ongoing task itself*. As we now view the task itself as the primary driving influence, then stress concerns are manifestly and evidently *central to all HCI issues*.

It is one of the clearest paradoxes of modern work that computer-based systems designed to reduce task complexity and cognitive workload actually often impose even greater demands and stresses on the very individuals they are supposed to be helping. Think of how many times in your own work that the computer has appeared to be a barrier to task completion rather than a helpful tool. How individuals cope with such stress has both immediate and prolonged effects on their performance and well-being. Although operational environments and their associated tasks vary considerably (e.g., air traffic control, baggage screening, hospital patient monitoring, power plant operations, command and control, banking/finance, and general office work), there are certain mechanisms that are common to all stress appraisals and thus to all task demands. Consequently, there are design and HCI principles to address the stress of task demand that can be generalized across many, if not all, domains (Hancock and Szalma 2003a,b). In this chapter we explore these principles to further understand and even exploit stress effects in the HCI domain.

The structure of this chapter flows from these fundamental observations: First, we provide the reader with a brief overview of stress theory and its historical development to set our observations in context. Then we articulate areas for future research, which is needed to more completely understand how stress and workload impact HCI and how their positive effects can be exploited while mitigating their negative effects. We conclude by providing an overview of these principles and some directions for future effort.

4.1 TRADITIONAL APPROACHES TO STRESS RESEARCH

As we have seen, stress has traditionally been conceived of as either an external, aversive stimulus (constituted of physical, cognitive, or social stimulation patterns) imposed on an individual or that person's individual response to such perturbations. Each of these theoretical perspectives has limited explanatory power. Considering stress as an external stimulation is useful for categorizing effects of physical environments (e.g., heat, noise, vibration), but such an approach cannot explain why the same stimulus pattern produces vastly different effects on different individuals. Physiological interpretations (e.g., Selye 1976) have utilized arousal explanations of stress. However, more recent demonstrations that different sources of stress are associated with different patterns of cognitive effects make it clear that adaptation or so-called arousal theories of stress cannot, by themselves, completely address the issue (Hockey 1984; Hockey and Hamilton 1983; Hockey, Gaillard, and Coles 1986).

Thus, to understand stress effects we now have to embrace an even wider, multidimensional perspective (e.g., Matthews

2001). In this chapter, we choose to emphasize a view of stress as primarily an outcome of the appraisal of environmental demands that either tax or exceed an individual's resources to cope with that demand. These person–environment *transactions* (Lazarus and Folkman 1984) occur at multiple levels within an organism (Matthews 2001; van Reekum and Scherer 1997). Further, these processes represent efforts by the organism to adapt to imposed demands via regulation of its own internal state while seeking to change the external environment (e.g., obtaining shelter). In Section 4.2, we describe the theoretical frameworks that guide our observations on stress in the context of HCI. These perspectives emerge from the work of Lazarus (1999; and see also Lazarus and Folkmanm 1984), Hancock and Warm (1989), and Hockey (1997).

4.2 THEORETICAL FRAMEWORKS

Herein is a brief introduction to key theories regarding stress and its effects on performance.

4.2.1 Appraisal Theory

Among the spectrum of cognitive theories of stress and emotion, perhaps the best known is the "cognitive–motivational–relational" theory proposed by Richard Lazarus and his colleagues (see Lazarus 1991, 1999; Lazarus and Folkman 1984). This theory is cognitive in that stress and emotion each depends on an individual's cognitive appraisals of internal and external events. These appraisals in their turn depend in part on the person's knowledge and experience (cf. Bless 2001). The theory is motivational in that emotions in general, including stress responses, are reactions to one's perceived state of progress toward or away from one's goals (see Carver and Scheier 1998). The relational aspect emphasizes the importance of the transaction between individuals and their environment. Together these three components shape the emotional and stress state of an individual. The outcomes of these processes are patterns of appraisal that Lazarus (1991) refers to as "core relational themes." For instance, the core relational theme for anxiety is uncertainty and existential threat, whereas that for happiness is evident progress toward goal achievement. Thus, when individuals appraise events relative to their desired outcomes (goals), negative, "goal-incongruent" emotions and stress can be produced if such events are appraised as hindering progress. Conversely, promotion of well-being and pleasure occurs when events are appraised as facilitating progress toward a goal (i.e., goal-congruent emotions). Promotion of pleasure and happiness (see Hancock, Pepe, and Murphy 2005; Ryan and Deci 2001), therefore, requires the design of environments and tasks themselves that afford goal-congruent emotions. The understanding of interface characteristics in HCI that facilitate positive appraisals and reduce negative appraisals is thus a crucial issue and an obvious avenue in which HCI and stress research can fruitfully interact.

A major limitation of all appraisal theories, however, is neglecting to understand how task parameters influence resulting coping response. Although the appraisal mechanism itself may be similar across individuals and contexts (e.g., see Scherer 1999), the specific content (e.g., which events are appraised as a threat to well-being) obviously varies across individuals and contexts. One would expect that the criteria for appraisal (e.g., personal relevance, self-efficacy for coping) are similar across individuals for specific task parameters as for any other stimulus or event. However, individual differences occur in the specific content of an appraisal (e.g., one person's threat is another's challenge) and therefore in the resultant response. An understanding of stress effects in HCI thus requires understanding the task and person factors and treating the transaction between the human being and the system as the primary unit of analysis (see Lazarus and Folkman 1984). This entails knowing how different individuals appraise specific task parameters and how changes in knowledge structures might ameliorate negative stress effects and promote adaptive affective states in human–technology interaction. A visual representation of this emergent unit of analysis that comes from the interaction of a person and the environment, including the task, is shown in Figure 4.1 (Hancock 1997).

4.2.2 Adaptation under Stress

A theoretical framework developed specifically for stress as it relates to performance is the maximal adaptability model presented by Hancock and Warm (1989). They distinguished three facets of stress and labeled them the "trinity of stress," as shown in Figure 4.2. Input refers to the environmental events to which an individual is exposed, which include information (i.e., displays) as well as traditional input categories such as temperature, noise, and vibration (e.g., Hancock, Ross, and Szalma 2007; Pilcher et al. 2002). The second is adaptation, which encompasses the appraisal mechanisms referred to previously. The third and final component is output level, which indicates how an organism behaves with respect to goal achievement. A fundamental tenet of the Hancock and

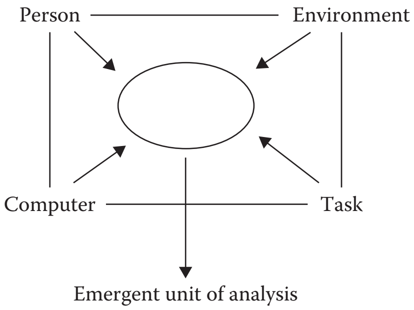

FIGURE 4.1 An illustration of the emergence of a supraordinate unit of analysis that derives from the interaction of an individual (person), the tool he or she uses (computer), the task he or she has to perform (task), and the context (environment) against which the action occurs.

Warm (1989) model is that in a large majority of situations (and even in situations of quite high demand) individuals do adapt effectively to input disturbance. That is, they can tolerate high levels of either overload or underload without enormous change to their performance capacity. Adaptive processes occur at multiple levels, some being the physiological, behavioral (i.e., performance), and subjective/affective levels. These adaptations are represented in the model as a series of nested, extended inverted-U functions (see Figure 4.3) that reflect the fact that under most conditions the adaptive state of the organism is stable. However, under extremes of environmental underload or overload, "failures" in adaptation do occur. Thus, as the individual is perturbed by the input, the first threshold one traverses is subjective comfort. This is followed by behavioral effects and finally failure of the physiological system (e.g., loss of consciousness). Examples of such extreme failures are relatively rare in most settings, although when they do occur (e.g., in conflict situations) they are often catastrophic for the individual and the system he or she is operating (e.g., Harris, Hancock, and Harris 2005).

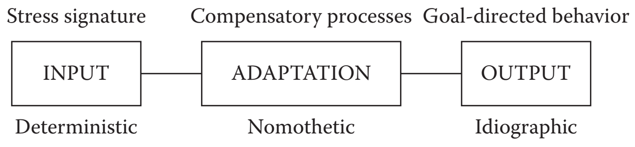

FIGURE 4.2 The trinity of stress, which identifies three possible "loci" of stress. It can be viewed as an input from the physical environment, which can be described deterministically. Since such a profile is by definition unique, it is referred to as a stress signature. The second locus is adaptation, which describes the populational or nomothetic reaction to the input itself. It is most evidently measurable in the processes of compensation. The third and final locus is output, which is expressed as the impact on the ongoing stream of behavior. Since the goals of different individuals almost always vary, this output is largely idiographic or person specific. It is this facet of stress that has been very much neglected in prior and contemporary research.

This model is unique in that it provides explicit recognition that the *proximal form of stress* in almost all circumstances is the task itself. Task characteristics are incorporated in the model by two distinct base axes representing spatial and temporal components of any specified task. Information structure (the spatial dimension) represents how task elements are organized, including challenges to such psychological capacities such as working memory, attention, decision making, and response capacity. The temporal dimension is represented by information rate. Together, these dimensions can be used to form a vector (see Figure 4.4) that serves to identify the current state of adaptation of the individual. Thus, if the combination of task characteristics and an individual's stress level can be specified, a vector representation can be used to predict behavioral and physiological adaptation. The challenge lies in quantifying the information-processing components of cognitive work (see Hancock, Szalma, and Oron-Gilad 2005).

Although the model shown in Figure 4.4 describes the level of adaptive function, it does not articulate the mechanisms by which such adaptation occurs. Hancock and Warm (1989) argued that one way in which individuals adapt to stress is by narrowing their attention by excluding task-irrelevant cues (Easterbrook 1959). Such effects are known to occur in

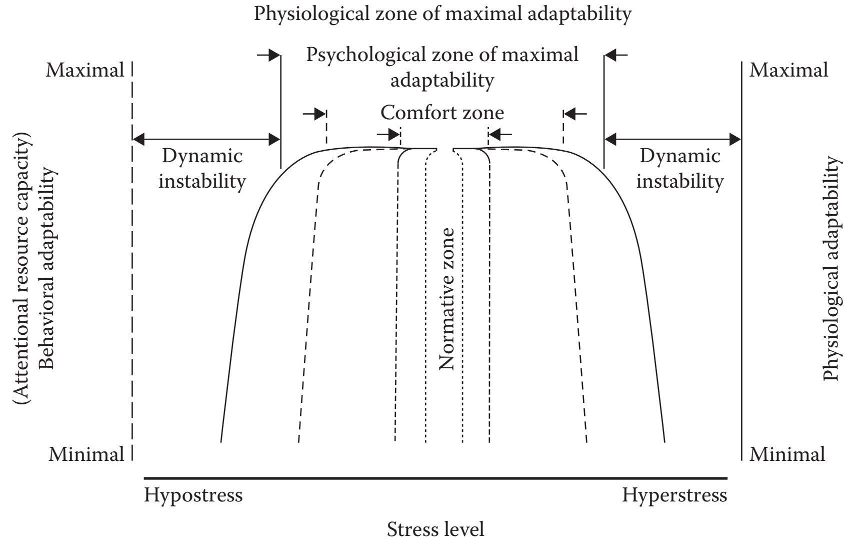

FIGURE 4.3 The extended-U relationship between stress level and response capacity. As is evident, the form of degradation is common across the different reflections of response. At the center of the continuum is the normative zone, which reflects optimal functioning. Outside of this is the comfort zone, which reflects the behavioral recognition of a state of satisfaction. Beyond this lies the reaction of psychological or cognitive performance capacity. Finally, the outer envelope is composed of physiological functioning. There are proposed strong linkages between the deviation from stability at one level being matched to the onset of radical failure at the more vulnerable level that is nested within it. The model is symmetrical in that underload (hypostress) has mirror effects to overload (hyperstress), which is usually considered the commonly perceived interpretation of stress.

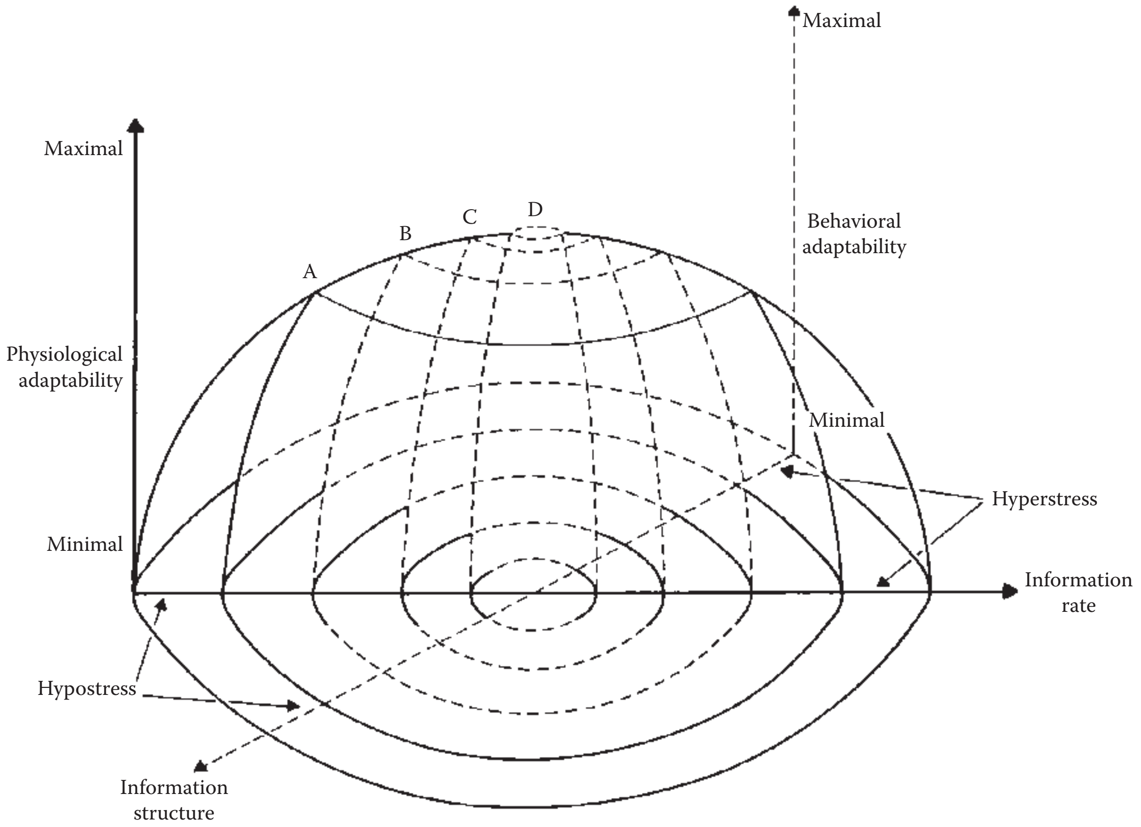

FIGURE 4.4 A three-dimensional representation of Figure 4.3. The description given in Figure 4.3 is now expanded into a three-dimensional representation by parsing the base hypostress–hyperstress axis into its two component elements. These divisions are composed of information rate (the temporal axis) and information structure (the spatial axis). Note that any one source of input stress can be described as a scalar on the base axis and these scalars can be summed to provide a multi-input stress vector that then provides a prediction of both performance and physiological adaptability, which are the primary descriptors on the vertical axis. A, B, C and D represent the thresholds of adaptability. A represents the physiological zone of maximal adaptability; B is the psychological zone of adaptability, C is the comfort zone, while D illustrates the normative zone.

spatial perception (e.g., Bursill 1958; Cornsweet 1969), and narrowing can occur at the levels of both central and peripheral neural systems (Dirkin and Hancock 1984, 1985; Hancock and Dirkin 1983). Further, Hancock and Weaver (2005) have argued that distortions of temporal perception under stress are related to this narrowing effect. However, evidence suggests that these two perceptual dimensions (space and time) may not share common perceptual mechanisms (see Ross et al. 2003; Thropp, Szalma, and Hancock 2004).

4.2.3 The Cognitive–Energetic Framework

The Hancock and Warm model accounts for the levels of adaptation and adaptation changes that occur under the driving forces of stress. However, it does not articulate precisely how effort is allocated under stress or the mechanisms by which individuals appraise the task parameters that are the proximal source of stress. The precise effort allocation issue is addressed by a cognitive–energetic framework described by Hockey (1997). The compensatory control model is based on three assumptions: (1) Behavior is goal directed. (2) Self-regulatory processes control goal states. (3) Regulatory activity has energetic costs (i.e., it consumes resources). In this model, a compensatory control mechanism allocates resources dynamically according to the goals of an individual and the environmental constraints. The mechanisms operate at two levels (see Figure 4.5): The lower level is more or less "automatic" and represents established skills. Regulation at this level requires few energetic resources or

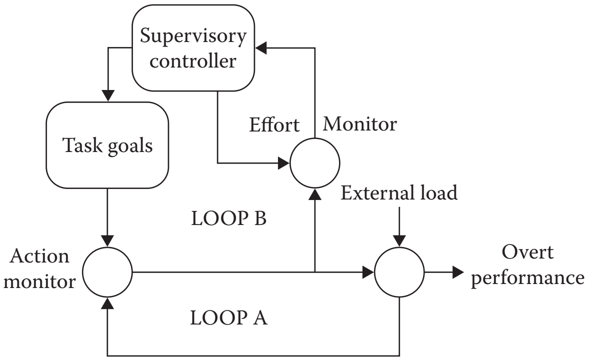

FIGURE 4.5 The two-level effort regulation model by Hockey: This model provides a mechanism by which an individual allocates limited cognitive resources to different aspects of performance. (From Hockey, G. R. J., *Biol Psychol*, 45:73–93, 1997. With permission.)

low active regulation and effort (cf. Schneider and Shiffrin 1977). The upper level is a supervisory controller, which can shift resources (effort) strategically to maintain adaptation, and reflects effortful and controlled processing. The operation of the automatic lower loop is regulated by an effort monitor, which detects changes in the regulatory demands placed on the lower loop. When demand increases beyond the capacity of the lower loop, control is shifted to the higher, controlled processing loop. Two strategic responses of the supervisory system are increase in effort and change in the goals. Goals can be modified in terms of their kind (change the goal itself) or strength (e.g., lowering the criterion for performance). From a self-regulation perspective, these modifications adjust the discrepancy between goal state and the current state by increasing effort or changing the goal (see Carver and Scheier 1998).

4.3 RELATIONSHIP BETWEEN STRESS AND COGNITIVE WORKLOAD

4.3.1 Cognitive Workload as a Form of Stress

The Hancock and Warm (1989) model explicitly identifies the task itself as the proximal source of stress. In operational environments, this is often manifested as increases or decreases in cognitive workload (Moray 1979). As in the case of stress, workload is easily identified colloquially but difficult to define operationally. Workload can manifest in terms of the amount of information to be processed (an aspect of information structure) and the time available for processing (information rate). Thus, the base axes of the Hancock and Warm model capture dimensions of workload as well as stress (and see Hancock and Caird 1993). Indeed, physiological measures of workload (O'Donnell and Eggemeier 1986) are often the same as the measures used to assess physiological stress. Similarly, subjective measures of workload and stress both reflect appraisals of the task environment and of its perceived effect on the individual (Hart and Staveland 1988). Although the two concepts were developed in separate research traditions, the artificial boundary between them should be dissolved as each term refers to similar processes. The implication for HCI is that computer-based tasks that impose either too much or too little demand will likely be appraised as stressful. In the latter case, the underload stress will be interpreted as boredom. Thus, the design process for the development of computer interfaces should include assessment of perceived workload as well as affective state.

4.3.2 Performance and Workload: Associations/Dissociations

It is often the case that performance is maintained under increased workload/stress, which is reflected in the extended-U model described by Hancock and Warm and in the mechanisms of Hockey's energetic model of compensatory control. Maintaining performance under stress is associated with costs, both physiologically and cognitively. Further, one would expect that in easier tasks performance is not as costly and that, therefore, there is a direct *association* between task difficulty and perceived workload. Such performance–workload associations do occur, and they occur most prevalently in vigilance tasks (Warm, Dember, and Hancock 1996; see also Szalma et al. 2004). However, other forms of workload–performance relations can occur. For instance, perceived workload may change as a function of change in task demand, but performance remains constant. Hancock (1996) refers to these situations as *insensitivities*, which can be diagnostic with respect to the relation between the individual and the task (see also Parasuraman and Hancock 2001). Thus, consistent with the frameworks of Hancock and Warm (1989) and Hockey (1997), one response to increased task demand is to exert more effort, thereby maintaining performance but increasing perceived workload. Alternatively, one could have a situation in which task demands increase and performance decreases, but perceived workload does not change. This suggests that appraisals of a task are not always sensitive to actual changes in that task.

Interesting corollaries of these observations are performance–workload *dissociations* that sometimes occur (Hancock 1996; Yeh and Wickens 1988). In such cases, decreased performance is accompanied by *decreased* workload. One possible reason for such a result is disengagement of the individual from the task (i.e., the person gives up; see Hancock 1996). In the case where increased performance is observed to be accompanied by increased perceived workload, the pattern suggests effective improvement of performance at the cost of increased effort allocation. An area of much-needed research is establishing which task parameters control the patterns of performance–workload associations and dissociations, and how these change dynamically as a function of time on task. It may well be that reformulating the task by innovations in the interface itself addresses these crucial concerns (see Hancock 1997). Indeed, the structure and organization of computer interfaces will be a major factor in determining both performance under stress and the relation of performance to perceived workload.

4.4 MITIGATION OF STRESS

If changing the fundamental nature of demand is one solution, we now look at other approaches to mitigate the negative effects of stress and workload on the performance of HCI tasks. These strategies include skill development (e.g., Hancock 1986), specific display design changes (Hancock and Szalma 2003a; Wickens 1996), as well as technologies employing adaptive automation and decision aids (Hancock and Chignell 1987). Developing skills so that they are relatively automatic as opposed to the alternative controlled processing (Schneider and Shiffrin 1977) and developing expertise can mitigate some of the negative effects of stress (Hancock and Hancock 2010). Regarding display design, simple, easily perceivable graphics can permit quick, direct extraction of information when cognitive resources are reduced by stress and workload (Hancock and Szalma

2003a). Adaptive automation can be employed by adjusting the level of automation and the management of that automation according to stress state (e.g., Scerbo, Freeman, and Mikulka 2003). In addition, adapting the form of automation (i.e., level, management type) to the operator based on their own personal style of interaction can serve to improve its utility for aiding performance and reducing stress and workload (see Thropp et al. 2004). Indeed, experimental findings are even now beginning to establish the relation for automation to effectively mitigate performance-related stress (Funke et al. 2007).

4.4.1 Theoretical Bases of Emotion (Stress) Regulation

In both theory and research, stress is clearly linked with the more general topic of emotion (Lazarus 1999). Indeed there is growing recognition of the need to consider a user's emotional response to a task or an interface as it is an important aspect of design. Emotions are valenced reactions to either internal or external stimuli, which trigger multisystemic changes in both physiology and behavior (Ochsner and Gross 2005). Emotions are therefore useful in presenting feedback concerning an operator's ongoing interaction with the environment and especially the computer-based technology with which they must interact (Folkman et al. 1986). The computer and the manner in which it functions can produce a range of emotional reactions in the operator who is attempting to manipulate the system. However, at present the computer has no concept of emotional experience or display, no matter how often humans might attribute these characteristics to the machine (Luczak, Roetting, and Schmidt 2003). Contrary to intuition, the computer is not malfunctioning in order to frustrate or spite its users and no amount of shouting or banging will presently instill it with a sense of motivation to work. However, this is not to say extensive efforts are not underway to develop computer systems that both recognize user emotions and generate emotional expressions on behalf of the computer system (Zhang et al. 2010). The very act of interacting with a computer represents an emotional experience as the machine is a tool by which the operator hopes to accomplish his or her desired goals. Events whereby the computer facilitates the achievement of a goal can result in pleasant emotions (i.e., accomplishment, relief, and happiness), whereas instances in which the interface component of the human–computer dyad is perceived as detrimental or as a barrier to goal fulfillment can produce negative valence emotions such as anger and frustration (Hassenzahl and Ullrich 2007). Therefore, emotions are an inherent feature of HCI as no human action, even one performed in tandem with an affectless instrument, takes place in a completely emotion-free context. Emotions then have the potential in HCI to become either stressors themselves or tools by which operators can cope with stress and enhance the effectiveness and efficiency of performance. Gross, Richards, and John (2006) have postulated that effective emotion regulation is a qualification for adaptive functioning in almost all everyday skills. Given the growing popularity and availability of technologies such as personal digital assistants and cellular telephones, HCIs are rapidly becoming modal everyday tasks. Techniques for regulating the pervasive influence of emotions are therefore useful skills for the operator to develop so that they may minimize the disadvantageous consequences of negative emotional experiences.

4.4.1.1 Psychological and Physiological Strategies for Emotion Regulation

Emotions are typically categorized based on two componential characteristics: (1) valence and (2) arousal (Lang 1995). Valence refers to the extent to which an operator interprets an emotion as pleasant or unpleasant. Arousal constitutes the extent to which an emotion evokes a response from the operator's physiological system. Stress is unique in that it has the ability to run the gamut on both dimensions; thus, it can be perceived as both pleasant and unpleasant, as well as inducing either mild or severe physiological reactions. Techniques for its regulation therefore incorporate methods to address both the psychological and physiological components of stress (see Hancock and Warm 1989).

A typical course of emotional experience, without any attempts at emotion regulation, begins with emotionally charged environmental cues eliciting intrapersonal emotional response tendencies, which lead to emotional responses (Gross 1998). Emotion regulation techniques may therefore intercede at a number of points in this process. Antecedent-focused strategies, such as cognitive reappraisal, specifically endeavor to manipulate the interaction between emotional cues and their subsequent response tendencies and are therefore a method of evaluation (i.e., viewing the interaction with the computer as a learning experience). Response-focused strategies such as expressive suppression, on the other hand, affect the relationship between an operator's response tendencies and the resultant emotional response and are therefore a method of modulation (i.e., ignoring any unpleasant feelings resulting from interaction with the computer). Both techniques have proved to be effective strategies, although the optimal technique heavily depends on the situation (Gross 2002).

4.4.1.2 Deliberate Emotion Regulation

Emotion regulation entails "processes that individuals use to influence which emotions they generate, when they do so, and how these emotions are experienced or expressed" (Ochsner and Gross 2005, p. 243). Active processing of this nature, which requires attentional resources, is referred to as deliberate emotion regulation. Recent research suggests the possibility that emotion regulation can take place automatically, at an unconscious level (Mauss, Bunge, and Gross 2007). While seminal research efforts investigating the influence of automatic emotion regulation on performance are currently underway (Hancock and Beatty 2010), our focus here necessarily concentrates on the more established deliberate emotion regulation strategies. The two strategies that are studied most often are cognitive reappraisal and expressive suppression. These techniques share a common goal of emotion regulation, but they differ in the aspects of emotion that they influence, when they begin to influence emotional experience, and their long-term versus short-term effectiveness.

4.4.1.3 Cognitive Reappraisal

Cognitive reappraisal is defined as the act of interpreting potential emotion-provoking stimuli in unemotional terms (Speisman et al. 1964). The purpose of cognitive reappraisal is therefore to influence an individual's cognition, in order to maintain control over emotional responses. As mentioned in Section 4.4.1.1, cognitive reappraisal is an antecedent-focused emotional regulation strategy. The intervention occurs as early as possible in the emotional experience so as to minimize deleterious performance consequences. Indeed, Gross (2002) reported that reappraisal is more effective than expressive suppression. Unlike suppression, it has no detrimental effects on other cognitive processes such as memory. The utilization of cognitive reappraisal is also associated with superior long-term health outcomes (Haga, Kraft, and Corby 2009).

4.4.1.4 Expressive Suppression

Expressive suppression is defined as the inhibition of emotionally expressive behavior despite emotional arousal (Gross and Levenson 1993). The primary aim of the suppression approach is therefore to minimize outward displays of emotion, that is, targeting overt behavior instead of cognition. As a response-focused strategy, suppression initiates its influence later in the process sequence than cognitive reappraisal (Gross 1998). Although cognitive reappraisal is more effective over the long term, suppression is the superior short-term option; operators employing expressive suppression may have more attentional resources available as they are not actively engaging in the continual assessment and reassessment of environmental stimuli. Operators engaging in HCIs under time constraints may therefore find this strategy more effective.

4.4.2 Changing the Person

To improve a stressful human-machine interaction, one viable option is to alter the human's attitudes or abilities either through training or selection.

4.4.2.1 Training/Skill Development

Clearly, the greater the skill of an individual the more resilient his or her performance under stress (Hancock 1986). This well-established phenomenon is incorporated into the energetic theories of stress and performance and is an approach most often taken to mitigate adverse workload and stress effects. However, training on relevant tasks is only one method of training for stress. There are also techniques for training individuals to cope more effectively with stress itself, such as the aforementioned emotion regulation techniques discussed in Sections 4.4.1.3 and 4.4.1.4, which essentially build stress-coping skills. An additional example of such an approach is stress exposure training (SET; Johnston and Cannon-Bowers 1996), a three-phase procedure in which individuals are provided information regarding the stress associated with task performance, are provided training on the task, and then practice their task skills under simulated stress conditions. This technique has been shown to be effective in reducing anxiety and enhancing performance (Saunders et al. 1996). There is evidence that coping skills learned with a particular type of stressor and task can be transferred to novel stressors and tasks (Driskell, Johnston, and Salas 2001). For such an intervention to succeed, however, it is crucial that the training is designed based on a complete and accurate analysis of the task environment (Johnston and Cannon-Bowers 1996). If task parameters that are the most responsible for the workload and stress are identified, these can be especially targeted in training.

An additional issue in training for more effective stress coping is modifying an individual's appraisal of events, an approach that is coincident with the emotion regulation technique of cognitive reappraisal discussed in Section 4.4.1.3. Learning to approach HCIs with effective coping is therefore a valuable skill to acquire as early as possible in any task training. Inducing automaticity in some skills permits reallocation of resources to coping efforts, as well as reducing the likelihood that the task environment itself is appraised as threatening. Even if an event is appraised as a threat to an individual's psychological or physical well-being, the highly skilled individual will appraise his or her coping ability as sufficient to handle such an increased demand. However, there has been limited research on how individuals who develop expertise also develop the capacity to effectively cope with the stress that accompanies performance in a given domain and on the extent to which stress-coping skills in one domain transfer to other domains. Deliberate practice generally facilitates skill development (Ericsson 2006). If one considers coping with stress to be a skill, then in principle deliberate practice should permit the development of expertise in coping with stress. This likely involves parsing the task into components, based on cognitive task analysis, and designing training procedures that target the stressful aspects of the task. However, such efforts require an understanding of how different forms of stress affect different forms of information processing. Since these variables are difficult to quantify, establishing these linkages must be driven by theory. Elucidation of these issues will provide the groundwork for future development of stress mitigation tools during training and skill development.

4.4.2.2 Personnel Selection

Selection techniques have been a popular choice for matching individuals to specific jobs, but the focus has traditionally and historically been on intellectual skills (e.g., Yerkes 1918). Selecting individuals for their stress-coping capability has been applied to the selection criteria for police officers, who therefore tend to be as stable as or more emotionally stable than the rest of the population (for a review, see the work by Brown and Campbell [1994]). Selecting individuals with proficient stress-coping skills becomes still more difficult given the complex criteria that define stress and the fact that "successful" coping skills vary by situation and desired outcome. Research is therefore needed that links particular traits to stress-coping skills for specific task environments. The effectiveness of everyday life stress coping, such as that observed in individuals who are extraverted (McCrae and Costa 1986; Penley and Tomaka 2002) or optimistic (Aspinwall, Richter, and Hoffman 2002; Scheier and Carver 1985), may not predict effective coping in specific task domains. Understanding which individuals will likely cope effectively with a particular task therefore requires first a thorough understanding of the perceptual, cognitive, and psychomotor characteristics of the task and then linking these parameters to trait profiles. By far the most research on the relation of affective traits to task performance has been conducted in the areas of extraversion and trait anxiety/neuroticism (see the work by Matthews, Deary, and Whiteman [2003] for a review). However, the characteristics of greatest interest may vary somewhat across domains, although some general traits (e.g., emotional stability, conscientiousness) would be expected to moderate performance across a variety of task environments.

4.4.3 Changing the Task

Modifying the technology component is another possibility for more effective HCI.

4.4.3.1 Display Design

Although training and selection can mitigate stress effects, the primary method of stress mitigation requires the tasks themselves to be redesigned. This is for two reasons: (1) There will be many instances where selection is not possible and expenditure of significant resources on training is undesirable. (2) There are instances in which one wishes to design an interface that requires little or no training and that can be used by any member of a large population of individuals (e.g., consumers). Particularly in light of the observation that task represents the proximal source of stress, future work in stress mitigation for HCI should focus on redesign of the task and of the interface itself. In previous work, we have argued that existing display design techniques that are simple and easily perceived would be the best choice for an interface that is used in stressful environments (Hancock and Szalma 2003a). Specifically, configural or object displays can represent complex, multivariable systems as simple geometric shapes or emergent features if those features are mapped well to system dynamics (see Bennett and Flach 1992). Under stress, it is the complex problem solving and analytical skills that are the most vulnerable and are apt to decline first. A display that allows fast extraction of information with minimal cost in working memory load can mitigate stress effects (Hancock and Szalma 2003a; Wickens 1996). A combination of training to automaticity and displays of information that can be perceived directly with a minimum of information-processing requirements is currently one of the best approaches for stress mitigation in cognitively complex environments.

4.4.3.2 Adaptive Automation

Another approach for stress mitigation is the allocation of function to automated systems (Hancock and Chignell 1987). The advent of modern automated systems allows for automation to adapt to the state of an individual (Scerbo, Freeman, and Mikulka 2003). Thus, at points in time when an operator is overstressed and overtaxed, the system can assume control of some task functions, thereby freeing resources to effectively cope with increased task demand. Two potential problems for automated systems are that overreliance can occur and operator skills can atrophy. However, a dynamic (adaptive) automated system that permits or requires the operator to perform functions at different points in time can reduce the probability of skill atrophy while still relieving the workload and stress of task performance.

However, the introduction of automation can itself induce stress. Operators who work with automated systems, particularly static, inflexible automated systems, are relegated to the role of monitors who must respond only when untoward events occur. Sustained attention requirements are in fact quite stressful (Warm, Parasuraman, and Matthews 2008) and paradoxically induce high perceived workload (Warm, Dember, and Hancock 1996). Adaptive automation can mitigate this problem by dynamically assigning tasks to the machine or the human being depending on the environmental conditions and the state of the operator (Hancock and Chignell 1987). Indeed, potential techniques for enabling the operator's neurological state to adjust to automation have been identified (e.g., Scerbo, Freeman, and Mikulka 2003).

4.4.4 Hedonomics: Promoting Enjoyable Human–Computer Interaction

Stress research has traditionally followed the edict of ergonomics and human factors, in general, to first do no harm and then seek to prevent pain and injury. As with the rest of behavioral science, stress researchers have often sought to treat the symptoms of stress and mitigate its negative effects on performance. However, with the advent of positive psychology (Seligman and Csikszentmihalyi 2000), there has been a movement to incorporate the promotion of pleasure and well-being rather than restrict efforts to pain prevention. Hancock (Hancock, Pepe, and Murphy 2005) coined the term hedonomics and defined it as that branch of science that facilitates the pleasant or enjoyable aspects of human–technology interaction. In short, the goal of hedonomics is to design with happiness in mind. Hedonomics is a fairly new research area, but during the last decade there has been a rapid growth in research concerning affect and pleasure. Affective evaluations provide a new and different perspective in human factors engineering. It is not how to evaluate users; it is how the user evaluates (Hancock et al. 2005). The research on hedonic values and seductive interfaces is in fact a welcome contrast to research on safety and productivity, which have dominated human factors and ergonomics (HF/E) for so long. It must be noted, however, that *pleasurable* interaction with technology is not necessarily conducive to *happiness*. Indulging in pleasures can sometimes interfere with happiness and well-being (see Fromm 1976; Kasser 2002; Ryan and Deci 2001).

Our argument is not that we should discard current methods in HF/E. Clearly functionality and usability are necessary conditions for pleasurable interaction with technology. If an interface does not function in a way that is congruent with the user's goals so that the user appraises the technology as an agent that is interfering with goal achievement, that interaction is likely to be stressful and performance may decline. However, functionality and usability are necessary but not sufficient conditions for pleasurable interactions with technology. The interface should be designed such that it affords appraisals of the technology as a convivial tool (Illich 1973) or aid. One can also utilize the human tendency to anthropomorphize technology to facilitate such appraisals of the technology as "helpful and supportive" rather than as "conflictive" or, worse, an "enemy" (Luczak, Roetting, and Schmidt 2003).

Hedonomic design is of obvious importance for the development of consumer products, but in principle it can also transform the very nature of work itself, rendering it "fun." Although there may be some tasks that will never be completely enjoyable, there are many individuals who have jobs that could be made more enjoyable by designing the tasks such that they promote teletic work (Csikszentmihalyi 1990) while also facilitating intrinsic motivation (Deci and Ryan 2000).

4.4.4.1 Teletic Work and Intrinsic Motivation

A useful theoretical framework for hedonomics is self-determination theory (SDT; Deci and Ryan 1985, 2000; Ryan and Deci 2000, 2001). From this perspective, there are three organismic needs that are essential for facilitating intrinsic motivation for task activity and the positive affect that can accompany such states. These needs are competence (self-efficacy; see also Bandura 1997), autonomy (personal agency, not independence per se), and relatedness. An important difference between this theory and other theories of motivation is the recognition that there are qualitatively different forms of motivation (Gagne and Deci 2005). Thus, in SDT five categories of motivated behavior are identified that vary in the degree to which motivation is self-determined. Four of the categories reflect extrinsic motivation and one category is intrinsic motivation. In the latter case, individuals are inherently motivated to engage in activity for its own sake or for novelty and challenge. The four extrinsic motivation categories vary in the degree to which regulation of behavior is internalized by the individual and, therefore, they are more autonomous and self-determined (Ryan and Deci 2000). The process of internalization involves transforming an external regulation or value into one that matches an individual's own values. The development of such autonomous motivation is crucial to skill development, since the person must maintain his or her effort throughout a long and arduous process. Individuals who are autonomously motivated to learn are those who develop a variety of effective self-regulation strategies, have high self-efficacy, and set a number of goals for themselves (Zimmerman 2000). Further, effective self-regulation develops in four stages: (1) observation, (2) emulation, (3) self-control, and (4) self-regulation. Successful skill development involves focus on process goals in the early stages of learning and outcome goals in the fourth stage (Zimmerman 2000).

4.4.4.2 Intrinsic Motivation and Skill Development

Research has established that intrinsic motivation is facilitated by conditions promoting autonomy, competence, and relatedness (see Deci and Ryan 2000). Three factors that support autonomy are as follows: (1) meaningful rationales for doing a task, (2) acknowledgment that the task might not be interesting, and (3) an emphasis on choice rather than control. It is important to note that externally regulated motivation predicts poorer performance on heuristic tasks (Gagne and Deci 2005), suggesting that as experts develop better knowledge representations it will be crucial to promote their internal regulation of motivation. Although intrinsic motivation has been linked to how task activities and environmental contexts meet psychological needs, it is not clear why skilled performers are able to meet these needs or why an individual chooses a particular computer interface. It is likely that interest in activities codevelops with abilities and traits (see Ackerman and Heggestad 1997), but this issue needs more thorough investigation in the context of complex computer environments that require highly skilled work.

Emotions can be powerful motivators of task performance, including tasks involving HCI. Both intrinsic motivation and emotional experience play critical roles in beginners' perceptions concerning their current and future interactions with a system (Venkatesh 2000). Although emotion cannot and most probably should not be designed out of an HCI, it is possible to design activities in which emotional experience facilitates learning and enhances an operator's intrinsic motivation for task mastery (Lepper and Cordova 1992). Such activities should also aim to simultaneously foster effective emotion regulation techniques. Learning to perform in the presence of common stressors early in the learning process will help to maintain task engagement. In addition to the aforementioned concern and the issues of efficacy and self-regulation, there is a need to examine the process by which individuals internalize extrinsic motivation as gain experience with a particular interface or system. In particular, Gagne and Deci (2005) noted that little research has examined the effect of reward structures and work environments on the internalization process. It is likely that environments structured to meet basic needs more likely facilitate internalization processes and inoculate learners against the trials and tribulations that face them as they interact with new technologies.

4.4.4.3 Teletic Work and Motivational Affordances

Teletic, or autoteletic, work refers to work that is experienced as enjoyable and is associated with "flow" or optimal experience characterized by a sense of well-being and harmony with one's surroundings (Csikszentmihalyi 1990). There is variation in both tasks and individuals with respect to the degree to which the human–technology interaction is teletic. There are four categories in which individuals tend to fall with respect to their relation to work: First, there is a small proportion of the population that is always happy in life, regardless of their activity. Csikszentmihalyi (1990) refers to these individuals as having an "autotelic personality." There is also a group of individuals who are naturally predisposed to being happy regarding a specific task. They appraise such tasks as enjoyable and often seek out these activities. The third group consists of individuals who enjoy specific activities but cannot do them professionally. This group includes individuals such as amateur athletes. The vast majority of people, however, do work for purely functional reasons (e.g., finances and security). For these individuals, work is boring and grinding because the task itself is nearly always considered aversive. A goal of hedonomics is to design work that can be enjoyed to the greatest extent possible. This means structuring the environment as an entire system, ranging from the specific cognitive and psychomotor demands to the organization in which a person works. Even in jobs that are not inherently enjoyable, some degree of positive affect can be experienced by workers if their environment is structured to facilitate a sense of autonomy (personal agency), competence, and relatedness (Deci and Ryan 2000; see also Gagne and Deci 2005). From an ecological perspective (Flach et al. 1995), this means identifying the *motivational affordances* in the task and work environment, and designing for these affordances. Thus, just as one might analyze the affordance structure of an interface using ecological interface design methods (e.g., Vicente and Rasmussen 1992), one can design an environment so that the elements of the physical and social environment afford stress reduction and enhanced intrinsic motivation. An affordance is a relational property that does not exist independent of the individual and the environment. Affordances therefore share conceptual elements of person–environment transactions that drive emotion and stress. They differ from each other in that the classical definition of affordance often describes it as a physical property of the environment (Gibson 1966, 1979), although more recent thinking suggests that no specific physical element connotes affordance. Thus, one cannot define either concept by isolating either the individual or the context (see Reed 1996).

Motivational affordances may be conceived as elements of the work environment that facilitate and nurture intrinsic motivation. The key for design is to identify *motivational invariants*, or environmental factors that consistently determine an individual's level of intrinsic motivation across contexts. There are some aspects of work that have been identified as important for facilitating intrinsic motivation and would thus be considered motivational invariants. For instance, providing feedback that is perceived as controlling rather than informative tends to undermine a sense of autonomy and competence and thereby reduces intrinsic motivation (Deci, Ryan, and Koestner 1999). Careful analyses of the motivational affordance structure permit design of tasks that are more likely to be enjoyable by rendering the tools convivial (Illich 1973) and thereby facilitating human–machine synergy (see Hancock 1997).

4.5 DIRECTIONS FOR FUTURE HUMAN–COMPUTER INTERACTION RESEARCH IN RELATION TO WORKLOAD AND STRESS

In this section, we identify directions for future research. These include a better understanding of resources and quantifying task dimensions defined in the Hancock and Warm (1989) model. Progress here likely reduces to the thorny problem of quantifying human information processing (see Hancock, Szalma, and Oron-Gilad 2005). Further, we discuss the need for research on performance–workload associations and dissociations, and the evident need for programmatic investigation of the role of individual differences in performance, workload, and stress.

The Hancock and Warm (1989) model of stress explicitly identifies task dimensions that influence stress state and behavioral adaptability. However, the metrics for these dimensions, and how specific task characteristics map to them, have yet to be fully articulated. Thus, future research should aim to examine how different task components relate to performance and subjective and physiological states. Development of a quantitative model of task characteristics will permit the derivation of vectors for the prediction of adaptability under stress. Cognitive neuroscience and neuroergonomics in particular offer a very promising approach to such understanding. An additional step in this direction, however, will be facilitated by improved quantitative models of how human beings process information (Hancock, Szalma, and Oron-Gilad 2005).

4.5.1 Understanding Mental Resources

One of the challenges for quantifying human information processing is that there is little understanding or consensus regarding the capacities that "process" the information. A central concept in energetic models of human performance is mental resources. Resource theory replaced arousal and serves as an intervening variable to explain the relations between task demand and performance. However, a continual problem for the resource concept is to operationally define what resources actually are. Most early treatments of resources used that term metaphorically (Navon and Gopher 1979; Wickens 1980, 1984), and the failure to specify what resources have led some to challenge the utility of the concept (Navon 1984). As resource theory is a central concept in theories of stress and represents one of the most important issues to be resolved in future research on stress and performance, we now turn to the definitional concerns associated with the resource construct and imperatives for future research to refine the concept.

4.5.1.1 Resource Metaphors

Two general categories of resource metaphors may be identified as structural metaphors and energetic metaphors. One of the earliest conceptualizations of resource capacity used a computer-based metaphor (Moray 1967). Thus, cognitive capacity was viewed as being analogous to the random access memory and processing chip of a computer, consisting of information-processing "units" that can be deployed for task performance. However, the structural metaphor has been applied more to theories of working memory than to attention and resource theory.* Most early resource theories, including Kahneman's (1973) original view and modifications by Norman and Bobrow (1975), Navon and Gopher (1979), and Wickens (1980, 1984), applied energetic metaphors to resources. These perspectives conceptualized resources as commodities or as pools of energy to be "spent" on task performance. In general, energetic approaches tend to employ either economic or thermodynamic/hydraulic metaphors. The economic model is reflected in the description of resources in terms of supply and demand: Performance on one or more tasks suffers when resource demands of the tasks exceed available supply. Presumably the total amount of this supply fluctuates with the state of the individual, and the "assets" diminish with increases in the intensity or duration of stress. Although Kahneman's (1973) original conception allows for dynamic variation of available resource capacity, most early models assumed a fixed amount of resources (see Navon and Gopher 1979). In thermodynamic analogies, resources comprise a fuel that is consumed or a tank of liquid to be divided among several tasks, and under stressful conditions the amount of resources available is insufficient to meet demand and thus performance suffers. There is no consensus as to the capacity or flexibility of such a tank or whether there are numerous malleable tanks that only store modality-specific resources (Young and Stanton 2002). In discussing his version of resource theory, Wickens (1984) warned that the hydraulic metaphor should not be taken too literally, but most subsequent descriptions of resources have employed visual representations of resources in just this form (i.e., a tank of liquid). Similarly, many discussions of resource availability and expenditure adopt the economic language of supply and demand, and Navon and Gopher (1979) explicitly adopted principles of microeconomics in developing their approach. An additional problem faced by resource theory is that in most cases (e.g., Navon and Gopher 1979; Wickens 1980, 1984) the structural and energetic metaphors are treated interchangeably, a further testament to the ambiguity of the construct.

A problem with using nonbiological metaphors to represent biological systems is that such models often fail to capture the complexity and the unique dynamic characteristics (e.g., adaptive responses) of living systems. For instance, a hydraulic model of resources links the activity of a tank of liquid, governed by thermodynamic principles, to the action of arousal mechanisms or energy reserves that are allocated for task performance. However, a thermodynamic description of the physiological processes underlying resources is at a level of explanation that may not adequately describe the psychological processes that govern performance. Thermodynamic principles can be applied to the chemical processes that occur within and between neurons, but they may be less useful in describing the behavior of large networks of neurons.† Similarly, economic metaphors of supply and demand may not adequately capture the relation between cognitive architecture and energy allocated for their function. Economic models of resources define them as commodities to be spent on one or more activities and they assume an isomorphism between human cognitive activity and economic activity, an assumption that may not be tenable. Indeed, Navon and Gopher (1979) admitted that their "static" economic metaphor for multiple resources may need to be replaced by a dynamic one that includes temporal factors (e.g., serial versus parallel processing; activity of one processing unit being contingent on the output of another). Such concerns over the metaphors used to describe resources are hardly new (Navon 1984; Wickens 1984); but the use of metaphors has become so ingrained in the general scientific thinking about resources and human performance that reevaluation of metaphors is more than warranted, it should be mandated. A regulatory model based on neurophysiological chemistry may serve as a better metaphor (and, in future, may serve to describe the actual nature of the resources themselves to the extent that they can be established) to describe the role of resources in human cognition and performance. However, even a physiology-based theory of resources must be tempered by the problems inherent in reducing psychological processes to physiological activity.

4.5.1.2 Function of Resources

Another problem faced by resource theory is the absence of a precise description of how resources control different forms of information processing. Do resources determine the energy allocated to an information processor (Kahneman 1973), do they provide the space within which the processing structure works (Moray 1967), or does the processor draw on the resources as needed (and as made available)? In the third case, the cognitive architecture would drive energy consumption and allocation, but the locus of control for the division of resources remains unspecified in any case. Presumably an "executive" function that either coordinates information processors drawing on different pools of resources or decides how resources will be allocated must itself consume resources, in terms of both energy required for decision making and mental "space" or structure required. Hence, resource theory does not solve the homunculus problem for theories of attention nor does it adequately describe the resource allocation strategies behind the performance of information-processing tasks.

4.5.1.3 Empirical Tests of the Model

Navon and Gopher (1979) commented on the problem of empirically distinguishing declines in performance due to insufficient supply from those resulting from increases in

* This is a curious historical development, since these relatively separate areas of research converge on the same psychological processes.

† The argument here is not that neural structures are not constrained by the laws of thermodynamics—clearly they are—but that thermodynamic principles implied by the metaphor are not sufficient for the development of a complete description of resources and their relation to cognitive activity.

demand. They asked, "When the performance of a task deteriorates, is it because the task now gets fewer resources or because it now requires more?" (Navon and Gopher 1979, p. 243). Navon and Gopher (1979) characterized the problem as distinguishing between changes in resources and changes in the subject-task parameters that constrain resource utilization. They offered two approaches to avoid this conundrum: One approach is to define the fixed constraints of a task and then observe how the information-processing system manages the processes within those constraints. The degree of freedom of the system, in this view, is the pool of resources available, in which the term resource is interpreted broadly to include quality of information, number of extracted features, or visual resolution. The subject-task parameters define what is imposed on the system (the demands) and the resources refer to what the system does in response to the demands (allocation of processing units). From this perspective, resources can be manipulated by the information-processing system within the constraints set by the subject-task parameters. A second approach is to distinguish the kind of control the system exerts on resources between control on the use of processing devices (what we have called structure) and control of the properties of inputs that go into these devices. The devices are *processing resources*. The other kind of control is exerted on *input resources*, which represents the flexibility a person has for determining which inputs are operated on, as determined by subject-task parameters. Processing resources are limited by the capacities of information processors, whereas input resources are limited by subject-task parameters (and allocation strategies that determine which information the operator attends to). Presumably the individual has some control over the allocation strategy, in terms of the processing resources devoted to a task, although these can also be driven by task demands (e.g., a spatial task requires spatial processing units). Navon and Gopher did not advocate either approach but presented both approaches as alternatives for further investigation. The implication for examining the resource model of stress is that one must manipulate both the subject-task parameters (e.g., by varying the psychophysical properties of the stimulus, manipulating the state of the observer, or varying the kind of information processing demanded by the task) and the allocation strategies used by the operator (the input resources, e.g., payoff matrices, task instructions). This would provide information regarding how specific stressors impair specific information-processing units and how they change a user's resource allocation strategies in the presence of stress that is continuously imposed on operators of complex computer-based systems.

In a later article, Navon (1984) moved to a position that is less favorable toward resources than his earlier approach, asserting that predictions derived by resource theory could be made, and results explained, without appealing to the resource concept at all (see also Rugg 1986). One could instead interpret effects in terms of the outputs of information processors. Most manipulations, such as task difficulty (which in Navon's view influences the efficiency of a unit of resources) or complexity (which affects the load, or the number of operations required), influence the demand for processing, with supply having no impact on their interaction. However, this approach assumes a clear distinction between outputs of a processing system and the concept of a resource, and Navon's (1984) notion of specific processors seems blurred with the notion of a resource, as both are utilized for task performance. Nevertheless, his critique regarding the vagueness of the resource concept is relevant, and Navon did argue that if resources are viewed as an intervening variable rather than a hypothetical construct the concept has utility.

4.5.1.4 Structural Mechanisms

If different kinds of information processing draw on different kinds of resources, in terms of the information processors engaged in a task, stressors may have characteristic effects on each resource. In addition, as Navon and Gopher (1979) have noted, an aspect of resource utilization is the efficiency of each resource unit. It may be that stress degrades the efficiency of information-processing units, independent of energy level or allocation strategy (cf. Eysenck and Calvo 1992). Investigation of such effects could be accomplished by transitioning between tasks requiring different kinds of information processing and determining if the effects of stress on one structure impacts the efficiency of a second structure.

The quality of resources can vary in terms of not only the kind of information-processing unit engaged but also the kind of task required. Following Rasmussen's (1983) classification system for behavior as a heuristic for design some tasks require knowledge-based processing, in which the operator must consciously rely on his or her mental model of the system in order to achieve successful performance. Other tasks fall under the category of rule-based behavior, in which a set of rules or procedures defines successful task response. The third category is skill-based behavior, in which a task is performed with a high degree of automaticity. Presumably each kind of task requires different amounts of resources, but they may also represent qualitatively different forms of resource utilization. In other words, these tasks may differ in the efficiency of a unit of resources as well as in effort allocation strategies. As task performance moves from knowledge- to rule- to skill-based processing (e.g., with training), the cognitive architecture may change such that fewer information-processing units are required and those that are engaged in the performance become more efficient. Moreover, the way in which each of these systems degrade with time under stress may be systematic with the more fragile knowledge-based processing degrading first, followed by rule-based processing, and skill-based processing degrading last (at this point, one may begin to see breakdown of not only psychological processes but also physiological ones; see Hancock and Warm 1989). This degradation may follow a hysteresis function such that a precipitous decline in performance occurs as the operator's resource capacity is reduced below a minimum threshold for performance. Moreover, these processes may recover in an inverse form with skill-based processing recovering first, followed by rule-based and knowledge-based processing.

Note that it may be difficult to distinguish "pure" knowledge-based processing from rule- or skill-based activity. An alternative formulation is the distinction between controlled and automatic processing (Schneider and Shiffrin 1977). Although originally conceived as categories, it is likely that individuals engaged in real-world tasks utilize both automatic and controlled processing for different aspects of performance and that for a given task there are levels of automaticity possible. Treating skills as a continuum rather than as discrete categories may be a more theoretically useful framework for quantifying resources and information processing, and thereby elucidating the effects of stress on performance.

4.5.1.5 Energetic Mechanisms

To investigate the energetic aspects of resources, one must manipulate environment-based perturbations, in the form of external stressors (noise, heat) and task demands, to systematically affect inflow versus outflow of energy. Presumably inflow is controlled by arousal levels, physiological energy reserves, and effort. One could examine performance under manipulations of energetic resources under dual-task performance (e.g., what happens to the performance on two tasks under conditions of sleep deprivation or caffeine consumption?). For example, the steady state can be perturbed by increasing (e.g., caffeine) or decreasing (e.g., sleep deprivation) energy while systematically varying the demands for the two tasks.

4.5.1.6 Structure and Energy

Another empirical challenge is to distinguish resources as structure from resources as energy. Given the definitional problems associated with the resource concept, it is not clear whether performance declines because of reduction in energy level or degradation of structures (i.e., failures or declines in the efficiency of processing units) or a combination of both. If structure and energy are distinct elements of resources it is hypothetically possible to manipulate one while holding the other constant, although the validity of this assumption is questionable. Is it possible to manipulate specific forms of information processing under constant energy level? Is it possible to manipulate energy level independent of which cognitive processes are utilized? If the decline in available resources is, at least in part, due to the degradation of particular information-processing units, then transferring to a task requiring the same processor should lead to worse performance than transferring to one that is different (cf. Wickens 1980, 1984). For instance, if a person engages in a task requiring verbal working memory while under stress and then transitions to a task requiring spatial discrimination, performance on the latter should depend only on energetic factors and not on structural ones. Note, however, that in this case the effects of different mental capacities would be confounded with the effects of novelty and motivation on performance.

4.5.1.7 Application of Neuroergonomics

The burgeoning field of neuroergonomics seeks to identify the neural bases of psychological processes involved in real-world human–technology interaction (Parasuraman 2003). As we state in Section 4.5 (Hancock and Szalma 2007), recent advances in neuroergonomics promise to identify cognitive processes and their link to neurological processes. For instance, the cognitive process of emotion regulation has been linked to genetic variation in the regulation of neuronal processes. Neuroscientists have isolated a particular genetic polymorphism, 5-HTTLPR, which moderates the level of an individual's emotional reactivity. The extent of emotional reaction influences the type and amount of mental resources mobilized for its regulation, which potentially signifies far-reaching effects for the entire HCI (Pezawas et al. 2005). Neuroergonomic research may therefore permit a more robust and quantitative definition of resources, although we caution that a simple reductionist approach is not likely to be fruitful as might initially be conceived (see Hancock and Szalma 2003b). In addition, the stress concept itself rests in part on more precise definitions of resources (Hancock and Szalma 2007). Thus, resolution of the resource issue with respect to cognitive processing and task performance would also clarify the workload and stress concepts. We therefore view neuroergonomics as one promising avenue for future research to refine the workload/stress and resource concepts.

4.5.2 Development of Adaptation under the Stress Model

Effective adaptation has always been key when performing in demanding environments. This section addresses how adaptation comes about.

4.5.2.1 Quantify the Task Dimensions

A major challenge for the Hancock and Warm (1989) model is the quantification of the base axes representing task dimensions. Specification of these dimensions is necessary if the vector representation postulated by Hancock and Warm is to be developed and if the resource construct is to be more precisely defined and quantified. However, task taxonomies that are general across domains present a theoretical challenge, because they require an understanding and quantification of how individuals process information along the spatial and temporal task dimensions, and how these change under stressful conditions. Quantification of information processing, and subsequent quantification of the base axes in the Hancock and Warm (1989) model, will permit the formalization of the vector representation of adaptive state under stress (see Figure 4.4).

4.5.2.2 Attentional Narrowing

Recall that Hancock and Weaver (2002) argued that the distortions of spatial and temporal perception have a common attentional mechanism. Two implications of this assertion are as follows: (1) Events (internal or external) that distort one dimension will distort the other and (2) these distortions are unlikely to be orthogonal. With very few exceptions, little research has addressed the possibility of an interaction between distortions of spatial and temporal perceptions in stressful situations on operator performance. Preliminary evidence suggests that these two dimensions may in fact not share a simple, common mechanism (Ross et al. 2003; Thropp, Szalma, and Hancock 2004), although further research is needed to confirm this finding. An additional important issue for empirical research is whether we are dealing with "time-in-memory" or "time-in-passing" (and to some extent, space-in-memory vs. space-in-passing). Thus, the way in which perceptions of space and time interact to influence operator state will depend on how temporal perceptions (and spatial perception, for that matter) are measured.

A possible explanation for perceptual distortions under conditions of heavy workload and stress concerns the failure to switch tasks when appropriate. Switching failures may be responsible for the observation in secondary task methodology that some participants have difficulty dividing their time between tasks as instructed (e.g., 70% to the primary task and 30% to the secondary task). This difficulty may result from the participant's inability to accurately judge how long he or she has attended to each task during a given time period. The degree to which distortions in the perception of space–time are related to impairments in task switching under stressful conditions and the degree to which these distortions are related to attention allocation strategies in a secondary task paradigm are questions for empirical resolution.

4.5.2.3 Stressor Characteristics

Even if space and time do possess a simple, common mechanism, it may be that specific stressors do not affect spatial and temporal perceptions in the same way. For instance, heat and noise may distort perception of both space and time but not to the same degree or in the same fashion. It is important to note that spatial and temporal distortions may *themselves* be appraised as stressful, as they might interfere with the information-processing requirements of a task. Consequently, some kinds of information processing might be more vulnerable to one or the other kind of perceptual distortion. Clearly, performance on tasks requiring spatial abilities, such as mental rotation, could suffer as a result of spatial distortion, whereas they might be unaffected (or, in some cases, facilitated) by temporal distortion. Other tasks, such as tasks that rely heavily on working memory or mathematical ability, or tasks requiring target detection, could each show different patterns of change in response to space–time distortion.

4.5.2.4 Potential Benefits of Space–Time Distortion

Under certain conditions, the narrowing of spatial attention can benefit performance through the elimination of irrelevant cues. The precise conditions under which this occurs, however, remains unclear. In addition, it is important to identify the circumstances under which time distortion might actually prove beneficial. Here, operators perceive that they have *additional* time to complete the task at hand (Hancock and Weaver 2005). This has great benefit in task performance situations where attentional narrowing is less likely to have deleterious effects. At this point in time, this is an empirical question that might be amenable to controlled testing.

4.5.2.5 Changes in Adaptation: The Roles of Time and Intensity

The degree to which a task or the physical and social environment imposes stress is moderated by the characteristics of the stimuli as well as the context in which events occur. However, two factors that seem to ubiquitously influence how much stress impairs adaptation are (appraised) intensity of the stressor and duration of exposure. We have reported meta-analytic evidence that these two factors jointly impact task performance across different orders of tasks (e.g., vigilance tasks, problem solving, tracking; see Hancock, Ross, and Szalma 2007; Szalma and Hancock 2011; Szalma, Hancock, and Quinn 2008). Duration is further implicated in information processing itself and may be a central organizing principle for information processing in the brain. Duration and intensity of environmental stimulation can likewise influence emotional reactions and consequently which emotion regulation or stress-coping strategy an individual opts to employ (Gross 1998, 2002). Empirical research is, however, still needed to explore programmatically the interactive effects of these variables across multiple forms of information processing.

4.5.3 Understanding Performance–Workload Associations/Dissociations

Factors that prompt associations or dissociations are herein discussed as well as their contribution to perceived workload.

4.5.3.1 Task Factors

Although Hancock (1996) and Yeh and Wickens (1988) have articulated the patterns of performance–workload relations and how these are diagnostic with respect to processing requirements, little systematic effort has been spent on further investigating these associations/dissociations. The primary question is what factors drive dissociations and insensitivities when they occur. For instance, for vigilance tasks mostly associations are observed, whereas for other tasks, such as those with high working memory demand, dissociations are more common (Yeh and Wickens 1988). Enhanced understanding of these relations would inform the Hancock and Warm (1989) model by permitting specification of the conditions under which individuals pass over the thresholds of failure at each level of person–environment transaction/adaptation.

4.5.3.2 Multidimensionality of Workload

To date, consideration of performance–workload dissociations has been primarily concerned with global measures of perceived workload. However, there is clear evidence that perceived workload is in fact multidimensional. For instance, vigilance tasks are characterized by high levels of mental demand and frustration (Warm, Dember, and Hancock 1996).

It is likely that the pattern of performance–workload links is different not only for different orders of performance (different tasks) but also for different dimensions of workload. One approach to addressing this question would be to systematically manipulate combinations of these two variables. For instance, if we consider performance in terms of detection sensitivity, memory accuracy, and speed of response, and the dimensions of workload defined by the National Aeronautics and Space Administration (NASA) Task Load Index (Hart and Staveland 1988), we could discuss how variations in memory load or discrimination difficulty link to each subscale.

4.6 INDIVIDUAL DIFFERENCES IN PERFORMANCE, WORKLOAD, AND STRESS

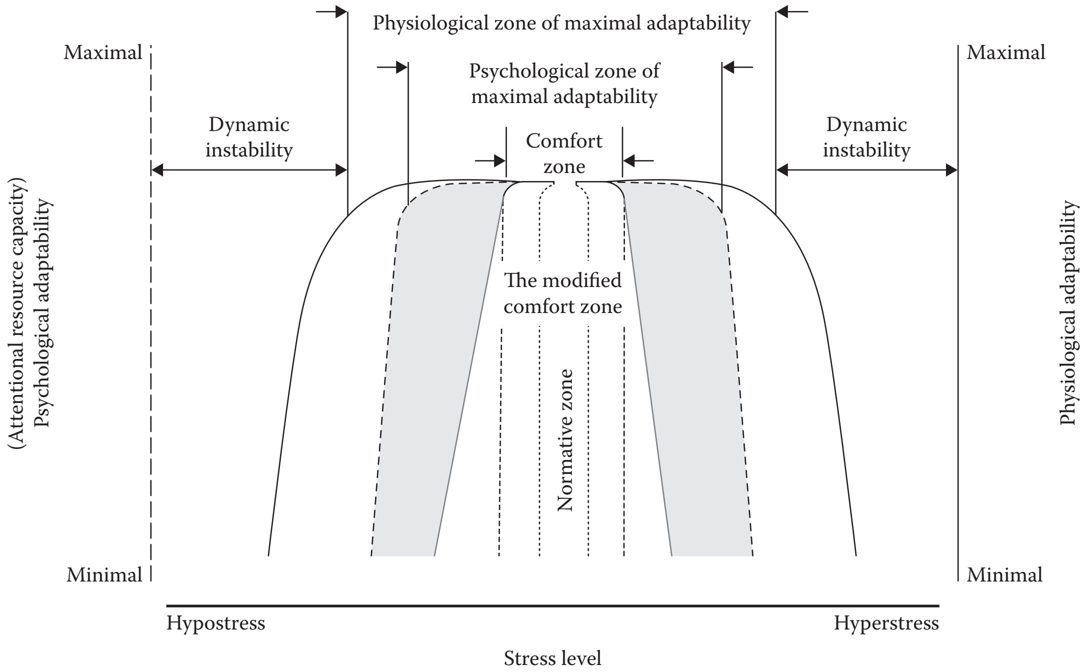
In previous work, we have reviewed the relations between individual differences in state and trait and efforts to quantify human information processing (Szalma and Hancock 2005). In this section, we address how individual differences (state and trait) are related to stress and coping.

4.6.1 Trait Differences

Individual differences research has been a neglected area in human factors and experimental psychology. Much of the early work on individual differences was done by researchers who were unconcerned with human–technology interactions to the extent that a bifurcation between two kinds of psychology occurred (Cronbach 1957). There is evidence, however, that affective traits influence information processing and performance. Thus, extraversion is associated not only with superior performance in working memory tasks and divided attention but also with poorer sustained attention (however, see Koelega 1992). Trait anxiety is associated with poor performance, although results vary across task types and contexts (Matthews, Deary, and Whiteman 2003; Szalma 2008). A possible next step for such research is to systematically vary task elements, as discussed previously (in Section 4.3.1) in the context of the Hancock and Warm model, and test hypotheses regarding how trait anxiety relates to specific task components. The theoretical challenge for such an undertaking is that it requires a good taxonomic scheme for tasks as well as a well-articulated theory of traits and performance. However, trait theories have neglected specific task performance, focusing instead on global measures (e.g., see Barrick, Mount, and Judge 2001), and there is a lack of a comprehensive theory that accounts for trait–performance relations (Matthews, Deary, and Whiteman 2003). Most current theories are more like frameworks that do not provide specific mechanisms for how personality impacts cognition and performance (e.g., see McCrae and Costa 1999). Although Eysenck (1967) proposed a theory of personality based on arousal and activation, which has found some support (Matthews and Gilliland 1999), there is also evidence to the end that arousal and task difficulty fail to interact as predicted (Matthews 1992). Eysenck's (1967) theory was also weakened by the general problems associated with arousal theory accounts for stress effects (Hockey 1984). An alternative formulation is that of Gray (1991) who argued for two systems, (1) one responding to reward signals and (2) one to punishment. The behavioral activation system (BAS) is associated with positive affect, whereas the behavioral inhibition system (BIS) is associated with negative affect. In a review and some comparisons of the Eysenck and Gray theories, Matthews and Gilliland (1999) partially supported both the theories but concluded that Gray's BAS/BIS distinction provides a superior match to positive and negative affect relative to Eysenck's arousal dimensions. Further, the BAS/BIS distinction accords with theories of approach/avoidance motivation (e.g., Elliot and Covington 2001). Indeed, intraindividual approaches to investigating the complex interplay between stress, coping, and performance outcomes are hailed as the most promising methodology (Folkman et al. 1986). There are also theories that focus on a particular trait such as extraversion (Humphreys and Revelle 1984) or trait anxiety (Eysenck and Calvo 1992). Although useful, such specific theories do not encompass other traits or interactions among traits. Such interactive effects can influence cognitive performance and perceived stress and workload (Szalma et al. 2005). These interactions should be further studied with an eye to linking them to information-processing theories.

4.6.2 Affective State Differences

It is intuitive that stress would induce more negative affective states and that traits would influence performance via an effect on states. For instance, one would expect that trait anxiety would influence performance because high trait anxious individuals experience state anxiety more frequently than those low on that trait. Although such mediation effects are observed, there is also evidence that for certain processes, such as hypervigilance to threat, trait anxiety is a better predictor of performance than state anxiety (Eysenck 1992). In terms of appraisal theory, traits may influence the form and content of appraisals, as well as the coping skills an individual can deploy to deal with stress. With respect to adaptation, it is likely that individual differences in both trait and state will influence adaptation, both behavioral and physiological, by affecting the "width" of the plateau of effective adaptation at a given level and by changing the slope of decline in adaptation when the adaptation threshold is reached. That is, higher skill levels protect from declines in adaptive function by increasing the threshold for failure at a given level (i.e., comfort, performance, physiological response). The modification of the Hancock and Warm (1989) model illustrating these individual differences in effects is shown in Figure 4.6 (and see Szalma 2008). Multiple frameworks of state dimensions exist, but most focus on either two (e.g., Thayer 1989; Watson and Tellegen 1985) or three (Matthews et al. 1999, 2002) frameworks. In the context of task performance, Matthews and his colleagues have identified three broad state dimensions reflecting the cognitive, affective, and motivational aspects of an individual's current psychological state.



Physiological zone of maximal adaptability
Maximal
Maximal
Psychological zone of maximal adaptability
Dynamic instability
Dynamic instability
Comfort zone
(Attentional resource capacity)
Psychological adaptability
The modified comfort zone
Physiological adaptability
Normative zone
Minimal
Minimal
Hypostress
Hyperstress
Stress level

FIGURE 4.6 Modification of the adaptability model shown in Figure 4.3. The adaptability model of Hancock and Warm (1989) shown in Figure 4.3 has been modified to illustrate how individual differences may influence stress and adaptation. It is likely that cognitive and affective traits influence the width of both the comfort and performance zones (i.e., the thresholds for declines in adaptation) as well as the rate of decline in adaptability when a threshold is crossed. For instance, individuals high in trait anxiety likely have a narrower plateau of stability and therefore manifest lower thresholds for discomfort and performance degradation than individuals low on that trait. Further, the rate of decline in adaptation may increase as a function of trait anxiety.

These dimensions are "worry," which reflects the cognitive dimension of stress, and "task engagement" and "distress," which reflect the affective, cognitive, and motivational components of state. Specifically, a high level of distress is indicative of overload in processing capacity, and task engagement reflects a theme of commitment to effort (Matthews et al. 2002). Matthews and his colleagues have demonstrated that changes in task demand influence the pattern of stress state. Should affective state fail to detrimentally influence task performance itself, it can still critically impact consequential levels of "psychophysiological activation, strain, and fatigue aftereffects" (Robert and Hockey 1997, p. 73). It is therefore important to incorporate assessment of operator state into the interface design process so that the interaction with technology fosters task engagement and minimizes distress and worry.

4.6.2.1 Attentional Narrowing and Adaptive Response

As with other aspects of perception, there are individual differences in the perception of space and time (Hancock and Weaver 2005; Wachtel 1967). Further, because the subjective experience of stress is often multidimensional, it may be that although two individuals are subjectively stressed by the same situation, their stress profiles differ. Affective states can likewise influence the extent of attentional allocation. Affective states high in motivational intensity, either pleasant or unpleasant, lead to a narrowing of attentional focus, whereas affective states low in motivational intensity, again regardless of valence, cause attentional broadening (Gable and Harmon-Jones 2009). Individuals are also likely to differ in the strategies they employ to cope with the distortions of space–time and emotional flux they experience while in a stressful environment, and these coping differences, if they exist, might depend on the quality (e.g., noise, heat, low signal salience) and source (e.g., the environment, the task) of the stress and the personality traits of an individual.

4.6.2.2 Hedonomics and Individual Differences

In addition to application of individual differences research to the development of training or selection procedures, individual difference variables can be used to promote hedonomic approaches to design and facilitate interface design. Thus, if the traits that influence the subjective experience of an interaction with technology are identified, that interface can then be configured to meet the preferences and the trait/state profile of an individual user and promote positive affective states. However, for such efforts to succeed, the relations among traits and cognitive, perceptual, and motor performance need to be established via theory-guided empirical research.

4.7 IMPLICATIONS OF STRESS FOR RESEARCHERS AND PRACTITIONERS

For both research and design applications, extant research on stress and performance indicates that assessments of workload and affective state are important for a more complete understanding of HCI. Such assessments can aid in identifying which components of an interface or task are appraised as stressful, and thus interfaces can be designed to mitigate their negative effects. For instance, research is needed to establish which task parameters control the patterns of performance–workload associations and dissociations and how these change dynamically as a function of time on task. The Hancock and Warm (1989) model of stress established general task dimensions (space–time) that influence stress state and behavioral adaptability, but the metrics for these dimensions remain elusive. This problem results from the central issue regarding how to quantify human information processing (Hancock, Szalma, and Oron-Gilad 2005) and define "mental resources" more precisely (Hancock and Szalma 2007). Efforts to resolve these definitional problems would improve stress theory and its application to interface design. Future research should therefore examine the relations between task dimensions and user characteristics and how these change over time and under high-stress conditions.

In addition to changing the task, there are other techniques that can be applied to the design of human–computer interfaces for use in stressful environments. These include skill development (e.g., Hancock 1986), use of configural displays (Hancock and Szalma 2003a; Wickens 1996), as well as use of technologies employing adaptive automation and decision aids (Hancock and Chignell 1987). With respect to skill development in particular, an area in need of research is how individuals who develop expertise in a task also learn how to cope with stress while performing the task. In order to understand how individuals accomplish this, one is required to understand in depth how different forms of stress influence different forms of information processing. Intuitively, automation and decision aids seem to be key tools for relieving stress during task performance. Although experiments have yielded some promising results (Funke et al. 2007), further research is necessary to determine this supposition under different kinds of stress as such technologies could merely serve to divert attentional resources away from the task.

It is also important for both researchers and practitioners to consider the characteristics of a user and how these characteristics interact with the task or interface to influence performance.

An understanding of how individual differences influence HCI can facilitate the development of tailored training regimens as well as interfaces that can more effectively adapt to the user. Systems that can respond to changes in operator affective state can achieve the desired human–machine synergy in HCI (cf. Hancock 2009). Realizing these goals, however, will require adequate theory development and subsequent empirical research to determine the nature of the relations among the person and environmental variables. It is particularly important to design interfaces that permit autonomous motivation (Deci and Ryan 2000) and to understand how operators of computer-based systems can internalize extrinsic motivation as they gain experience on the task (Gagne and Deci 2005). We suggest here that researchers and designers identify the motivational affordances in the task environment and utilize them to enhance the experience of HCI and improve overall system performance under stress. Motivational affordances will be elements of the work environment that facilitate and nurture intrinsic motivation. Particularly important for design will be the identification of motivational invariants, which are those environmental factors that consistently determine an individual's level of intrinsic (or extrinsic) motivation across contexts. Careful analyses of the motivational affordance structure will permit design of tasks that are more likely to be enjoyable by rendering the tools convivial (Illich 1973) and thereby facilitating human–machine synergy (see Hancock 1997).

4.8 SUMMARY AND CONCLUSIONS

In this chapter, we review theories of stress and performance and their relevance to human–technology interaction. We also show that despite being developed in separate research traditions, workload and stress can be viewed as different perspectives on the same fundamental problem. We outline general principles for stress mitigation and discuss issues that require further research. Of particular importance are establishing sound measures of information processing and mental resource expenditure as well as articulating the relevant task dimensions and how they trigger self-regulatory mechanisms, specifically emotion (stress) regulation techniques. Given that stress can be understood only in relation to the transaction between an individual and the environment, it is crucial to establish how trait and state characteristics of the individual influence their appraisals. Finally, it is important in practical applications to treat stress at multiple levels, ranging from the physiological to the organizational sources of adverse performance effects. Different emotion regulation strategies attempt to mitigate stress at these various levels; which techniques are chosen by an operator to utilize can significantly influence the success of an HCI. Traditional attempts to treat stress problems unidimensionally will continue to fail until the person, task, and the physical and social/organizational environment are treated by analysis as a coherent system. Researchers and practitioners in HCI should therefore expand their efforts beyond the design of displays and controls of interfaces and include assessments of person-related factors that influence performance as well as the design of the physical and social environment in which an HCI occurs.

5 Choices and Decisions of Computer Users

Anthony Jameson

CONTENTS

5.1 INTRODUCTION

5.1.1 CONCEPTS AND GOALS

Computer users are constantly making small choices and larger decisions about how to use their computing technology, such as the following:

- Which of the available photo management apps shall I use on my smartphone?
- Shall I dictate this e-mail message using speech recognition or tap in the text with a stylus?
- How should I configure my privacy settings?

This chapter focuses on cases, like these, in which a user can choose among two or more *options*, none of which is correct or incorrect but one of which can be *preferred* to the others. The term *preferential choice* will be used to distinguish this situation from *nonpreferential* choices that concern the correct way to operate a system, such as "Which of these unfamiliar icons do I have to click on to send off my e-mail message?”

We will use the terms *choice* and *decision*, together and in alternation, to do justice to the variety of forms that the processes in question can take. *Decision* suggests a thorough, effortful process, whereas *choice* suggests a quick selection that may be based, for example, on habit. Both types of process occur in computer users, often with regard to the same set of options.

The following are the goals of this chapter:

1. Bring preferential choices and decisions of computer users into the foreground as a topic in human–computer interaction (HCI).
2. Provide access to the relevant psychological and HCI literature by summarizing key concepts and results and listing references.
3. Provide a framework for thinking about how to help computer users make better preferential choices and decisions.

5.1.2 Relationships to Other Human–Computer Interaction-Related Research

Figure 5.1 visualizes the relationships between these goals and the goals of three other broad types of research that fall within or overlap with the HCI field.

5.1.2.1 Interaction Design Guidelines and Principles; Help and Training

Much of what is known about how to design interactive systems and their associated help and training material can be seen as concerning ways of helping users to make the right choices: to click on the right icon or web link, select the correct command from a menu, or identify the part of the system that will provide the needed functionality. Interaction designers have become skilled at helping users to make these choices well, for example, by designing effective visual displays, making the user’s options clearly identifiable and understandable, providing informative feedback on the user’s actions, and making the actions reversible in case they do not yield a satisfactory result (see, e.g., Johnson 2010, for a collection of well-known sets of user-interface design guidelines). Similarly, those who develop online help and training programs have worked out a rich set of best practices for instructing and advising users about the choices that they need to make. Most of the content of help and training concerns the general question of how to operate the system in question, but some of it explicitly addresses preferential choices, such as when to use each of two available methods for accomplishing a particular goal or what type of configuration is best under what circumstances (e.g., “This setting is recommended if you often work off-line”).

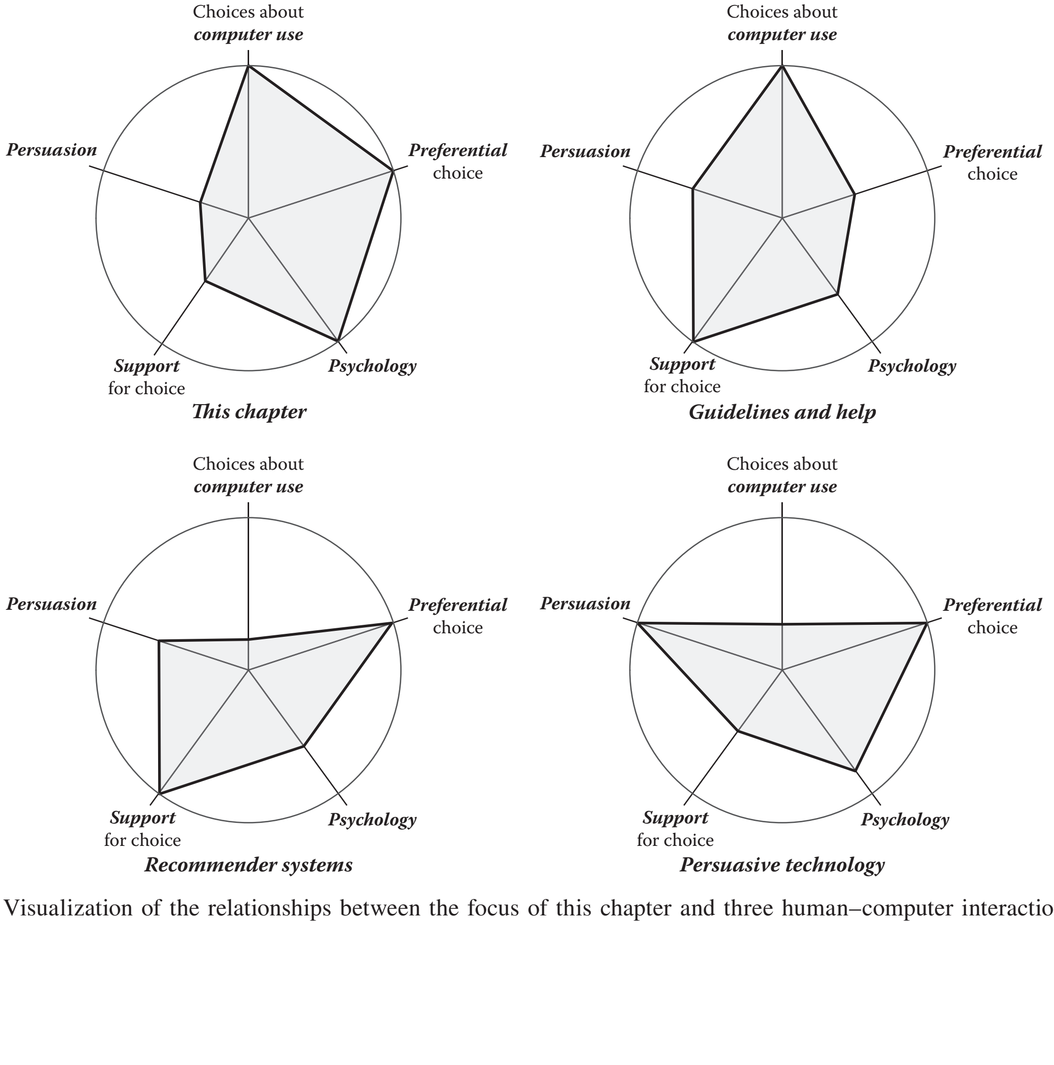

FIGURE 5.1 Visualization of the relationships between the focus of this chapter and three human–computer interaction-related areas of research.

Guidelines and design principles are rarely tailored explicitly to supporting preferential choices and decisions, and the related research hardly ever refers to the psychological literature on these topics that is covered in this chapter.

5.1.2.2 Recommender Systems

A focus on preferential choice and decisions is found, by contrast, in research on recommender systems (see, e.g., Jannach et al. 2011; Ricci et al. 2010) which aim to support and influence users' choices concerning products to buy, documents to read, and a variety of other types of items. As Figure 5.1 shows, recommender systems almost always support decisions that are not about the use of computing technology as such. The work in this area tends to be based to some extent on knowledge about psychological processes involved in preferential choice, but the main focus of attention is on accurately predicting what items will satisfy a user, rather than on understanding and influencing the user's decision-making processes.

5.1.2.3 Persuasive Technology

Yet another line of research (see, e.g., Fogg 2003; Fogg, Cueller, and Danielson 2008) differs from the previous paradigm mainly in its emphasis on motivating and persuading people to do some particular thing (e.g., save energy), which either that person or someone else has decided is best for the person in question. This line of research has yielded a wealth of ideas about how computing technology can be deployed to influence people's beliefs and behaviors. But only a few of the choices and behaviors targeted for persuasion (e.g., none of the 12 "domains for persuasive technology" listed in Table 7.1 of Fogg, Cueller, and Danielson 2008) concern computer use as such.

As Figure 5.1 indicates, this chapter will not go into much depth on the question of how to support and influence preferential choices concerning computer use. Instead, by foregrounding this class of choices and by providing an introduction to the large areas of relevant psychological literature, it aims to encourage and support increased attention to this topic.* Systematic efforts to support choices and decisions of this type should be able to benefit greatly from appropriately adapted knowledge transferred from the other three areas of research, notwithstanding the various differences visualized in Figure 5.1.

5.1.3 Preview of Aspects of Preferential Choice and Decision Making

Figure 5.1 reflects the fact that psychological research about how people make preferential choices and decisions has received limited attention in HCI so far.† One reason may be the fact that there is no single relevant theory in psychology that could be straightforwardly adapted to the needs of the HCI field. Although dozens of books and hundreds of articles from relevant psychological research exist, they come from several research traditions that only partly overlap and refer to each other. The discussion in this chapter will draw from these areas: judgment and decision making (see, e.g., Hastie and Dawes 2010; Koehler and Harvey 2004; Lichtenstein and Slovic 2006; Schneider and Shanteau 2003; Newell, Lagnado, and Shanks 2007; Weber and Johnson 2009); naturalistic decision making (Klein 1998), the reasoned action approach (Fishbein and Ajzen 2010), research on habitual behavior (Wood and Neal 2007), behavioral economics (Ariely 2008; Iyengar 2010; Thaler and Sunstein 2008), and research on self-control (Rachlin 2000) and on compliance tactics (Cialdini 2007).

As a way of providing a reasonably coherent overview despite the differences among these research traditions and their terminologies, Table 5.1 lists the aspects of choice and decision processes that will be covered in turn in this chapter, formulating each one in terms of one or more "questions" that a computer user might conceivably "ask" him- or herself while considering a choice or decision. Although in some cases such questions may be consciously asked and addressed by a computer user, the processing represented in the table by a question often occurs without any verbal formulation or conscious deliberation—whatever particular definition of the elusive concept of *consciousness* one may prefer to use (see, e.g., Wilson 2002).

With any given choice or decision for a particular person, in general only some subset of these considerations will be relevant, and the table is not intended to convey a particular temporal order of processing: Because of the variety of forms that

TABLE 5.1
Preview of the Aspects of Preferential Choice and Decision Making Discussed in This Chapter

Topic	Questions That a Decision Maker May Consider
Focusing on goals and values	What is a good decision-making process for this situation? What are my relevant goals and values?
Situation assessment and option identification	What's going on in this situation? What are my options?
Anticipation of consequences	What would the consequences be if I chose this option? How desirable would they be?
Intertemporal choice	How should I value consequences that will not occur until sometime in the future? How should I deal with a sequence of repetitions of basically the same choice?
Reuse of previous choices	What did I choose the last time I had a choice like this?
Social influence	What do other people choose in this situation? What do they want or expect me to choose?
Learning from experience	What can I learn from the results of the choice that I have made?

* A first step toward a systematic approach to supporting preferential choice on the basis of the conceptual framework of this chapter is offered by Jameson et al. (2011).

† Two thorough book-length syntheses of cognitive psychology research for HCI (Gardiner and Christie 1987; Johnson 2010) include hardly any references to the sort of psychology literature cited in this chapter.

preferential choices and decisions can take, it would not be realistic to try to formulate a causal model or a process model, for example, in the form of a flowchart, though models of this sort are often found useful for particular types of choice or decision-making situation (see, e.g., Wickens and Hollands 2000, Chapter 7; Fishbein and Ajzen 2010; Klein 1998, Chapter 3).

5.2 GENERAL PREFERENTIAL CHOICE PROBLEMS

Although opportunities to make preferential choices and decisions crop up constantly with just about every type of interactive system, there are three generic classes of choice that are worth distinguishing, because of their frequency of occurrence and because they have attracted a fair amount of attention in HCI research. Table 5.2 introduces them to facilitate reference to them at various points later in the chapter.

5.2.1 Decision about Whether to Use a Given System

One type of decision that a person can make with regard to computer use is that of whether to use a given system at all. The most extensive line of research that has looked into this question is research on *technology acceptance*. A good entry point to this literature is the influential article by Venkatesh et al. (2003), which presented the Unified Theory of Acceptance and Use of Technology (UTAUT), a model that integrates eight previously developed models, including the especially widely studied *technology acceptance model* (see, e.g., Venkatesh and Davis 2000). These models in turn drew their inspiration from more general theories from social psychology and sociology, such as the precursors of the recently formulated *reasoned action approach* of Fishbein and Ajzen (2010).

TABLE 5.2
Three General Types of Preferential Choice That Have Been Studied in Human–Computer Interaction

Generic Choice Problem	Selected Research Issues
Decision about whether to use a given system	What variables influence people's decisions about whether to use a given system if it is made available to them (usually: within an organization)? What are the causal relationships among these variables? How can these variables be measured?
Choice of a method from a set of alternative methods	When more than one method is available for a particular subtask, how do users decide which one to use? Why do even experienced users sometimes persist in using inefficient methods?
Configuration decision	How do people decide whether and when to configure an application? What difficulties do they encounter when making configuration choices?

Table 5.3 gives an impression of the basic nature of the models in this area by depicting the four main variables in the UTAUT model that influence intention to use a given system and actual use of the system, along with examples of questionnaire items typical of those used to measure these variables. The model also includes claims about several variables that moderate the influence of these main variables: *gender, age, experience*, and *voluntariness of use*.

Although some of these questions are reminiscent of questions from usability scales such as System Usability Scale (SUS) (Brooke 1996), the overall goal of the model and the associated measuring instruments are not to assess usability but rather to predict whether potential users (typically, employees in a given company) will actually use a given system (e.g., a new videoconferencing system) if it is made available to them. Note that most of the questions related to the variables *social influence* and *facilitating conditions* concern considerations other than usability.

Researchers and practitioners in the HCI field usually want to go beyond *predicting* whether people in a given target group will use a given (type of) system, to attempt to improve the system (and/or related resources) to increase the likelihood that the system will be used and the success of its use. Still, the large amount of information collected in the technology acceptance area about variables related to choices about system use and about ways of measuring these variables can help to stimulate and structure thinking about this class of choices. Researchers in this area regularly introduce new variables and new perspectives that shed light on different aspects of acceptance decisions (see, e.g., Bagozzi 2007; Loraas and Diaz 2009).

TABLE 5.3
The Four Main Variables in the UTAUT Model and Typical Questionnaire Items Used to Measure Them

Performance expectancy
- Using the system in my job would enable me to accomplish tasks more quickly.
- Using the system would improve my job performance.
- Using the system would make it easier to do my job.

Effort expectancy
- Learning to operate the system would be easy for me.
- My interaction with the system would be clear and understandable.
- I would find the system to be flexible to interact with.

Social influence
- People who influence my behavior think that I should use the system.
- People who are important to me think that I should use the system.

Facilitating conditions
- I have control over using the system.
- I have the resources necessary to use the system.
- I have the knowledge necessary to use the system.
- The system is not compatible with other systems I use.

5.2.2 Choice of a Method

In all but the simplest interactive systems, there is often more than one method available for achieving a given goal. Whenever the user can choose freely between two or more methods, the choice is preferential. Card, Moran, and Newell (1983) introduced in their Goals, Operators, Methods, and Selection Rules (GOMS) model (described most completely in Card, Moran, and Newell 1983; see also Kieras 2008) a notation for such cases: the two or more available methods are described as part of the model for a given task, and it is assumed that each user has learned a selection rule for making the choice (e.g., "Use the mouse instead of the cursor keys if the target is more than a couple of inches away on the screen"); this assumption is plausible given that the GOMS model assumes that users have considerable experience with the system and the tasks in question.

In the intervening years, some research has looked at the ways in which users learn selection rules on the basis of experience with the methods in question (see, e.g., Gray and Boehm-Davis 2000) and at the considerations that users take into account when choosing among methods (see, e.g., Young and MacLean 1988; Jameson and Klöckner 2005), whereas other researchers have investigated situations in which users systematically fail to use suitable methods that are available to them (Carroll and Rosson 1987; Bhavnani and John 2000; Bhavnani, Peck, and Reif 2008; Charman and Howes 2003).

5.2.3 Configuration Decision

A usually more complicated type of choice that users can make concerns whether, when, and how to configure an application to suit their own tastes and needs. Over the years, researchers have repeatedly found this type of problem to be challenging for most users (see, e.g., Mackay 1991; McGrenere, Baecker, and Booth 2007), and it has attracted increased attention in recent years because of the practically important problem of configuring privacy settings in social network platforms (see, e.g., Iachello and Hong 2007).

5.3 FOCUSING ON GOALS AND VALUES

The first of the general considerations listed in Table 5.1 concerns the basic values that a chooser will be guided by when making a choice. Although computer users often do not think explicitly about these values, interaction designers ought to be aware of them when considering how to support good choices; and calling these issues to the user's attention may be an effective tactic.

5.3.1 What Constitutes a Good Choice or Decision?

The most fundamental question is that of what constitutes a good choice in the first place. Before considering what choosers think about this issue, we should notice a shift in the thinking of scientists who have studied decision making. Traditional notions of what constitutes a good decision are that a decider should (1) apply a decision procedure that is normatively justifiable (e.g., consistent with the laws and principles of logic, probability, and expected utility) and (2) choose the action that will maximize desirable (and minimize undesirable) outcomes under idealized conditions (see, e.g., Gigerenzer and Todd 1999, Chapter 1; Gigerenzer 2007, Chapter 5). More recently, researchers have become impressed by the extent to which animals and humans can function quite effectively by using decision procedures that are justifiable only in the sense that they work well in the environment in which they are applied and make good use of the decider's limited time and cognitive resources. For example, a web searcher's strategy of clicking on the first link on the search result page that looks reasonably relevant would be hard to justify in terms of a normatively optimal general strategy; but if the user's previous experience with the search engine in question has shown that the first reasonably relevant-looking link is almost always the best one, this strategy can be considered *ecologically rational* for that search engine. The same point can apply to the decision rule of always buying your smartphone applications from your favorite vendor or always accepting the default configuration when installing new software. In cases where the choices of a computer user make sense only given particular assumptions about the structure of the environment, the best way to help the user make good choices may be to ensure that the environment fulfills these assumptions.

Researchers have also investigated the question of what constitutes a good decision process from the point of view of the decision maker (see, e.g., Bettman, Luce, and Payne 2006; Hastie 2001; Yates, Veinott, and Patalano 2003). Although specific answers to this question vary, the following statements are widely accepted:

1. Choosers want their decision to yield a good outcome.

   This point is not as straightforward as it may seem, because what counts as a good outcome depends in turn on a variety of factors, as we will see.
2. Choosers do not want to invest time and effort in the decision-making process itself that is out of proportion to the benefits of doing so.

   For example, when installing a new application, a user who is asked which specific components should be installed may choose the option "Everything" simply to save the time of deciding about the individual components, since the possible benefits of choosing any other option (e.g., saving a few megabytes of hard disk space) do not seem to justify the investment of even a few seconds of decision time.
3. Choosers prefer to avoid unpleasant thoughts.

   Some ways of thinking about a decision can involve distressing thoughts, as when a driver faces a choice between (1) ignoring an incoming text message from his boss and (2) driving less safely for a while in order to respond to the message. A user may be motivated to think about the decision in a way that avoids such thoughts (e.g., by convincing himself that he can respond to the boss's message without taking the slightest risk).

4. Choosers often want to be able to justify the decision that they have made to other persons—or to themselves.

   Justifiability is often simply a necessary condition for being able to implement a decision (cf. Lerner and Tetlock 2003). For example, even if a business person would really like to buy an iPhone for professional use, they may prefer a Blackberry instead because they think that this choice is more likely to be approved by their company's purchasing department. But even just the desire to convince another person or oneself that a decision was sound can cause people to look for justifiable decisions (see, e.g., Shafir, Simonson, and Tversky 2006).

   Consequently, one way of supporting preferential choice is to make it easy for the user to come up with a satisfying justification of whatever option is best for him, for example, by supplying a justification explicitly (as is done by many recommender systems) (see Tintarev and Masthoff 2010) or by structuring the situation in such a way that a justification is easy to derive.

5.3.2 Current Goals and Values

One characteristic of preferential choice is its dependence on the particular goals that the chooser is currently focusing on (see, e.g., Schneider and Barnes 2003). To a certain extent, this dependence is obviously necessary and appropriate: Your choice of an application to prepare a text document with should depend on whether you want it to be beautifully formatted or whether you just want to get it finished as quickly as possible. But the dependence on current goals can also lead to some curious phenomena: Both anecdotal evidence and some research (e.g., Iachello and Hong 2007, Section 3.3.2; Mackay 1991) concerning configuration decisions tell us that users often accept the default configuration of a system until some negative event (e.g., a privacy violation or a need to repeat a given tedious operation multiple times) prompts them to change the configuration. A normatively more rational way of deciding when and what to configure would involve something like estimating the total (discounted) benefit of the improved configuration over an extended period of system use. In contrast, reactive configuration can be seen as a response to the goal of preventing the specific negative thing that just happened from ever happening again. Whether this configuration action is really a good idea in the long run will depend on how well the short-term goal happens to coincide with the user's larger pattern of goals and use situations. Mackay (1991) and Iachello and Hong (2007) offer perceptive discussions of strategies for dealing with this type of discrepancy.

Keeney (1992) discusses in great depth the importance of ensuring that decisions depend on the decision maker's true values rather than on temporarily salient considerations such as those that are suggested by the set of options that are immediately available. Although interaction designers rarely, if ever, have an opportunity to support their users with in-depth decision analysis, calling the user's attention to important goals and values on a much smaller scale does represent a promising way of supporting preferential choice. Two experiments by Mandel and Johnson (2006) demonstrate clearly how a goal or value (e.g., "safety" or "economy" for a prospective car buyer) can be activated by a change in interface design (e.g., the colored background of the web pages of an e-commerce site), mostly without awareness on the part of the user.

5.4 SITUATION ASSESSMENT AND OPTION IDENTIFICATION

To be able to make a choice or decision, the chooser must normally in some sense be aware of the fact that a choice is available—though in extreme cases the awareness can be minimal, as when the choice is made out of habit or when it involves accepting the status quo or default option by doing nothing.

In experimental laboratory studies, the way in which the chooser perceives or "frames" the choice problem is largely under the control of the experimenter. Some well-known and striking results concern the effects on choice of the way in which the problem is framed. For example, people tend to be influenced strongly by whether options are described in terms of people being "saved" versus people "dying," even when the situations described in these terms are objectively identical. An important part of one of the dominant theories of judgment and decision making, *prospect theory* (originally presented by Kahneman and Tversky 1979), concerns the process of "editing" the initial representation of a choice problem to arrive at the chooser's own representation; but choosers often stick with the initial representation.

Like laboratory experimenters, interaction designers often have control over the way in which a choice is presented to the user. For example, users who purchase a software product are often offered an option like "Check this box to receive news about updates and special offers," which a user may mentally edit into a representation like "Check this box to get even more spam."

When decision making occurs outside the laboratory, the presentation of the choice problem is often less clear-cut; understanding the situation and identifying the available options can be a complex process (often called *situation assessment*) that calls for considerable expertise. This process has been extensively studied within the research paradigm of *naturalistic decision making* (see, e.g., Klein 1998; Klein 2008; Maule 2010). This type of decision making is typified by the situation of a fire brigade arriving at the scene of a burning building: The problem situation is changing rapidly over time, even as the decision makers contemplate how to deal with the fire; there is considerable stress because of the high stakes and because of environmental factors such as noise and heat; and on the positive side, the decision makers typically possess considerable experience in dealing with such situations, which makes it unnecessary for them to analyze the problem from first principles. Some key results of this research will be summarized below in Section 5.7.1. For now, the main point is that recognizing the need for a choice and identifying or generating one or more options is sometimes the most important and challenging aspect of a decision problem.

An implication for interaction design is that we should look out for situations in which recognizing and interpreting a decision situation may be unnecessarily or unduly challenging for at least some users. For example, a sophisticated user who installs a new web browser is likely to recognize the need to choose security and privacy settings that are well adapted to the context in which the browser will be used; a less sophisticated user is likely to accept the default settings, perhaps without even being aware that a choice exists.

In fact, the widespread tendency of people to overlook or ignore choice opportunities and accept the default represents a major way in which *choice architects* (to use the suggestive term of Thaler and Sunstein 2008), including interaction designers, can influence choices. Widely discussed controversies concerning computer use include the bundling of software with the Windows operating system (which offers new users a convenient default option for many application choices that they would otherwise have to make) and the default privacy options for social network platforms like Facebook. Outside of the arena of computer use, one of the primary and most successful tactics of interventions based on behavioral economics (such as the *libertarian paternalism* of Thaler and Sunstein 2008) is to provide a default option which is thought to be in the best interest of the people making the choice in question or of society as a whole (e.g., laws that state that every person can be viewed as an organ donor unless they have specified otherwise; see Johnson and Goldstein 2006).

5.5 ANTICIPATION OF CONSEQUENCES

The most dominant traditional view of decision making is a *consequentialist* one: that of a person who contemplates the (perhaps uncertain) consequences of choosing each of the available options and bases the decision on an evaluation of those consequences. As Table 5.1 indicates, there are other considerations that can affect a decision, and in fact, choosers sometimes do not contemplate consequences at all.

Still, computer users do sometimes anticipate the possible consequences of their choices, and one question that arises is that of what sorts of consequence they anticipate. If computer users were concerned only about traditional usability criteria, they might make their decisions solely on the basis of consideration of consequences like those covered by UTAUT's *performance expectancy* and *effort expectancy* variables (Table 5.3). The growing interest in recent years in a broader view of user experience (see, e.g., Law et al. 2009; Kuniavsky 2010) can be viewed as an awareness of a wider range of types of consequence that can influence users' evaluations of systems and possible actions.

5.5.1 Anticipating Experience

But how accurately can computer users anticipate the consequences of options? Even just anticipating the enjoyableness of an experience that has been described to you (e.g., using an allegedly delightful photo management app on a smartphone) is not as straightforward as it would intuitively seem. Trying the experience out briefly (e.g., with a demo version of the app) is not always a reliable test, partly because of people's tendency to adapt their tastes and expectations on the basis of new experience (see, e.g., Wilson 2002, Chapter 7). And if a user's initial expectation is (erroneously) that an experience will not be positive, he or she may refrain from trying it out in the first place.

A straightforward effort of designers to support the anticipation of the experience of performing an action is found in promises such as "Filling in our customer satisfaction questionnaire will take just 2 minutes of your time" or "Configuring the application is quick and easy." But this method presupposes that the user is likely to believe claims like these. An alternative approach is to consider nonverbal ways of previewing the consequences of an action. This general strategy has been explored extensively in the area of persuasive technology (see, e.g., Fogg 2003, Chapter 4), as with the "Baby Think it Over" infant simulator, which helps teen-aged girls anticipate realistically what it is like to take care of a baby. Some further work will probably be required before this strategy can be applied widely to (1) decisions concerning computer use and (2) decisions where it is not a priori clear which option is best for the chooser—that is, where the chooser must really *choose*, as opposed to being persuaded (cf. Figure 5.1).

5.5.2 Anticipating the Consequences of Configuration Choices

One challenge for users in connection with the configuration of applications (Mackay 1991; Iachello and Hong 2007) is that the consequences of configuration actions tend to be hard to anticipate. First, there is the question of how time-consuming, tedious, and risky the configuration actions themselves will be. Then there is the fact that the consequences of a configuration decision are often not immediately visible; they consist in changes to the computing environment that will have consequences in the future which will in turn depend on actions of the user and other configuration settings.

Gabrielli and Jameson (2009), applying an adapted heuristic walkthrough to parts of four widely used applications, found that about three-quarters of the formulations used to describe configuration options (e.g., "Accept cookies from third parties") did not appear to convey to a typical user a clear idea of the meaning of an option, the consequences of choosing it, or the overall desirability of choosing it. The proportion of problematic cases diminished to about one-half if the help texts explaining the options were taken into account.

5.6 INTERTEMPORAL CHOICE

5.6.1 Time Discounting

Humans and animals alike tend to prefer a benefit that will come soon to an equal benefit that will occur later in time. That is, they *discount* future benefits. For example, a member of an online community may be more willing to make a contribution if it appears on a web page immediately, so that its positive consequences (which can take various forms) occur without delay. As is the case with monetary investments, there are various good reasons to discount temporally distant benefits (including uncertainty about whether they will actually come about). A straightforward design implication is that, to encourage a user to choose a particular option, you can try to arrange for its benefits to come sooner rather than later. This strategy was applied by McDowell et al. (2003) to encourage nontechnical users to annotate HTML data for semantic web services.

But there are some more subtle aspects of time discounting that deserve attention.* These can be illustrated with reference to the frequent situation in which a person can choose between (1) an option that will bring a small benefit soon and (2) another option that will yield a larger benefit at a later time. If people's discount curves were exponential—as is the case with typical discount rates for financial investments and in early normative models of time discounting (see, e.g., Read 2004)—then people would always show *time consistency* in their preference between the smaller-sooner and the larger-later option: If, when asked on Monday, you prefer a larger benefit on Saturday afternoon to a smaller benefit on Friday afternoon, then you will express the same preference on Friday morning. As is illustrated in Figure 5.2, the discounting curves in question never cross.

Many studies with humans and animals have shown, however, that discounting curves are better described by a hyperbolic function (Figure 5.3) than by an exponential one. One implication of the mathematical form of a hyperbolic function (see, e.g., Read 2004) is that the curves in a problem like the one we are considering can cross. Concretely, in our example, when Friday morning arrives and the small benefit could be obtained almost immediately, the chooser may change his mind and opt for the smaller benefit after all. This particular type of *preference reversal* has been documented countless times in studies with animals (e.g., pigeons) and humans (see, e.g., Rachlin 2000, Chapter 2), and it corresponds to our everyday experience that benefits which are tangibly near can loom disproportionately large.

Often, people are aware of the danger of such a last-minute preference reversal and are willing to avoid it by *committing* themselves at an early point in time to the option with the larger-later benefit (Rachlin 2000, Chapter 3). One strategy is to eliminate the option with the smaller-sooner benefit (e.g., by permanently discontinuing membership in an online community that offers immediate but trivial rewards). A softer commitment mechanism involves arranging for a punishment or other disadvantage to be associated with the smaller-sooner option (e.g., throwing away your password for the online community in question, though you know you can always get a new one with some effort). A drawback of the softer mechanisms is that people may still succumb to the temptation of the smaller-sooner benefit and willingly accept the associated punishment, in which case they are worse off than they would have been without the commitment.

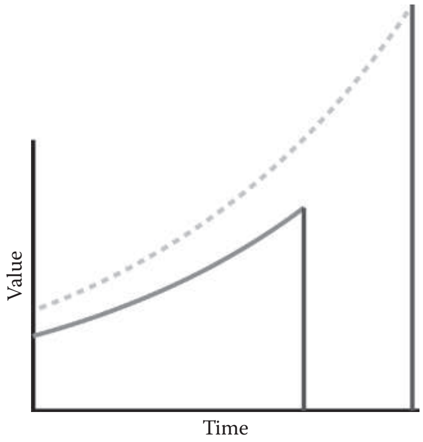

FIGURE 5.2 Exponential time discount functions for a smaller-sooner and a larger-later benefit. (Each of the vertical line segments on the right represents the value of a benefit at the point in time at which it occurs. Each curve represents the discounted value of the anticipated benefit at an earlier point in time.)

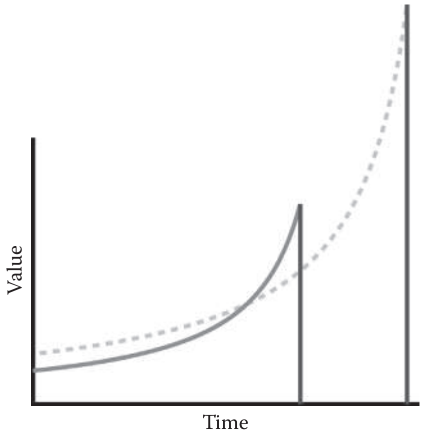

FIGURE 5.3 Hyperbolic time discount functions that cross. (Compare with Figure 5.2: The larger-later benefit is preferred until shortly before the time at which the smaller-sooner benefit will occur.)

One very general strategy for helping users to make better choices is to make available suitable commitment mechanisms. Many of the strategies applied within the paradigm of persuasive technology can be seen as ways of helping people to stick to a commitment that they have made (e.g., to exercise regularly). Where the choices in question concern computer use (which is normally not the case in the persuasive technology paradigm), there are additional forms

* Useful collections of articles on phenomena that arise when choices and/or their consequences are distributed over time have been edited by Loewenstein and Elster (1992) and by Loewenstein, Read, and Baumeister (2003).

of commitment mechanisms available, because the decision environment is more under the control of the designer and the user. For example, mechanisms that are commonly used to make it impossible for children to visit certain websites or to use certain applications can also be used as self-control mechanisms that people can willingly apply to themselves.

5.6.2 Choice Bracketing

The choice between a smaller-sooner and a larger-later benefit is actually quite straightforward compared with many situations that arise when options and their consequences are distributed over time. One key concept is that of *choice bracketing* (Read, Loewenstein, and Rabin 2006). Although the concept is actually more general, we will discuss only *temporal bracketing*, which is illustrated graphically in Figure 5.4.

The issue arises when a chooser confronts a sequence of similar choices—for example, which of two alternative keyboards to use to enter text on a smartphone: the traditional QWERTY keyboard or an unfamiliar keyboard that has been optimized for one-handed text input. Conceivably, a user could make this choice separately every time it arises, which would be an example of *narrow bracketing*. If instead the user opts for *broad bracketing*, she will think in terms of a general policy, such as the choice between: (1) "Always use the QWERTY keyboard"; (2) "Always use the alternative keyboard"; or (3) "Use the alternative keyboard when you have a lot of text to enter." Research has brought to light a number of typical advantages of broad bracketing, most of which are illustrated by this example.

One benefit is that a sequence of choices can have important properties that the chooser cannot see when contemplating the individual choices. For example, if the user consistently uses the alternative keyboard, she will initially enter text more slowly and with greater mental effort than with the QWERTY keyboard; but if she persists long enough, the alternative keyboard will eventually become easier and faster to use than the QWERTY keyboard. Similarly, the user's tastes can change: she will probably find the appearance of the alternative keyboard less strange and distracting.

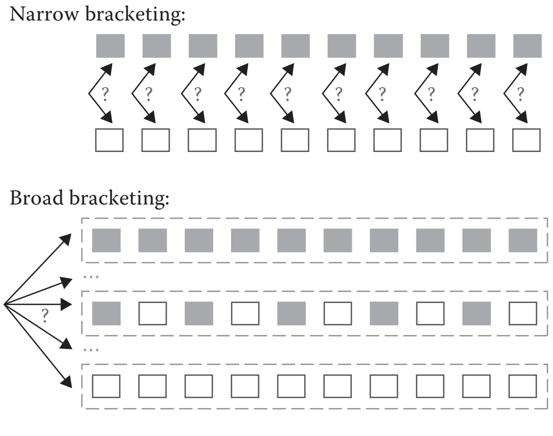

FIGURE 5.4 Visualization of the distinction between narrow and broad *temporal choice bracketing.*

Another emergent property of a sequence of choices is the amount of variety associated with it: A user might prefer to alternate between the use of a trackball and the use of a mouse to avoid one-sided use of her hand and arm muscles.

Situations where broad bracketing is possible may also involve time discounting: The user in our example might opt for narrow bracketing because she heavily discounts the long-term benefits of using the alternative keyboard. But the issues just discussed cannot all be reduced to time discounting. Rachlin (2000) uses the terms *complex ambivalence* and *simple ambivalence*, respectively, to distinguish the two cases.

Designers of interactive systems have many opportunities to encourage broad bracketing in cases where doing so seems conducive to good decision making. For example, instead of making two different virtual keyboards readily available at all times, the designer can make the choice of keyboard a configuration option—perhaps one that is difficult to change—so as to encourage the user to take a broader view. Conveying a realistic idea of the consequences associated with broadly bracketed options is more of a challenge, because by definition these consequences cannot be experienced immediately. In particular, the general strategy of trying something out to see if you like it is relatively hard to apply in cases where broad bracketing is appropriate.

5.7 REUSE OF PREVIOUS CHOICES

Sections 5.5 and 5.6 have shown that making choices on the basis of anticipated consequences can be an effortful and error-prone process. These considerations help to explain why choosers often apply a simpler general strategy: Choose the same option that you chose the last time you were in this situation, maybe adapting it a bit. Several complementary lines of psychological research help to understand how and why choices are often repeated.

5.7.1 Recognition-Primed Decision Making

The concept of *recognition-primed decision making* was developed by Klein and collaborators in the context of their studies of naturalistic decision making (introduced in Section 5.4).

On the basis of previous research on decision making, most of it in the laboratory, Klein expected that decision makers such as fireground commanders would typically consider two possible courses of action before deciding which one to execute. They were surprised to find that usually, the "decision makers" seemed not to be making decisions at all: Most often, they would evaluate the situation confronting them, remember a course of action that they had previously applied in one or more similar situations, and proceed to implement that action. As Table 5.4 indicates, a somewhat more complex variant of this basic procedure was observed in cases where a contemplated action was not obviously appropriate: The decision maker would anticipate the consequences of the action by a process called *mental simulation* and if necessary modify it until the mental simulation produced a satisfactory result. In

TABLE 5.4
Three Forms of Recognition-Primed Decision Making

Straightforwardly retrieve an action
Experience the situation.
Recognize it and identify a typical action for that situation.
Implement that action.
Retrieve, evaluate, and modify an action
Experience the situation.
Recognize it and identify a typical action for that situation.
Evaluate that action via mental simulation.
Until it seems likely to work in its familiar form, modify it and evaluate it again.
When satisfied, implement it.
Make sense of the situation and consider more than one action
Experience the situation.
Try to make sense of the situation until you have identified it as matching a familiar pattern.
Generate one or more plausible actions for this type of situation.
Evaluate each action via mental simulation, modifying it if necessary, until you have found one that seems likely to work.
Implement the selected action.

Source: Summarized on the basis of Klein, G. 1998. *Sources of Power: How People Make Decisions*. Cambridge, MA: MIT Press, Chapter 3.

a small fraction of cases, the decision makers really did find it necessary to consider (and perhaps modify) two or more alternative options before arriving at a satisfactory course of action. Some of the characteristics that make recognition-primed decision making ecologically rational are (1) the decision maker has a great deal of experience with previous similar situations; and (2) there is no time available for exhaustive generation and comparison of the alternative options.

These two conditions often apply to computer users as well, though the time pressure is usually not due to a dynamically changing emergency situation but rather to a need to proceed briskly with the activities that really interest the user.

5.7.2 Coherent Arbitrariness

A different line of research that revealed a striking tendency of people to repeat previous choices was conducted by Ariely (see, e.g., Ariely, Loewenstein, and Prelec 2006; Ariely 2008, Chapter 2).* In one typical experiment, Ariely asked study participants to state how much money they would want to be paid to endure unfamiliar unpleasant sounds of various durations. This choice problem was used because a participant's choice was bound to be largely arbitrary: Because people have no previous experience in paying money to avoid unpleasant sounds of this sort, there is no a priori notion of what a reasonable amount might be. And indeed, it was found that participants differed in the amounts they required and that their requirements could be influenced strongly by the manipulation of asking them about a particular price at the beginning ("Would you be willing to endure this sound for $.10/for $.50?").† But despite this arbitrariness, the participants' payment requirements were *coherent*: If one of them required a given amount of money to endure 10 seconds of a sound, they would require predictably larger amounts to endure 30 seconds or 60 seconds of the same sound. Evidently, participants were inclined to state their requirements in a way that was consistent with whatever requirement they had specified initially. The impact of the manipulation of the initial level could still be detected even after participants had received a good deal of relevant new information (e.g., information about the requirements of other participants).

One way of viewing coherent arbitrariness is as a result of reusing previous choices so as not to bother having to make the same choice over again. But it can also be seen as a reflection of people's desire to exhibit a consistent pattern of choices (see, e.g., Cialdini 2007, for a discussion of the ways in which *compliance professionals* such as salespersons exploit this tendency).

5.7.3 Choices Based on Habit

The most familiar way in which people repeat previous choices is when they act out of habit. The topic of habits is one of the oldest in psychology, but it continues to be an active area of research, bringing forth new theoretical perspectives, many of which now make use of neuropsychological concepts and research methods (see, e.g., Fu and Anderson 2006; Bayley, Frascino, and Squire 2005). For HCI researchers, a useful current synthesis is found in an article by Wood and Neal (2007, p. 813), who characterize habits as follows: "Habits are learned dispositions to repeat past responses. They are triggered by features of the context that have covaried frequently with past performance, including performance locations, preceding actions in a sequence, and particular people. Contexts activate habitual responses directly, without the mediation of goal states."

Although the ability to be triggered independently of any particular goal is a characteristic feature, habits can also interact with goals in various ways (Table 5.5), which are of particular interest to interaction designers who wish to take into account—or influence—habit-based behavior. The ways in which goals control habits are relevant to attempts to help users form appropriate habits or to leverage habits that they already have. The ways in which habits can conflict with goals are relevant, for example, to attempts to induce users not to act in accordance with an existing habit.

5.7.4 The Role of Skill Acquisition

Yet another reason why people often repeat previously made choices was already mentioned in the discussion of choice bracketing (Section 5.6.2): Suppose a user can choose between

* Paradoxically, Ariely introduced the term *coherent arbitrariness* in the first publication and switched to *arbitrary coherence* in the 2008 book.

† The provision of an *anchor* in this way is a frequent experimental method for influencing a judgment. Epley (2004) discusses the psychological mechanisms that underlie anchoring effects.

TABLE 5.5
Forms of Interaction between Goals and Habits

Relationship between Goals and Habits	Example
1. *Goals control habits*	
A person may intentionally form a habit.	"I'll back up my computer every evening just before leaving the office, so as to get into the habit of backing it up once a day …"
A person's goal-directed behavior may lead to the formation of a habit, without the person having any such intention.	"I decided on several days in a row to start my day by checking Facebook messages; and it became a bad habit."
A person can intentionally put themselves into a position where their choices can be made on the basis of habits.	"I make a point of shopping online only at my favorite web-based store: Once I've decided what to buy, I can go through the procedure of ordering the product without any attention or difficult decision making."
2. *Habits give rise to (inferences about) goals*	
A person can observe their own habitual behavior and make inferences about their own goals.	"I guess I assign high priority to good spelling and grammar: I always check the language of every e-mail message carefully before sending it off."
These inferences can in turn give rise to new goals.	"… So I guess I should spend more time proofreading my scientific articles before submitting them."
3. *Habits can conflict with goals*	
A person is sometimes aware that some habitual behavior of theirs conflicts with a goal that they have.	"I really have more important things to do at the beginning of each day than checking my Facebook messages."
But this awareness is not in itself enough to overcome the habitual behavior; two strategies are often successful:	
A. Actively and effortfully resist performing the undesired habitual response.	"I'm going to ignore the Facebook notification that just arrived!"
B. Change the situation so that you are no longer exposed to the cues that trigger the behavior.	Disable automatic notification about incoming Facebook messages; disable your entire Facebook account.

Source: Formulated on the Basis of Figure 1 of Wood, W., and D. T. Neal. 2007. *Psychol Rev* 114(4):843–63.

two ways (*A* and *B*) of performing a particular task, both of which seem about equally desirable at first (e.g., two different search engines for executing a web search; two alternative websites for downloading software; using the touch-pad or the isometric joystick on a new laptop). Even if the user's initial choice of *A* is essentially arbitrary, after executing *A*, the user will have become a bit more skilled at using *A*. So the next time, basically the same choice comes up, *A* should in principle be more attractive in terms of the user's skill at executing it. The user who engages in broad bracketing can anticipate this skill acquisition and take it into account when making the initial decision. But even a user who does not think that far ahead may notice the additional advantage of *A* after having chosen it at least once.

5.7.5 Example from Research on Method Selection

The importance of reusing previous choices was discussed in an influential article by Carroll and Rosson (1987) on the problem of method selection (Table 5.2). The authors began with the observation that computer users often persist in employing a relatively inefficient method to perform a given task even when they have more efficient methods available. One of the two explanations that the authors offered was *assimilation bias*: The authors noted that, if users can immediately think of an adequate method for performing a given task, they may use that method instead of taking the trouble to search for a better method. Assimilation bias is consistent with all four of the forms of repetition of previous choices discussed in Sections 5.7.1 through 5.7.4.*

5.7.6 Concluding Remarks on the Reuse of Past Choices

This section has shown that there are several different ways in which what a person chooses now can influence what they will choose in the future: Today's action can serve tomorrow as an example of a successful action or as a precedent; it can strengthen a habit or increase a person's skill. A negative implication is that an inappropriate choice can have more serious negative effects in the future than one would intuitively expect. The positive side is that, by supporting or influencing the user's actions in the short term, an interaction designer can increase the likelihood of appropriate choices in the longer term as well.

5.8 SOCIAL INFLUENCE

Another important general alternative (or complement) to consequentialist decision making is to be guided by the social context—specifically the examples, norms, and expectations

* The second explanation offered by Carroll and Rosson (1987), a production bias, can be seen as another example of the role of the user's current goal: the goal of getting the current job done is usually more important than the goal of increasing skill at using the system.

established by other people and the advice that they explicitly give.* For example, a person who has acquired a new computer for home use may consider at length what applications to install, what privacy and security settings to choose, and how to communicate with friends. When the same person works at the office, many of these decisions are likely to be influenced by written or unwritten rules, conventions, or social examples.

March (1994) offers a deep discussion of the view of decision making as *rule following*, which he contrasts with consequentialist decision making. In a similar vein, many authors in the HCI field have emphasized the importance of social and organizational context in influencing users' behavior (see, e.g., Button 2003). The point of view taken in this chapter is that social context accounts for some of the many considerations that are involved in decision making by an individual. In particular, a carefully selected presentation of aspects of the social context to an individual user can support or influence that user's choices.

The fact that the social environment often exerts a powerful influence on people's choices and decisions is known from everyday experience, and the mechanisms of social influence have been analyzed thoroughly in theories from social psychology and sociology. The diverse perspectives are associated with different concepts and terminology. The summary in Table 5.6 summarizes some commonly accepted ideas in everyday terms.

Note that, except for the final one, all of these considerations have something to do with consequences, either social or nonsocial. But when making a specific choice, a person may simply follow the general pattern of conforming to examples and expectations, without wondering about any associated consequences.

When it comes to interaction design and providing information to users, one general strategy is to provide users with more accurate or useful information about social examples and norms. The widely used paradigm of *collaborative filtering* for recommender systems (Jannach et al. 2011; Ricci et al. 2010) can be seen as providing information about choices that like-minded people have made. Most straightforwardly, this type of information serves the first function listed in Table 5.6. One of the relatively few applications of collaborative filtering to the support of choices about computer use, for the recommendation of commands, was presented recently by Li et al. (2011) (discussed in Chapter 20 of this handbook).

TABLE 5.6
Reasons Why People Can Be Influenced by Social Examples, Expectations, and Norms

Reason to choose in accordance with social influence	Example: using the company's social network
If others set an example (without necessarily expecting you to follow it):	
Their experience is a useful source of information.	"If these coworkers have acquired experience with this social network and are still using it, their experience must have been positive."
You want to enjoy practical benefits of conformity.	"There will be direct practical benefits to being in the same network as my coworkers, such as being able to exchange information with them conveniently."
You want to feel that you belong to their group.	"If I use the social network, I will feel more like a typical employee of this company."
If others expect you to make a particular choice:	
They can reward or punish you.	"If I don't use it, I may be subject to disapproval or even concrete disadvantages."
They have a legitimate reason for their expectation.	"The managers in my company have a right to expect me to do things like this."

The provision of extensive information about choices of other users is a typical feature of Web 2.0. Many online communities provide explicit information about the contribution behavior of their members, which can influence the contribution behavior of other members in several of the ways listed in Table 5.6.

These practices suggest that social information could be leveraged more extensively for the support of preferential choices and decisions about computer use—for example, to follow up belatedly on the observation made by Mackay (1991, p. 159) on the basis of her study of customization that "users want information about their own use and that of other people with similar job responsibilities and attitudes [on] which they can base their customization decisions."

5.9 LEARNING FROM EXPERIENCE

Especially when we consider sequences of similar choices that are made repeatedly, which is a typical HCI case, it becomes clear that an important aspect of choice and decision processes is what happens *after* the user has selected an option and experienced (to some extent) the consequences of a choice (see, e.g., Newell, Lagnado, and Shanks 2007). Aspects of learning have already been mentioned at various points in Section 5.7.

The model of action introduced by Norman (1986), which is well known in the HCI field, is worth bearing in mind in this context, even though it was not specifically intended to illuminate processes of preferential choice. In his discussion

* Many choices are made by a group of people rather than by an individual, as when a group of collaborating authors decides what text processing system to use to prepare their joint article. Group decision making in general involves some processes, such as interpersonal negotiation of compromises in cases of conflict of interest, which are not found in individual decision making (see, e.g., Kameda, Tindale, and Davis 2003, and Sorkin, Luan, and Itzkowitz 2004, for general treatments of group decision making; and Jameson and Smyth 2007, for a discussion of the special characteristics of recommender systems that make recommendations to groups). Although group decision making about computer use appears to be growing in importance with the increasing interconnectedness of computer users, the topic is omitted from this chapter for reasons of space.

of the *gulf of evaluation*, Norman distinguishes the phases of perceiving, interpreting, and evaluating the results of an action. Each of these phases can be seen as a way in which a chooser may have difficulty in learning from experience in making a certain type of choice. For example, a person who has acted on a decision to contribute one paragraph to a Wikipedia article will probably never know how many people have read the paragraph or how much they benefitted from it. The author may well notice the changes that other Wikipedia contributors make to the paragraph, but he may interpret them unrealistically and thereby arrive at an inappropriate evaluation of his original decision to contribute the paragraph.

Another example comes from the area of research on method selection: Bhavnani and John (2000) studied in depth expert users of computer-aided design systems who persisted in using inefficient methods: Among other things, they tended not to take advantage of the opportunity that their systems offered to perform an operation on multiple objects at one time. For example, when they needed to create three identical objects, they would draw them separately, instead of drawing one object and making two copies of it. One of the authors' explanations for the persistent use of inefficient methods concerned the fact that the users did not obtain clear feedback that revealed the inefficiency: The quality of the resulting drawings was in general identical, and the difference in execution times was not easy to notice from experience, especially if the users never tried the more efficient method in the first place. In view of this and other obstacles to spontaneous learning of the more efficient procedures, Bhavnani and his collaborators concluded that explicit training was required (see, e.g., Bhavnani, Peck, and Reif 2008).

In contrast, Gray and Boehm-Davis (2000) showed that, under more favorable learning conditions, users can sometimes take into account a difference between alternative *microstrategies* that involves only milliseconds of execution time. It can be seen, then, that the exact nature of the feedback that users receive about their choices can be crucial in determining whether preferential choices will improve on the basis of experience.

A recent trend in laboratory research on judgment and decision making (see, e.g., Rakow and Newell 2010) is to study *experienced-based choice*, where a person's choices about typical experimental problems such as pairs of gambles are based on concrete experience with the problems in question rather than on descriptions of the problems. For example, instead of being told that Option *A* offers a 10% chance of winning $12, whereas Option *B* guarantees a win of $1, a participant is allowed to click repeatedly on two buttons corresponding to the two options and observe the resulting rewards. An important issue in this sort of situation is the tension between *exploration* and *exploitation*: In order to learn efficiently which of the two options is preferable, a chooser should in principle systematically "explore" both of them, trying them out until it is clear which one is better—a process that may take some time, as in the example just given. But in practice, once a chooser has the impression, say, that Option *B* is better, there is a temptation to "exploit" this insight by consistently choosing *B*. The *production bias* observed by Carroll and Rosson (1987) can be interpreted in part as a result of users assigning higher priority to exploitation than to exploration.

Another typical obstacle is the difficulty of learning from one's own everyday experience very low probabilities such as those of a major hard disk failure, identity theft due to inadequate security measures, or an accident due to texting while driving.

As was mentioned in connection with choice bracketing (Section 5.6.2), one obstacle with broad bracketing is that it can be difficult for the chooser to learn from experience which of the broadly bracketed options yields the best results.

In cases like these, in which individual learning from experience faces serious obstacles, sources of guidance such as norms, policies, and the behavior of similar other persons play an especially important role. These cases also offer opportunities for interaction designers to improve choice and decision making noticeably by identifying the learning difficulty and taking steps to compensate for it.

5.10 CONCLUDING REMARKS

Readers who follow up on the references given in this chapter will discover many additional theoretical concepts, empirical results, and suggestive examples, including many on aspects of choice and decision making that could not be discussed in this chapter for reasons of space.* This literature can serve as a rich source of ideas about new ways to apply the HCI knowledge that is documented so thoroughly in the other chapters of this handbook.

ACKNOWLEDGMENTS

Preparation of this chapter benefited greatly from extensive discussions with Silvia Gabrielli, Per Ola Kristensson, Katharina Reinecke, Federica Cena, Cristina Gena, and Fabiana Vernero. Alan Dix supplied creative feedback and suggestions on several occasions. The author is grateful to the Handbook's editor, Julie Jacko, for her openness to the inclusion of a chapter on a new topic. The development of the perspective presented in the chapter was supported by the Autonomous Province of Trento in the context of the 2-year targeted research unit Prevolution. Preparation of the chapter itself was supported in part by the 7th Framework EU Integrating Project Glocal: *Event-based Retrieval of Networked Media* (http://www.glocal-project.eu/) under grant agreement 248984.

* For example, the collections edited by Koehler and Harvey (2004) and by Lichtenstein and Slovic (2006) include articles about the influence on decision making of affect and of culture.

Part II

Computers in HCI

6 Input Technologies and Techniques

Ken Hinckley and Daniel Wigdor

CONTENTS

6.1 INTRODUCTION: A SHIFTING LANDSCAPE

The barometer has fallen and a brisk wind blows. Input and interaction are not what they used to be. Gusts drift over the line in the sand that separates input from output. The academic division between input and output as topics of study was never a principled one to begin with. But this is perhaps clearer now than ever before: Many people now primarily experience computing by direct-touch input on their displays. The shifting sands are rapidly unearthing a future where any surface on which we can display information will also serve as a surface that sees, hears, feels, and otherwise senses all our interactions. As some would have it, the encroaching dunes have all but buried the mouse, keyboard, and other indirect-input devices as archeological curiosities to be unearthed by a future generation of researchers, explorers, and scoundrels.

What is the prospector of innovative devices and interaction techniques to make of this new landscape? Is it a desert or is it an oasis? In our view it is a little bit of each. Everyone is now familiar with multitouch as the defining example of direct interaction, but it is not the whole story. As our colleague Bill Buxton constantly likes to remind us, a key lesson to remember is the following: *Everything, including touch, is best for something and worst for something else*.

The goal of this chapter is to help you to understand why, how, and under what circumstances, a given input modality is most appropriate. This will be done by way of a survey of illustrative examples, devices, techniques, and conceptual tools. It will also help you to understand why direct interaction is about much more than just multitouch. Direct interaction includes not only many variations on touch itself but also modalities such as pen input, motion and postural sensing, and proximal and spatial interactions in the physical space beyond the display. Each of these in turn exhibits its own idiosyncratic strengths and weaknesses.

6.1.1 Every Coin Has Two Sides

Having said that every coin has two sides, is it even desirable to think of devices and modalities in terms of strengths and weaknesses? Perhaps not, and indeed we encourage the reader to move beyond this categorical mind-set. Input modalities share a number of common properties. If a designer understands these properties thoroughly, then nearly any property of an input device can be turned to one's advantage when used appropriately in an interface design.

For example, take the property of *mechanical intermediary*. A modality either requires a mechanical intermediary, such as a pen, or it does not, as is the case with direct-touch input. Think of this property of mechanical intermediary as a coin with two sides: Heads requires an intermediary, but tails does not. Which side of the coin should we choose? Well, of course, it depends.

If we choose heads, then *the pen* has an advantage because it employs a mechanical intermediary. A stylus is a familiar tool to which users may bring highly developed skills for handwriting, sketching, and drawing. The body of the pen provides a lever arm that affords a tripod grip for precise control, and its tapered tip enables one to indicate small objects on the screen. It also affords a purchase for secondary controls such as buttons, an eraser head, or perhaps a trigger (as in an airbrush, e.g., which modulates the flow of paint). A skilled interaction designer can leverage these attributes to produce compelling user experiences.

If we choose tails instead, on the other side of the coin, then touch has an advantage because it does not require a mechanical intermediary. Unlike a stylus, there is nothing to lose. The user always carries their finger with them. Furthermore, the user can start interacting immediately. There is no additional *acquisition time* required to grasp or unsheathe a stylus. This becomes a critical factor in mobile interaction, where interacting with the real world and other individuals is the user's primary task, forcing users to wedge their interactions with a device into ever-narrowing fragments of time and attention.

That is, the property of mechanical intermediary shared by both the pen and touch input modalities is neither inherently good nor inherently bad. It is just a property. Correctly choosing heads or tails depends on what the user is trying to accomplish, as well as how that task fits into the larger set of activities that a designer seeks to support with an interface. The *exact same property* of a modality that offers a marked advantage for one task, or context of use, turns about-face and becomes a crippling liability in another task. In our example, the requirement of a mechanical intermediary is both a strength and a weakness for the pen, as is the lack of an intermediary for touch. But having these two opposing sides makes the coin no less valuable. Indeed, our ability to trade off these two opposing facets against one another is precisely what gives the coin its value in the currency of design.

Hopefully by now the lesson is clear. The designer should not just extol the virtues of a particular modality. The designer does not truly understand an input until he or she can articulate its shortcomings just as thoroughly as he or she can articulate its advantages. The emerging trend of user experiences that integrate both pen and touch inputs (as well as other modalities) illustrates the practical need for this perspective (Hinckley et al. 2010; Zeleznik, Bragdon, Ko et al. 2010; Frisch, Heydekorn, and Dachselt 2009; Brandl et al. 2008).

6.1.2 From a Competitive to a Cooperative Landscape of Devices

Let us now step away from the computer for a moment and look at the example of handwriting with pencil and paper. These are "devices" that one interacts with in the real world, after all. Consider the simple question: *Which hand do you write with, right or left?* When we give talks on this subject, we have the audience raise their hands. Who uses their right hand? Do we have any left-handers in the audience? Which hand would you, the reader, raise? Now, of course, we have led you into a trap because *you are all wrong. No matter which hand you raised, you are wrong.* This is not a trick question. Rather, the question is fundamentally ill posed. People write with both hands, as demonstrated by Guiard (1987).

What Figure 6.1 shows is the result of writing on a sheet of paper. On the right, we see the impressions left by the pen on a sheet of transfer paper surreptitiously left underneath. That is, it records the movements of the pen relative to the desk rather than relative to the paper, and it reveals that the nonpreferred hand dynamically adjusts the position of the paper to suit the action of the preferred hand. Hence, both hands play a role in handwriting, but each hand plays a *specialized role* that is *complementary* to the other hand. In the same way that one's hands are specialized, we can think of input modalities and devices as taking on specialized roles in a larger ecosystem of interaction.

In both popular press and research papers, one often sees input modalities framed in *competitive* terms. How many times have we seen headlines proclaiming that the next magical device will make the mouse and keyboard obsolete? How many studies have we seen that compare device A with device B for some task? This implies a winner, as in a football match, where either A or B achieves victory. These type of headlines and studies beg research questions, even if only implicitly, of the following form: *Which is better, touch or stylus (or the mouse, or motion sensing, or freehand gesturing, or name your favorite input modality, device, or interaction technique)?*

If we find ourselves asking a question of this sort, then we must once again recognize it as an ill-posed query. We are not saying that studies that compare individual techniques cannot be illuminating. They can be illuminating if done in a principled manner that carefully assesses and controls the factors underlying performance, rather than just comparing two arbitrary techniques. However, isolated studies cannot be the only things that we publish nor should they be framed

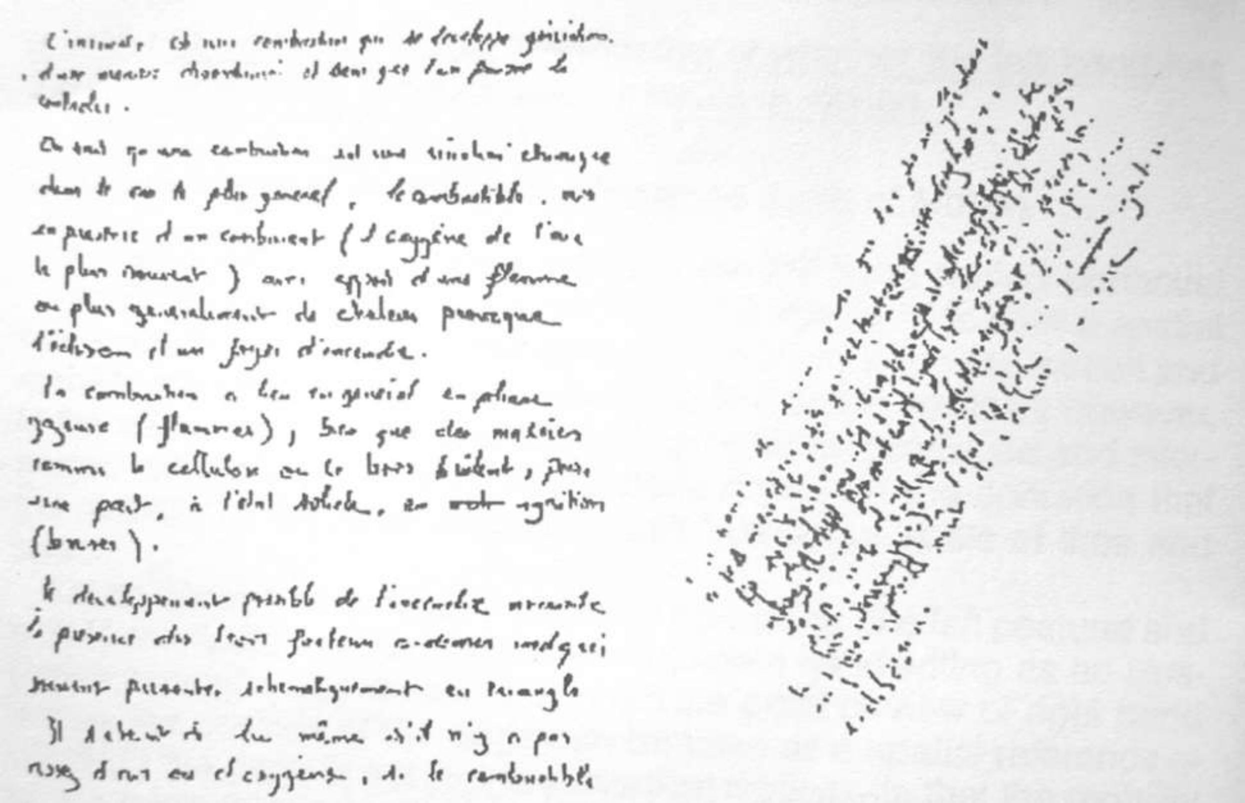

FIGURE 6.1 Guiard's transfer paper experiment, with the full sheet of paper shown on the left and the impressions left on an underlying sheet of transfer paper shown on the right. This shows how the nonpreferred hand orients and shifts the sheet of paper to suit the action of the preferred hand while writing. (From Guiard, Y., *J Motor Behav*, 19(4):486–517, 1987. http://www.informaworld.com. With permission.)

and extrapolated without due consideration of the ecology of devices and techniques in which they reside.

Following Guiard (1987), we believe the correct question to ask is one that takes a *cooperative* perspective, as well as a broad view of input modalities and form factors. There are multiple modalities and devices. We should not try to do everything with any one of them. We should instead seek to understand how input modalities and techniques can complement one another such that the advantages of one make up for the shortcomings of another.

Interactive system design should encourage a division of labor between a collection of input devices, sensing modalities, and interaction techniques that together sum to more than the whole of the parts. We should seek out logical design principles (or rules of thumb) that help to guide the ways in which we combine techniques. That is, we should frame our input research and system designs around questions of the following form: *What is the logic of the division of labor between touch, pen, motion and postural sensing, proximal and spatial interactions beyond the display, and a diverse ecology of devices and form factors?*

If we can succeed in bringing about this shift in perspective, then perhaps this chapter can form a more enduring survey of the terrain than the gold rush that the industry is witnessing to do anything and everything with touch, and with touch alone.

6.1.3 Multiple-Modality Perspective

The discussion in Section 6.1.2 implies that the reader should take a multiple-modality perspective on the design of interactive systems. The Apple iPhone has been lauded for its multitouch interface, but do not forget the additional modalities such as the use of proximity sensing to avoid “ear dialing” (Dietz and Yerazunis 2001) or the use of orientation sensing to automatically rotate the screen (Hinckley et al. 2000; Schmidt, Beigl, and Gellersen 1999), both of which enrich the experience offered by the device.

If we accept then that multitouch is likely the tip of the iceberg in terms of what is possible for a natural and compelling direct-input user experience, then the combination and infusion of touch with rich sensory information from other modalities represents the great frozen massif beneath the waterline in terms of future innovation and research contributions. Rather than focusing on one modality, such as touch, our collective goal as a community of researchers, designers, and practitioners should be to understand how to most effectively design systems that use input modalities in combination, where the strengths of one compensate for the limitations of another. When a system does not have to provide coverage of all possible functions with a single input modality, implicitly this leads one to ask where each modality should be used to the best advantage, where a particular modality should not be used, and in what cases modalities should perhaps be treated interchangeably (Hinckley et al. 2010).

Nonetheless, we must be pragmatic and recognize that at times an interface design must focus on a single modality. But even if your intention is to design a single-modality user experience, such as a touch-screen device, our belief is that you can design a better and more compelling experience if you do so with a broad perspective of the limitations of that modality, as well as good working knowledge of the capabilities of other modalities. Perhaps you can even anticipate future developments and dovetail your design to intersect with capabilities that other modalities may add to the user experience in future generations of a device or system, or enable richer capabilities in the presence of secondary sensors or peripherals that augment a system’s core capabilities.

6.1.4 Breadth–Depth Dichotomy

With respect to systems and devices, there are two basic design strategies: (1) We can design for breadth, supporting a wide ecosystem of hardware and modalities with a one-size-fits-all design. Designing for breadth creates a common platform that unifies many different devices and experiences, with all the benefits (as well as the drawbacks) that are inherent in an accretion of features and interfaces. (2) Or we can design for depth, with a core sample carefully drilled through the many strata of target market, user experience, input modality, display size and form factor, operating system, and application design. The market shows that designing for depth can yield simplification of user interfaces as well as compelling experiences. Yet the market has also shown that designing for breadth has immense value when done well. Which way to turn? We refer to this fundamental design dilemma as the *breadth–depth dichotomy*.

This dichotomy pervades every element of design as well as software and hardware development. Successfully addressing this tension is a key challenge for designers of software and of devices supporting direct interaction. It is as if we are lost at sea and are awaiting the arrival of an automated method to “convert” applications and experiences for different contexts of use, but none is apparent on the horizon. This chapter aims to provide the reader with a modest navigational tool to help find his or her way through this unsettled ocean of design decisions and their subtle implications.

Whether one adopts a unimodal or a multimodal perspective, excellence in user interface design requires tailoring an interface to the input method. This tailoring extends to form factor as well as modality. Multitouch interaction with a phone is often conducted with thumbs while holding the device. Multitouch interaction with wall-mounted displays is conducted with fingertips and by keeping the arms extended. The physicality of the interaction is clearly different for the two cases, as is the context of use; it is likely the tasks that the user will be performing are also different. As another example, many common websites and applications have both desktop and mobile editions. Students of human–computer interaction (HCI) should consider these and ask the following: *Does each have a different user interface model? What are the commonalities, and what are the differences?* The answer varies depending on the application, because no standard has yet been reached.

This further extends to a society of devices that users expect to work together with consistent experiences that are nonetheless tailored to the form factor. User interface consistency should not be viewed as a rigid construct but as a flexible one that maintains *consistency of user expectations* given the form factor, input modality, context of use, and the specific task at hand. Handheld devices, e-readers, tablets, booklets, slates, desktops, tabletops, laptops, and wall-mounted displays each have their own unique affordances, and each may be encountered by the same user in varying contexts. Thus, from the user's perspective, the most "consistent" user experience may in fact be one that is not consistent with respect to the specific actions that the user must articulate to use a given form factor.

6.1.5 Designing User Interfaces: The Loss of a Closely Held Abstraction

The widespread shift to direct interaction, in service of mobility as well as other concerns, has ushered in a storm that batters us on our voyage of discovery. We have arrived at a strange land lashed by impetuous gales that we must weather while avoiding the uncharted seamounts and rocky shoals that abound its wild coast. But in the lee of the tempest, islands of compelling new interactions, form factors, and user experiences can be discovered that tempt both the adventurous and the foolhardy to ply these treacherous waters. The result, certainly, will be many shipwrecks, and also some wondrous new systems and devices that were never before imagined.

Our voyage has led us far away from the Old World of the so-called WIMP (windows, icons, menus, and pointers) desktop user interface. This paradigm has been painstakingly designed over more than four decades for multimodal control with a keyboard and with a mouse, and was achieved in no small part through the cursor. The cursor is a logical abstraction of the user's locus of attention, known by many names (originally as the bug, and alternately as the telepointer, pointer, or tracking symbol). The abstract representation of the cursor serves as an intermediary that separates the concerns of input and output. Direct interaction does away with this separation and abstraction, leading us toward a world where each device requires specific and particular software design.

One must keep in mind that the WIMP graphical user interface (GUI) is highly optimized for the particular pairing of mouse and keyboard input devices. Although it is possible to control the pointer and enter text using other input devices, doing so is more difficult and less efficient than that with mouse and keyboard. Many modern platforms rely on the accoutrements of the WIMP interface (buttons, sliders, checkboxes, windows, and so forth), simultaneously forgetting that these are optimized for a pair of input devices that are not actually present on the systems supported by the platforms. In short, new modalities require new user interfaces and interaction techniques if one wishes to make the most of their capabilities.

To the extent that we succeed, this chapter forms a chart, which, despite being a rough guide riddled with terra incognitae, can assist the explorers of this new interactive world. Through this exercise, we seek to equip the explorer with what we believe is the most valuable tool of all: the confidence in knowing which questions to ask. This will be based on as deep an understanding of the properties of input devices as we are able to impart through this short chapter, and which will be rooted in perhaps the only indisputable fact in the ever-changing landscape of design: Everything is best for something and worst for something else.

Section 6.2.1 first considers, in a little more depth, what is actually meant (in our opinion) by "natural" user interfaces. We discuss terminology; enumerate some common properties of input devices; and provide examples of how these properties apply to familiar examples of devices such as touch screens, pens, and mice. However, our emphasis is more on the particular concerns of direct-input devices and less on indirect devices. We then turn our attention to state-transition models of devices and how these relate to interactive techniques, as well as the hierarchies of fundamental tasks that delineate the units of interaction in a user interface. We briefly examine a number of models and theories that are commonly used to evaluate human performance with interaction techniques and devices. We discuss how to transform input signals for use in applications and analyze some factors and considerations for the design of appropriate feedback in response to inputs. The chapter then takes a brief sojourn into the specialized realm of discrete symbolic entry, including mobile and keyboard-based text entry. In Sections 6.11 and 6.12, we consider some higher-level topics such as input modalities and general strategies for interaction that transcend particular input devices, as well as the impact on input techniques of a diverse and evolving ecosystem of form factors. We conclude with some thoughts about future trends and opportunities in this field.

6.2 UNDERSTANDING INPUT TECHNOLOGIES

Input devices sense physical properties of people, places, or things. But any treatment of input devices without considering corresponding visual feedback is like trying to use a pencil without paper. This chapter treats input technologies at the level of interaction techniques, which provide a way for users to accomplish tasks by combining input with appropriate feedback. An interaction designer must consider the physical sensor, feedback presented to the user, the ergonomic and industrial design of the device, and the interplay between all the interaction techniques supported by a system, as well as the interplay between a specific device and other devices in its surrounding digital ecology.

A designer who understands input technologies and the task requirements of users has a better chance of designing interaction techniques that match a user's natural workflow and that take appropriate advantage of a user's innate abilities. Making an optimal choice for tasks in isolation often leads to a poor design, so the designer must weigh competing design requirements as well as transitions between tasks.

6.2.1 Is This Input Method Natural?—Why This Is an Ill-Posed Question

The word natural can be applied to interactions with systems. A reasonable operational definition for a natural UI is that the experience of using a system matches expectations such that it is always clear to the user how to proceed and only a few steps (with a minimum of physical and cognitive effort) are required to complete common tasks. It is a common mistake to attribute the naturalness of a product to underlying input technology. A touch screen, or any other input method for that matter, is not inherently natural.

A common naive reaction to direct-touch and gestural input, for example, is to suggest that it is "more natural" than other input methods because interactions can be accomplished by hand gestures that correspond to movements that users naturally make as a result of their everyday real-world experiences. Wobbrock, Morris, and Wilson (2009) explored this hypothesis. They presented user-study participants with "before" and "after" images depicting a particular interaction, such as moving an object, duplicating an object, or changing the color of an object. They then asked the participant to perform the gesture they believed would create that change in the system. Three of their experimental tasks are summarized in Figure 6.2.

You can conduct this experiment on yourself: Given a multitouch screen, what gesture do you expect will transform Example 1 in Figure 6.2 from its before state to its after state? For Example 1, almost everyone suggests the same action as you likely just envisioned, that of dragging the square with a single finger.

For Example 2, results are more equivocal. You probably have to think a bit longer before deciding on an appropriate gesture. If we present this example to multiple users, there is some agreement across users, but there are also a number of different gestures that users choose to naturally indicate the duplication of an object.

For Example 3, all bets are off. There is almost no agreement across a set of users as to a natural manipulative gesture to change the color of an object.

What this exercise shows is that *there is no inherently natural set of gestures* for performing anything beyond a couple of the most commonplace multitouch manipulations. The gestures that users suggest for a manipulation can be used as a source of design inspiration, but this observation does not lead to a set of gestures that is consistent or inherently more natural than any other set.

6.2.2 Terminology: Input Device versus Interaction Technique versus Conceptual Model versus User Experience

We take a brief pause in this section to clarify the terminology we use. To some extent we can use devices, techniques, models, and experiences as interchangeable terms, but what is more important is for the designer to think about these things at different conceptual levels so as to consider a holistic view of interactive systems. The terminology used is as follows:

Input device: An input device is a transducer that senses physical properties of people, places, or things. What we normally conceive of as an input device (such as a mouse) is often a collection of transducers (Card, Mackinlay, and Robertson 1990, 1991), such as a relative (x, y) motion sensor, physical buttons, and a wheel for scrolling.

Conceptual model: A conceptual model is a coherent model that users visualize about the function of a system—what the system is, how it works, and how it will respond to users' input. Thus users can determine what input they need to give to the system to achieve a desired result. Conceptual models can be taught, but they are continually refined throughout a user's interaction with a system, given its responses to the user's input. For example, the core conceptual model of a GUI is the point-and-click metaphor of moving the tracking symbol on top of objects on the screen and then acting on them by clicking or dragging the mouse. Likewise, the desktop metaphor of folders and files is a higher-level conceptual model of how information is stored and retrieved in a computer.

Interaction technique: An interaction technique is the fusion of input and output, consisting of all hardware and software elements, that provides a way for a user to accomplish a task for a particular conceptual model. For example, pinch-to-zoom has become a de facto standard for touch-screen devices, just as clicking and dragging the mouse as a way to move items is a staple of the desktop metaphor. It is important to remember that the cursor itself is a single element of an interaction technique and that this is just one of many possible ways to interact using a relative pointing device. Interaction techniques typically

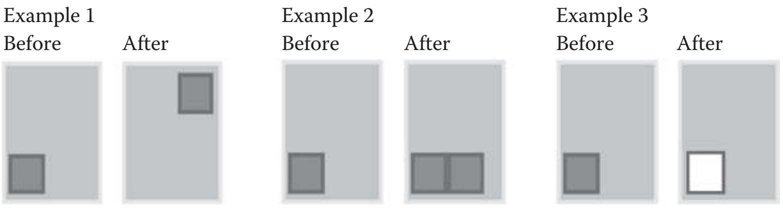

FIGURE 6.2 Before–after pairs for three example gestures that a user performs on a hypothetical multitouch system. What touch gesture would you expect transforms each example from its before state to its after state?

vary across input devices based on the strengths the device's sensing capabilities, the ability to readily incorporate *state transitions* such as button presses into the design of the device, and the user's physical abilities and hand comfort when using the device.

User interface: A user interface is the representation of a system—the summation of all its input devices, conceptual models, and interaction techniques—with which a user interacts. It is the responsibility of the user interface to represent and reinforce the user's conceptual model of the system in concert with the input device and interaction techniques, as well as presenting affordances and constraints that make it clear to the users how to achieve key tasks. User interfaces, despite being stereotyped as GUIs, also include auditory, tactile, and kinesthetic qualities, even if such secondary feedback results only from the passive mechanical feedback from physical input devices.

User experience: User experience is the broad array of outputs perceived and inputs given by a user when interacting with a user interface, as well as the higher-level goals, cognitive states, emotions, and social interactions that such experiences support and engender.

6.2.3 Input Device Properties

The variety of pointing devices available is bewildering, but a few common properties characterize the important characteristics of most input sensors. These properties help a designer in understanding a device and in anticipating potential problems. We will first consider these device properties in general and then show how they apply to some common input devices.

Property sensed: Most devices sense linear position, motion, or force; rotary devices sense angle, change in angle, and torque (Buxton 1995c; Card, Mackinlay, and Robertson 1991). For example, touch screens sense the position of one or more fingers, mice sense motion (change in position), and isometric joysticks sense force. The property sensed determines the most appropriate mapping from input to output, or transfer function, for a device. Position-sensing devices are absolute input devices, whereas motion-sensing devices are relative input devices. A relative device, such as the mouse, requires visual feedback in the form of a cursor to indicate a screen location.

States sensed: Direct-input devices, such as touch screens, touchpads, and pen input devices, are unique in that they sense not only position but also contact events (i.e., finger-down and finger-up events), an ability that traditional pointing devices lack (Hinckley and Sinclair 1999). Action of these devices cannot be treated as the equivalent of mouse-click events. This distinction is obvious, but its implications can be quite subtle in the design of interaction techniques even for a designer well versed in designing such devices. See Section 6.5 for further discussion.

Number of dimensions: Devices sense one or more input dimensions. For example, a mouse senses two linear dimensions of motion, a knob senses one angular dimension, and a magnetic tracker with six degrees of freedom measures three position dimensions and three orientation dimensions (Bowman et al. 2004; Hinckley et al. 1994a; Zhai 1998). A pair of knobs or a mouse with a scroll wheel senses separate input dimensions and thus forms a "1D + 1D" device (where 1D stands for one dimensional) or a "2D + 1D" (where 2D stands for two dimensional) multichannel device, respectively (Zhai, Smith, and Selker 1997).

Device acquisition time: The average time to move one's hand to a device is known as acquisition time. Homing time is the time to return from a device to a "home" position (e.g., return from mouse to keyboard). The effectiveness of a device for pointing tends to dominate acquisition time (Douglas and Mithal 1994). Thus, integration of a pointing device with the keyboard may not improve overall performance, but evaluations must still assess any influence of acquisition times (Dillon, Eday, and Tombaugh 1990; Hinckley et al. 2006) to be certain that a comparison between the devices is fair. The elimination of acquisition time is a key advantage of touch interaction for mobile interactions, but of course some homing time is still required to bring one's hand into contact with the screen.

Other metrics: System designers must weigh other performance metrics also (Card, Mackinlay, and Robertson 1990), including pointing speed and accuracy, error rates, learning time, footprint and gain (Accot and Zhai 2001; MacKenzie 1995; Jellinek and Card 1990), user preference, comfort, and cost. Other important engineering parameters include sampling rate, resolution, accuracy, and linearity (MacKenzie 1995).

6.3 DIRECT-INPUT DEVICES

A direct-input device has a unified input and display surface. A mouse, by contrast, is an indirect-input device because the user must move the mouse on a surface (a desk) to indicate a point on another surface (the screen). Direct devices such as touch screens, or display tablets operated with a pen, are not necessarily easier to use than indirect devices. Direct devices often lack buttons for state transitions. Occlusion is also a major design challenge: The finger or pen covers the area where the user is pointing, so the user may not be able to see all the options in a pop-up menu, for example. The hand and arm may also occlude visual feedback, dialogs, status indicators, and other controls. Indirect input scales better to large interaction surfaces, since it requires less body movement and also allows interaction at a distance from the display.

Since direct input represents a major trend in both research and industry, we give a detailed treatment here of a number of design dimensions and considerations for direct devices with a more brief assay on indirect devices in Section 6.4 that follows.

In addition to having unified input and display surfaces, with direct-input devices a system's feedback for user input is typically localized to the physical points of contact. Some direct-input devices can sense only a bare finger. Others such as resistive touch screens can sense either a plastic stylus or a bare finger but cannot distinguish one type of contact from the other. Transparent electromagnetic digitizers, such as those found on tablet personal computers, require the use of a special pen and cannot sense touch unless the system integrates a second touch-sensitive digitizer. Some commercially available digitizers based on capacitive coupling can sense a special pen and simultaneously differentiate it from multitouch inputs (Engelhard 2008).

Since there is not yet any "perfect" pen, touch, or combined pen + touch technology, a few of the key questions to ask are as follows:

- Can a digitizer sense touch? If so, is it a "soft-touch" screen or is a definite contact pressure required to sense touch? If significant pressure is required, it makes touch-based dragging operations more fatiguing and more difficult for the user to perform successfully (e.g., without the finger skipping). On the flip side many "hard-touch" screens can be used while the operator wears gloves, making such screens well suited to demanding working environments, whereas capacitive touch screens require contact from bare fingers in order that touch is sensed.
- How many points of contact can a digitizer sense? Many current devices are limited to two to four touch points, which limits the multitouch or hand palm contact signals that a device can reliably sense. In some cases, two-point devices have further limitations (such as line-of-sight issues with optical sensing techniques or reporting only the bounding box of the touch points, rather than the actual touch points themselves, with some touch-screen technologies). On some devices, large-contact-area touches, such as those from a thumb or palm, may be reported as two or more points of contact, which introduces further complexities in the software and interaction design. Likewise, closely spaced contacts may merge into a single contact on many touch screens producing further potential difficulties and technical limitations. Such complexities often result from the use of sophisticated filtering techniques, firmware, and drivers rather than the hardware per se, but nonetheless they pervade commercially available touch devices.
- Can the touch contact area or pen pressure be sensed and reported to applications, or is each contact reduced to a single (x, y) point? If contact area is sensed can applications access the actual image or contour of the contact, or is it only reported as a bounding ellipse (or other simplified representation) of the contact?
- If a stylus is supported at all is a special pen required, or can contact from any hard object be sensed? If a special stylus is required, keep in mind that it is not a matter of *if* but rather of *when* the user loses the stylus. Most special pens on the market are powered by inductive coupling, but some are active pens that require batteries.
- Can pen contacts be distinguished from touch contacts? Capacitive styli are available for many touch screens, although typically these inputs cannot be differentiated from ordinary finger contacts.
- Can pen contacts also be sensed while one is touching the device? Can touch still be sensed while the pen remains in the proximity of the screen? Many current devices stop reporting touch when the pen is in the range of the screen so as to reduce false inputs triggered by palm contact. Also, note that most digitizers can sense only a single pen at a time, and typically one pen cannot be distinguished from another (e.g., although some high-end Wacom display tablets have a "PenID" feature that can distinguish various types of pens in order to support facile swapping between custom brush settings, e.g.).

Standard data sheets for digitizers often leave these questions unanswered, and it may be unclear what brand or type of digitizer an integrated product uses, which makes it difficult to ascertain exactly what a particular device offers. Buyers beware, and ask a lot of questions. On the flip side, if you are designing an application without direct knowledge of the underlying hardware that a user will actually be using to experience your software, then you must somehow choose a design path that takes into account all these possible hardware manifestations. This is akin to successfully guiding a single thread through a gauntlet of needles in the dark. Welcome to the breadth–depth dichotomy.

We stated in Section 6.1 that every input modality is best for something and worst for something else. Ultimately it is the designer's job to know what to use when, for whom, for what, and why. From a technology standpoint, much of this is based on a nuanced understanding of the properties of an input modality. To offer insight into the main issues for commonplace devices, Table 6.1 summarizes the interaction properties shared by pen and touch. We do not characterize these properties as pros and cons to accentuate our belief that almost any property of a device when used appropriately can be advantageous in a design. A number of recent systems that explore combined pen and touch input epitomize this approach to design (Hinckley, Pahud, and Buxton 2010; Hinckley et al. 2010; Zeleznik, Bragdon, Ko et al. 2010;

TABLE 6.1
Comparison of Several Key Properties Shared by Touch and Pen Input Devices

Property	Pen	Touch
Contacts	1 point A single well-defined point	1–10+ contact regions Often with shape information (Cao et al. 2008)
Occlusion	Small (pen tip) But hand still occludes screen	Moderate (fat finger) to large (pinch, palm, whole-hand gestures)
Precision	High Tripod grip/lever arm affords precision, writing, and sketching tasks.	Moderate Nominal target size for rapid acquisition via touch is about 10–18 mm^2. (Vogel and Baudisch 2007) (Sears 1993) (Lewis, Potosnak, and Magyar 1997)
Hand	Preferred hand	Either hand/both hands
Elementary inputs	Tap, drag, draw path	Tap, hold, drag finger, pinch
Intermediary	Mechanical intermediary Takes time to unsheathe the pen. Pen can be forgotten.	None: bare-handed input Nothing to unsheathe, nothing to lose. No lever arm
Acquisition time	High (first use: unsheathe the pen) Moderate on subsequent uses: pen tucked between fingers	Low No mechanical intermediary to acquire
Buttons	Barrel button, eraser (some pens)	None
Activation	Nonzero	Zero (capacitive touch)
force	Tip switch or minimum pressure	Note that resistive touch requires some force.
False inputs	Palm rejection: palm triggers accidental inputs, fingers drag on screen while writing, etc. This is a difficult problem. Designs must accommodate incidental palm contact when it inevitably occurs.	"Midas touch problem" Fingers brush screen, finger accidentally rests on screen while holding the device, etc. "Chess player's syndrome" Device senses touch when none occurs. Common problem on optical touch screens.

Source: Hinckley, K., M. Pahud et al., Paper read at Society for Information Display 2010 Digest, 2010; Hinckley, K., K. Yatani et al., Paper read at 2010 Symposium on User Interface Software and Technology, New York, 2010. With permission.

Brandl et al. 2008; Brandl et al. 2009; Frisch, Heydekorn, and Dachselt 2009). Beyond pen and touch, we believe this is a valuable perspective for a broad class of input devices, modalities, and form factors, as exemplified by other research studies on multimodal input (Bolt 1980; Cohen et al. 1997; Tse et al. 2008; Levine and Ehrlich 1991).

This limited survey shows that pen and touch, although sharing common ground as direct-input modalities, exhibit many important differences, and these again differ substantially from the properties of indirect pointing devices such as the mouse. However, also keep in mind that Table 6.1 is just a summary of some common properties of these devices and the properties of specific pen or touch devices can vary widely, as we now discuss.

Single touch versus multiple touch: Devices capable of detecting touch are often classified colloquially as either touch or multitouch devices, but there is subtle distinction between the two. Single-touch devices, such as traditional resistive touch screens, are adequate for emulating a mouse and for detecting most of the gestures employed in commercial multitouch software today (Potter, Weldon, and Shneiderman 1988).

Multitouch devices can be further classified by the number of finger contacts they are able to detect and track. Multiple contacts are required for a user to perform true multitouch gestures, such as pinch-to-zoom or multifingered grabbing (Krueger, Gionfriddo, and Hinrichsen 1985; Moscovich and Hughes 2006). Still more contacts must be tracked to enable multiple users to perform multitouch gestures at the same time, as desired for tabletop interfaces, for example.

Many devices reputed to be multitouch can, in fact, only sense limited information about touch contacts, such as the bounding box (rather than the actual *x*, *y* coordinates) of the touches. This class of devices includes the DiamondTouch table (Dietz and Leigh 2001) and some optical touch-sensing technologies. These are sometimes referred to as "1.5D" devices since they do not support two fully independent degrees of freedom for each touch point. Nonetheless, such devices can implement a wide array of multitouch interaction techniques (Wu and Balakrishnan 2003; Forlines and Shen 2005).

Pressure and contact area sensing: Pressure is the measure of force that a user exerts on an input device.

Pressure sensing is often confused with contact area sensing. True pressure sensing is supported by many pen-operated devices, but typically only contact area can be sensed by touch-screen interfaces. The two are related; although contact area is a useful proxy of pressure, it cannot be treated as a true equivalent of pressure for the purposes of interface and interaction technique design. For example, a woman with long fingernails who touches a screen will produce a touch with a large contact area, even though the actual force applied may be very light. With contact area, rather than relying on an absolute degree of contact one should emphasize on *changes in contact area* as a more controllable parameter that users can modulate, such as by rolling one's finger in contact with the display (Benko, Wilson, and Baudisch 2006). Contact area has been demonstrated to add states to touch devices (Forlines and Shen 2005), allowing a type of hover state when touching lightly and then committing to a particular action when the user presses more forcefully. Used as a continuous parameter, contact area can enable a continuous control of the thickness of a paint stroke or set the *z*-order of on-screen objects (Davidson and Han 2008), for example.

However, some touch devices do offer true pressure-sensing capability. For example, some laptop touchpads include sensors that measure the force exerted on the pad. In multitouch systems, such approaches typically provide only an aggregate of forces across all contact areas rather than an independent measure of pressure for each touch.

Users are able to perceive up to seven distinct levels of pressure, provided there is suitable visual feedback (Ramos, Boulos, and Balakrishnan 2004). Pressure can then be used for a variety of interaction techniques such as mode switching (Agarawala and Balakrishnan 2006) or continuous adjustment of parameters while drawing a pen stroke (Ramos and Balakrishnan 2005; Ramos, Boulos, and Balakrishnan 2004; Ramos and Balakrishnan 2006).

Hand postures and shape-based input: Devices that can sense not only points of contact but also shape of the contact region can allow for richer input (Krueger 1991; Cao et al. 2008). Researchers have also used the sensed contact region to compute a user's perceived point of contact for high-precision touch interaction. For example, Holz and Baudisch (2010) used a fingerprint sensor to determine a finger's contact, orientation, and position and mapped these parameters to more precisely determine a user's intended touch location. Subtler uses of shape-based input have demonstrated the advantage of using a geometric representation of the contact area instead of the traditional reduction of all touch information to a single point, so as to enable rapid interaction with multiple widgets (Moscovich 2009) or to support greater expressiveness from each touch (Cao et al. 2008; Zeleznik, Bragdon, Adeputra et al. 2010). A challenge for the effective and practical use of shape-based touch interaction is the lack of a commonly accepted input event and interaction model for software development and user interface design. It remains difficult to develop practical multitouch applications that wander too far from the path followed by the traditional point-based hit testing model of interaction. Probabilistic approaches offer one potential solution to this dilemma (Schwarz et al. 2010).

In-air hand postures and direct sensing beyond the display: Recent approaches have also demonstrated the utility of in-air hand postures as opposed to those that occur while in contact with a device (Grossman, Wigdor, and Balakrishnan 2004; Hilliges et al. 2009; Wilson and Benko 2010). For example, the SecondLight system can see through the display and can project both light and sense interactions in the volume above the display itself. Using this system, Hilliges (Hilliges et al. 2009) used cameras to detect simple postures both in air and when in contact with the display, using the moment of contact as a state transition to delimit interactions. This enables both the user and the system to agree on, and differentiate between, hand gestures that occur in contact with the display as opposed to incidental movements of hands in the air. Thus, detecting and differentiating system response based on physical contact with the screen delivers an experience with discrete and controllable states, even though the device perceives similar hand movements in either case. Wilson and Benko (2010) further explore the possibilities of this space using multiple depth cameras and projectors.

Furthermore, this demonstrates once again how direct input is about much more than touch alone: The positions of users relative to the display (Ballendat, Marquardt, and Greenberg 2010), motions of their hands above the display (Tang et al. 2010), and posture of the hand as it comes into contact with the display (Holz and Baudisch 2010) are all forms of direct input that can extend and enrich user interfaces. What is critical to note about these examples is that there is no attempt to use in-air gesturing to replace the mouse, simulate text entry on a virtual keyboard, or replace established touch gestures. Rather, the aforementioned examples leverage the distinct properties of spatial sensing to provide new capabilities that are differentiated well from direct touch and other inputs.

Finger differentiation, user differentiation, and user identification: Some touch devices are able to determine which of a user's fingers are in contact with the display. For example, the Microsoft Surface images enough of the hand in proximity to the display that it is often possible to determine which fingers of a hand are in contact with the display (Lepinski, Grossman, and Fitzmaurice 2010). Some systems can identify the source of contacts, such as those using capacitive coupling techniques (Dietz and Leigh 2001), so that a touch from one user can be distinguished from the touch of another user. User identification is a stronger form of differentiation that persists in the distinction between multiple users across sessions. One way to achieve this is through the sensing and identification of a user's fingerprints while he or she is touching a display (Holz and Baudisch 2010), although current demonstration systems cannot achieve such sensing in real time. Computer vision technologies have also been demonstrated, which can identify users or distinguish which fingers of a user's hand are touching the display, based on visual features.

Parallax: Parallax error is a mismatch between sensed input position and apparent input position due to viewing angle. *Display parallax* is the displacement between the sensing and display surfaces. Of course zero parallax is ideal, but a rule of thumb used by industry practitioners is that if the display parallax is less than about 2 mm then its practical impact is not that significant. *Transducer parallax* is caused by any additional parallax error that may result from the offset between the tip of a mechanical intermediary and the actual component that is sensed, such as the coil that sits higher up in the body of Wacom electromagnetic pens. If tilt angles of the pen are known, this offset can be corrected.

Latency: Latency is a problem for all interactive systems, but its effects are particularly insidious for direct-input devices because any discrepancy between the actual position of fingers or the pen and the position currently sensed by a system becomes immediately obvious to the user. Latency is the end-to-end measure of the time elapsed between the moment a physical action is performed by a user and the moment the system responds to it with feedback that the user can perceive. This round-trip time between cause and effect comes from many sources; it is difficult to minimize and impossible to eliminate in practical systems design. Sources of latency include hardware sampling rate, time a system takes to report samples to the operating system as well as report events to applications, time required by software to compute results, time required to refresh the frame buffer, and the physical screen's rate of update to make the results visible to the user. Seow (2008) offers a detailed study on the effects of latency on user perception. In experiments, latency typically exhibits strong negative effects on user performance starting at about 100 milliseconds (Card, Mackinlay, and Robertson 1991; MacKenzie and Ware 1993). In modern direct-input systems with pen or touch input, latencies far less than 100 milliseconds must be achieved (Card, Mackinlay, and Robertson 1991; MacKenzie and Ware 1993) if one wishes users to perceive the interface as crisp and responsive.

6.4 INDIRECT-INPUT DEVICES

An indirect-input device is one that does not provide input in the same physical space as the output. Indirect devices eliminate occlusion of the screen by the user's hand and fingers. However, typically they require more explicit feedback and representation of the input device (such as a cursor), intended target on the screen (such as highlighting icons when the cursor hovers over them), and current state of the device (such as whether a button is held or not).

Virtual devices: Most operating systems treat all input devices as virtual devices, which tempts one to believe that input devices are interchangeable; however, details of what the input device senses, how the device is held, the presence or absence of buttons, and many other properties can significantly impact the interaction techniques—and hence, the end-user tasks—that a device can effectively support. Although the virtual devices abstraction has been a successful strategy in addressing the breadth–depth dichotomy for indirect devices, largely because the tracking symbol serves as an intermediary between the type of device and the interaction techniques that it supports, it is becoming increasingly clear that the virtual devices abstraction is far less satisfactory when extended to direct-input devices.

Indirect digitizing tablets and absolute versus relative input: An absolute input device senses the position of an input and passes this message along to the operating system. Relative devices sense only changes in position. Digitizing tablets can operate either in absolute mode, with a fixed control-to-display (C:D) gain between the tablet surface and the display, or in relative mode, in which the tablet responds only to the motion of a stylus or finger. If the user touches the stylus or finger to the tablet in the relative mode, the cursor resumes motion from its previous position; in absolute mode, it jumps to the new position. Absolute mode is generally preferable for tasks such as drawing, handwriting, tracing, or digitizing, but relative mode may be preferable for traditional desktop graphical user interaction tasks such as selecting icons or navigating through menus. Digitizing tablets thus allow coverage of many tasks (Buxton, Hill, and Rowley 1985), whereas mice can operate only in relative mode.

Mixing indirect and direct inputs: It is possible to emulate the properties of an indirect-input device using a direct one, simply by offsetting the device's apparent input target from its physical location. This leads to an interesting class of hybrid techniques that mix direct and indirect representations within the user experience of a direct-input device (Buxton, Hill, and Rowley 1985; Brown, Buxton, and Murtagh 1990; Sears and Shneiderman 1991; McCallum and Irani 2009). For example, HybridPointing provides a cursor that remains directly beneath an input stylus, but can also decouple to allow pointing at distant targets on very large displays without great physical movement (Forlines, Vogel, and Balakrishnan 2006). Such techniques also support high precision pointing on touch screens (Vogel and Baudisch 2007).

6.4.1 Brief Tour of Indirect-Input Devices

The following tour discusses important properties of several common indirect-input devices, such as mice, joysticks, touchpads, trackballs, and stand-alone touch tablets and pen digitizer tablets:

Touchpads: Touchpads are small, touch-sensitive tablets often found on laptop computers. Touchpads usually use relative mode for cursor control because they are too small to map to an entire screen, but most touchpads also have an absolute mode to allow interactions such as character entry or sliding along the edge of the pad to scroll. The small size of touchpads necessitates frequent clutching, and touchpads can be awkward to use while holding down a button unless the user employs his or her other hand. Traditionally, touchpads have supported clicking by recognizing tapping or double-tapping gestures, but accidental contact (or loss of contact) can erroneously trigger such gestures (MacKenzie and Oniszczak 1998). To reduce these types of problems, some modern touchpads often include a microswitch underneath the pad, so that pressing down the pad produces a mechanical click.

Multitouch pads: Modern touchpads are increasingly becoming multitouch devices as opposed to the single-touch models that were commonplace in the past. The multitouch interaction model for indirect touchpad typically differs from that for direct-touch displays. If both the devices are natural multitouch devices, then why are two different interaction models necessary? The indirect touchpad must support relative cursor control and typically single touch is mapped to move the cursor. Thus two fingers are required to scroll or pan documents. With a direct-touch input device, cursor tracking is not necessary and hence single touch can pan and scroll. This underscores why characterizing a device as simply a touch device is not sufficient to understand its properties. Furthermore, it underscores why the assumption that touch inherently produces a natural interface is a fallacy. Finally, this demonstrates why an inconsistency between two related devices—here, an indirect- versus a direct-touch device—is often necessary to produce a user experience that feels logically consistent to the user given the device and form factor at hand.

Indirect multitouch pads can also support additional novel techniques such as targeting many degrees of freedom to a single cursor position or representing each point of contact with a separate cursor (Moscovich and Hughes 2006). Such models have also been explored in the context of mice augmented with multitouch input surfaces (Villar et al. 2009; Benko et al. 2010). An alternative to cursors that can be useful on both direct and indirect devices is to present a "shadow" of the whole hand (Krueger 1991; Wigdor, Forlines et al. 2007a; Tang et al. 2010).

Mice: Douglas Englebart and colleagues (English, Englebart, and Berman 1967) invented the mouse at the Stanford Research Institute, Menlo Park, California. More than 40 years later, use of the mouse persists because its properties provide a good match between human performance and the demands of graphical interfaces (Balakrishnan et al. 1997). For typical pointing tasks on a desktop computer, one can point with the mouse about as well as with the hand (Card, English, and Burr 1978). Because the mouse stays put when the user releases it (unlike a stylus, e.g.), the user can reacquire it quickly and designers can integrate multiple buttons or other controls on its surface. Users exert force on mouse buttons in a direction orthogonal to the mouse's plane of motion, thereby minimizing inadvertent motion. Finally, with mice all the muscle groups of the hand, wrist, arm, and shoulder of users contribute to pointing, allowing high performance for both rapid, coarse movements and slow, precise movements (Guiard 1987; Zhai, Buxton, and Milgram 1996). These advantages suggest the mouse is hard to beat; it will remain the pointing device of choice for desktop graphical interfaces for many more years to come.

Trackball: A trackball senses the relative motion of a partially exposed ball in two degrees of freedom. Trackballs have a small working space (footprint), afford use on angled surfaces, and sometimes are weighted to afford spinning the ball with physical inertia. Trackballs may require frequent clutching movements because users must lift and reposition their hand after rolling the ball through a short distance. The buttons are located to the side of the ball, which can make them awkward to hold while rolling the ball (MacKenzie, Sellen, and Buxton 1991). A trackball engages different muscle groups compared to a mouse, offering an alternative for users who experience discomfort when using a mouse. Trackballs are also well suited to non-preferred-hand input in combination with a mouse (Bier et al. 1993).

Isometric joysticks: An isometric joystick (e.g., the IBM Trackpoint) is a force-sensing joystick that returns to center when released. Most isometric joysticks are stiff, offering little feedback of the joystick's displacement. The rate of cursor movement is proportional to the force exerted on the stick; as a result, users must practice in order to achieve good cursor control. Isometric joysticks are particularly appealing when space is at a premium (Douglas and Mithal 1994; Rutledge and Selker 1990; Zhai, Smith, and Selker 1997).

Isotonic joysticks: Isotonic joysticks sense the angle of deflection. Some hybrid designs blur the distinctions between isometric and isotonic joysticks, but the main questions that characterize the design space are the following:

- Does the joystick sense force or angular deflection?
- Does the stick return to center when released?
- Does the stick move from the starting position?

For a more thorough discussion on the complex design space of joysticks, we recommend the study by Lipscomb and Pique (1993).

6.4.2 Summary of and Perspective on Indirect-Input Devices

Although one may feel that many of the indirect-input devices are antiquated in the context of modern system design trends, such devices still have their uses and can offer important lessons to a student of HCI. Furthermore, often consoles or workstations for dedicated and highly specialized tasks, such as driving a car, still incorporate many creative combinations of such devices in conjunction with physical buttons, switches, and dials. To anyone who has attempted the dangerous exercise of operating a touch-screen navigation system while driving, it should come as no surprise that rich spatial arrangements of physical input devices with complementary and specialized roles offer a highly effectively solution while placing fewer demands on an operator's visual attention (e.g., Fitzmaurice, Ishii, and Buxton 1995). Hence, combinations of indirect-input devices are ideally suited for many applications and remain important to understand for interaction designers worthy of their name.

6.5 INPUT DEVICE STATES

Any device that returns a coordinate can be considered a pointing device; but there remains a critical missing ingredient: the *event* that a device generates, such as when a finger comes into contact with a screen, a button is depressed on a mouse, or a pen leaves the proximity of a digitizer. These events trigger state transitions, which in turn are the building blocks of interaction techniques. All of this seems blatantly obvious until one realizes that there are subtle discrepancies between the events and properties sensed by various devices while in different states. This innocent façade of greenery conceals a nightmarish thicket that can entangle the designer in stinging nettles and poisonous ivies of failed or severely compromised interaction techniques.

There is a fundamental mismatch between the demands of traditional graphical interfaces and the states and events that can be sensed by devices such as touch screens, touchpads, and pen-operated devices, which makes it difficult for such devices to support the full set of desktop GUI primitives, including click, drag, double-click, and right-click. There is no easy solution that does not involve design compromises. When considering such devices, to make device limitations and differences concrete, diagramming all the states and transitions can be an enlightening exercise.

Input devices in general support three possible states (Table 6.2): (1) out-of-range, (2) tracking, and (3) dragging states. Practitioners refer to these as state 0, state 1, and state 2, respectively, of the three-state model (Buxton 1990b). This model is useful for understanding the relationship between events sensed by an input device and demands of interaction techniques.

The three-state model describes the mouse as a two-state device supporting state 1, the cursor-tracking state, as well as state 2, the dragging state (Figure 6.3). State 1 provides cursor feedback of the screen position on which the device

TABLE 6.2
Comparison of Several Key Properties Shared by Touch and Pen Input Devices

State	Description
0	Out of range: The device is not in its physical tracking range.
1	Tracking: Device motion moves only the cursor.
2	Dragging: Device motion moves objects on the screen.

Source: Hinckley, K., M. Pahud et al., Paper read at Society for Information Display 2010 Digest, 2010; Hinckley, K., K. Yatani et al., Paper read at 2010 Symposium on User Interface Software and Technology, New York, 2010. With permission.

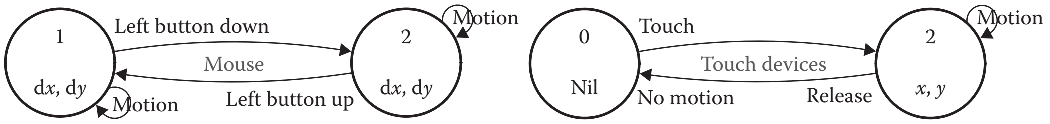

FIGURE 6.3 State-transition diagram for standard mouse and touch input devices. Each device senses two states, but critically not the same two states.

will act, whereas state 2 allows the user to drag an object by holding down the primary mouse button while moving the device. The mouse senses movement in both the tracking and dragging states, as represented by the (d*x*, d*y*) in each state in Figure 6.3 (left), which is shorthand to indicate relative motion tracking capability (Hinckley, Czerwinski, and Sinclair 1998).

Many touch-activated devices, such as touch screens and touchpads, are also two-state devices, but *they do not sense the same two states as the mouse* (Figure 6.3, right). For example, a mobile phone touch screen can sense a finger when it is in contact with the display; this is the equivalent of the mouse's dragging state (state 2). The touch screen can also sense when the finger is removed from the screen, but once the finger breaks contact this enters state 0 (out-of-range state), where no motion can be detected (emphasized by the annotation Nil in state 0 of Figure 6.3 [right]). Thus, although the mouse and the touch screen both sense two states, the lack of a second motion-sensing state on the touch screen means that it will be difficult to support the same interaction techniques as that of the mouse. For example, should sliding one's finger on the device move a cursor or drag an object? The designer must choose one; a touch-screen or touchpad device cannot support both behaviors at the same time.

If we add pens for tablet computers to the mix, we now have a third state: Many pens can sense when they enter or leave the proximity of the screen (Figure 6.4). But despite the addition of the third state, the input events sensed by the pen still differ from those sensed by the mouse, as well as those sensed by touch. Hence, all three devices are mutually incompatible in subtle ways and interactive techniques that attempt to support all these devices at the same time will likely encounter various inconsistencies and usability problems as a result.

Pen and touch devices often lack a button suitable for right-click, leading to the heavy use of awkward interface Band-Aids such as a touch-and-hold solution to invoke context menus. Even if a pen does include a barrel button, it is relatively slow to access as well as being prone to inadvertent activation (Li et al. 2005). The press-and-hold solution has become standard on mobile devices, but the time-out introduces an unavoidable delay. For rapid activation the time-out should be as short as possible, whereas to avoid inadvertent activation paradoxically the time-out must be as long as possible. A 500-millisecond time-out offers a reasonable compromise, but as most commercial devices assume that context menu invocation occurs only infrequently they use delays of about 1000 milliseconds to further tip the design balance toward reducing accidental activations. Techniques designed for pen-operated devices (Apitz and Guimbretière 2004; Kurtenbach and Buxton 1991a; Kurtenbach and Buxton 1991b; Moran, Chiu, and van Melle 1997) should afford rapid and unambiguous activation of one of several possible actions as fundamental building blocks (Hinckley, Baudisch et al. 2005) to avoid inefficient or highly modal interactions (Hinckley et al. 2006).

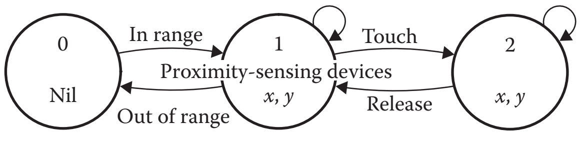

FIGURE 6.4 State-transition diagram for proximity-sensing devices, such as a pen on a tablet personal computer.

Similar issues plague other interaction modalities also, such as motion-sensing mobile devices (Hinckley, Pierce et al. 2005; Hinckley and Song 2010), camera-based tracking of the hands (Wilson and Oliver 2003), and spatial input devices (Hinckley et al. 1994). All these techniques require a method for users to move a device or their hands without accidentally performing an action, which speaks to the appeal of hybrid solutions such as the combination of spatial sensing with direct-touch input (Wilson and Benko 2010). State transitions thus form fundamental indications of intent that are essential to the construction of rapid, dependable, and habit-forming interaction techniques.

6.6 COMPOSITION OF USER TASKS

One way of reasoning about input devices and interaction techniques is to view a device or technique in light of the tasks that it can express. But what sort of tasks are there?

6.6.1 Elemental Tasks

Although computers can support many activities, at the input level some subtasks appear repeatedly in GUIs, such as pointing to a target on the screen or typing a character. Foley, Wallace, and Chan (1984) identified "elemental" tasks including text (entering symbolic data), select (indicating objects from a set of alternatives), position (pointing to a screen coordinate), and quantify (specifying an exact numeric value). However, if these are elemental tasks then where do devices such as global positioning system readers, cameras, and fingerprint scanners fit in? These offer new elemental data types of location, images, and identity, respectively. Elemental tasks are difficult to fully enumerate, because advances in technology continue to yield data types that enable new tasks and scenarios of use. Furthermore, the perspective of what tasks are elemental depends in part on the input devices, as well as the interaction design, through which an interface expresses them.

6.6.2 Compound Tasks and Chunking

A fundamental problem with the elemental task approach is that the level of analysis for elemental tasks is not well defined. For example, a mouse indicates an (x, y) position on the screen, but an Etch A Sketch separates positioning into two subtasks by providing a single knob for x and a single knob for y (Buxton 1986b). If position is an elemental task, why must we subdivide this task for some devices but not others? One way to resolve this puzzle is to view all tasks as hierarchies of subtasks (Figure 6.5). Whether or not a task is

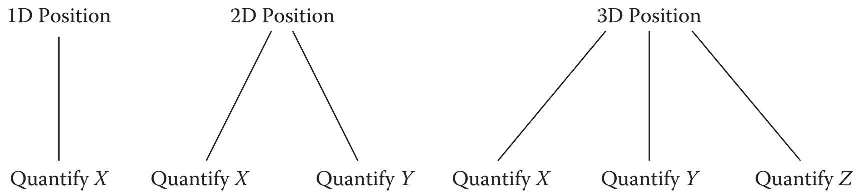

FIGURE 6.5 User tasks conceived as unitary actions, or as assemblies of subtasks.

elemental depends on the input device being used: The Etch A Sketch supports separate *quantify X* and *quantify Y* tasks, whereas the mouse supports a compound *2D position* task (Buxton 1986). Now, if a user wishes to indicate a point on the screen, the integrated (*x*, *y*) position of the mouse offers the best solution. But if the user wishes to precisely specify an *x* coordinate independent of the *y* coordinate, then the Etch A Sketch more directly expresses this concept.

From the user's perspective, a series of elemental tasks may seem like a single task. For example, scrolling a web page to click on a link could be conceived as an elemental 1D positioning task followed by a 2D selection task or it can be viewed as a compound navigation/selection task (Buxton and Myers 1986b). An interaction technique can encourage the user to work at the higher level of the compound task, for example, by scrolling with one hand while pointing to the link with the other hand. This is known as "chunking."

These examples show that the choice of device influences the level at which a user is required to think about the individual actions that must be performed to achieve a goal. The design of input devices and interaction techniques can help to structure the interface in such a way that there is a more direct match between user's tasks and the low-level syntax of individual actions that must be performed to achieve those tasks. The choice of device and technique thus directly influences the steps required of the user and hence the apparent complexity of an interface design (Buxton 1986).

6.6.3 Phrasing

Most of the examples of chunking mentioned in Section 6.6.2 revolve around the integration of multiple degrees of freedom to support higher-level tasks. Another implement in the toolbox of the interface designer to afford the design of compound tasks is *phrasing*, which is the use of muscular tension to maintain a temporary state that "glues together" multiple subtasks (Buxton 1995). A good example is that of a pull-down menu for which holding down the mouse button integrates the tasks of activating the menu, sliding the pointer to the desired menu item, and then lifting the button to select the menu item. The muscular tension from maintaining contact with a touch screen or from holding down a button on a mouse provides continuous and salient proprioceptive feedback to the user that the system is in a temporary state, or mode, where movement of the input device navigates the menu instead of moving the cursor. Another key property of phrasing is that closure is inherent in the means used to introduce the phrase: Simply releasing the mouse button returns the system to its default state. Obviously, this approach has its limits as the user cannot maintain muscular tension for very long without discomfort and fatigue, but it has been shown to reduce mode errors for frequent and temporary mode switches (Sellen, Kurtenbach, and Buxton 1992). Although the preceding example of the pull-down menu requires a mouse button, phrasing can also be achieved on direct-input devices by maintaining finger contact with a touch screen (Hinckley et al. 2010) or by holding a pen against a digitizer while articulating a compound gesture (Kurtenbach and Buxton 1991; Apitz and Guimbretière 2004).

6.7 EVALUATION AND ANALYSIS OF INPUT DEVICES

Beyond standard usability engineering techniques, there are several techniques tailored to the study of input devices and interaction techniques. Representative tasks (Buxton 1995), such as target acquisition, pursuit tracking, freehand drawing, and dragging versus tracking performance (MacKenzie, Sellen, and Buxton 1991), can be used to formally or informally evaluate devices. Here, we focus on formal analysis using Fitts's law, the steering law, and the keystroke-level model (KLM), but we begin with a high-level perspective on how to honestly evaluate interaction techniques in general.

6.7.1 Evaluating the True Cost of a Technique in the Context of Surrounding Operations

When evaluating an interaction technique, one must fully consider the true cost to invoke a command (Dillon, Eday, and Tombaugh 1990) as well as the context of surrounding actions that are necessary to set up and recover from a particular action (Appert, Beaudouin-Lafon, and Mackay 2004; Hinckley et al. 2006). Commands that act on a selection are one example: The interaction technique used to select objects can influence how effectively one can act on the selection (and vice versa). Indeed, if one views selection–action phrases as a compound interaction technique rather than studying selection in isolation from command activation, new approaches that optimize a compound task may become possible (Kurtenbach and Buxton 1991; Hinckley, Baudisch et al. 2005; Apitz et al. 2004). A discussion of which techniques are most appropriate for a given task can be found in the work by Mackay (2002).

As another "toy" example, let us say that a user's task is to create a single square. What is the best interaction technique to perform this task? Tapping on a mechanical button is very fast. Perhaps the user could tap a button on a pointing device to create a square centered on the current cursor location. But what if the user must be able to produce circles, triangles, and polygons also? Creating a square from just a button tap will no longer work because one needs a way to specify the type of shape to be created. Perhaps depressing a button to invoke a menu where one can stroke in a particular direction to create the desired shape will work well (Kurtenbach and Buxton 1991). What this toy example makes clear is that one cannot optimize the *create square* interaction in isolation. One must also consider the set of surrounding interactions and tasks that together comprise the user interface.

We must consider this same perspective when evaluating interaction techniques. To extend the aforementioned example a bit further, what if the user also wishes to be able to make notations in free hand with the same input device? One then has to manage the mode of the device, with a *command mode* to create the shapes and an *inking mode* to make freehand strokes. The cost of invoking the create square command now depends on the total time taken to enter the mode, articulate the create square command, and then return back to the original mode. We cannot just measure the time it takes to draw the create square gesture. Even costs such as repositioning the pointer to the working area of the user interface or the user's mental preparation time to plan the next step must be considered. We cannot honestly evaluate the *true cost* of articulating the command without a full and diligent account of its entire lifecycle.

Furthermore, the context of surrounding operations can influence the efficacy of a technique as well. What if the user's task was to create many squares in a row? What if it was to interleave the creation of single squares with the drawing of freehand marks? Our view of which technique is most effective in a given context may depend on such usage patterns (Hinckley et al. 2006; Appert, Beaudouin-Lafon, and Mackay 2004; Guimbretiere, Martin, and Winograd 2005).

6.7.2 Fitts' Law

Fitts' law has been so widely applied to the design and evaluation of input devices that the mere mention of it is taken as a dirty word in some quarters. Nonetheless, it is a highly sensitive tool for evaluating input devices and techniques when used appropriately.

Fitts' law (Fitts 1954) is an experimental paradigm that has been widely applied to the comparison and optimization of pointing devices. Fitts' law is used to measure how effectively a pointing device can acquire targets on a screen. This law was first applied to the study of input devices by Card, English, and Burr (1978); it is now a standard for device comparisons (Douglas, Kirkpatrick, and MacKenzie 1999). Fitts' law can be applied to remarkably diverse task conditions, including rate-controlled devices (MacKenzie 1992a), area cursors (Kabbash and Buxton 1995), scrolling (Hinckley et al. 2002), and zooming (Guiard et al. 2001). For further guidance on conducting studies on Fitts' law, see the studies by Douglas, Kirkpatrick, and MacKenzie (1999); MacKenzie (1992); and Raskin (2000).

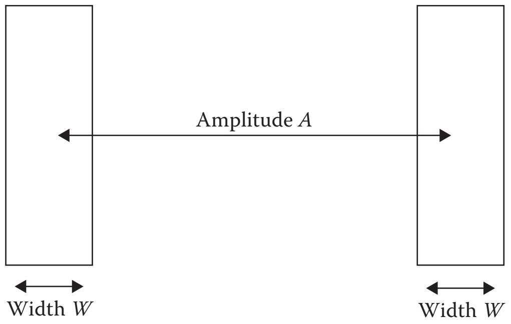

FIGURE 6.6 Canonical Fitts' task, with a pointing amplitude A between targets of width W.

The standard Fitts' task paradigm measures the movement time MT between two targets separated by amplitude A, with a width W of error tolerance (Figure 6.6). Fitts' law states that a logarithmic function of the ratio of A to W predicts the average movement time MT. The Fitts' law formulation typically used for input device studies is as follows:

$$MT = a/b \log_2\left(A/W + 1\right) \tag{6.1}$$

Here, the constants a and b are coefficients that fit to the average of all observed MT for each combination of A and W in the experiment. One calculates a and b via linear regression using a statistical package or spreadsheet. The constants a and b depend heavily on the exact task setting and input device, so be wary of substituting "typical" values for these constants or of comparing constants derived from different studies.

Psychomotor interpretations of Fitts' law have been proposed (Douglas and Mithal 1997). However, since the law does not characterize individual pointing movements but rather the central tendency of a large number of pointing movements, the law may simply reflect information-theoretic entropy (MacKenzie 1989).

6.7.3 Steering Law and Minimum Jerk Law

Steering a cursor through a narrow tunnel, as required to navigate a pull-down menu, is not a Fitts' task because steering requires a continuous accuracy constraint: The cursor must stay within the tunnel at all times. For a straight-line tunnel (Figure 6.7) of width W and length A, for example, the steering law models movement time as a linear function of A and W:

$$MT = a/bA/W \tag{6.2}$$

The steering law can alternatively model instantaneous velocity (Accot and Zhai 1997). A limitation of the law is that it models only the successful completion of a task; errors are not considered.

The minimum jerk law (Viviani and Flash 1995) characterizes the dynamics of motions that lack a continuous accuracy constraint. No one has yet formulated a universal law that handles varying accuracy constraints and curvature (Lank and Saund 2005).

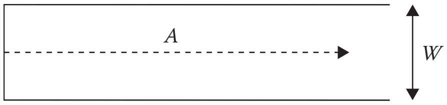

FIGURE 6.7 Steering through a tunnel of length *A* and width *W*.

6.7.4 Keystroke-Level Model and the Goals, Objects, Methods, and Selection Rules Analysis

The KLM is an engineering and analysis tool that can be used to derive a *rough estimate* of the time needed for expert users to complete a routine task (Card, Moran, and Newell 1980). To apply KLM, count the elemental inputs required to complete a task, including keystrokes, homing times to acquire input devices, pauses for mental preparation, and pointing at targets. For each elemental input, substitute a constant estimate of the average time required using the values from the study by Card, Moran, and Newell (1980) or by collecting empirical data (Hinckley et al. 2006), and sum them to yield an overall time estimate. The model assumes error-free execution, so it cannot estimate time for the problem-solving behaviors of novices; but it does employ several heuristics to model mental pauses (Raskin 2000).

The goals, objects, methods, and selection rules (GOMS) models extend KLM (John and Kieras 1996). Some GOMS models can account for user knowledge and the interleaving of tasks, but they are more difficult to apply than KLM. Both GOMS and KLM models are engineering tools that produce estimates for expert completion time of routine tasks. These models do not replace the need for usability testing and evaluation, but they do offer a means to assess a design without implementing software, training end users, and evaluating their performance (Olson and Olson 1990). Physical articulation times derived from KLM or GOMS analyses can also be used to interpret results of empirical studies (Hinckley et al. 2006).

6.8 TRANSFER FUNCTIONS: HOW TO TRANSFORM AN INPUT SIGNAL

A transfer function is a mathematical transformation that scales the data from an input device. Typically, the goal is to provide more stable and more intuitive control, but one can easily design a poor transfer function that hinders performance. Here we discuss some simple transformations that are commonly used for various interaction techniques, although the reader should be aware that a deep understanding of the topic requires expertise in control theory, which is well beyond the scope of this chapter (and indeed beyond the expertise of its authors):

Appropriate mappings: A transfer function that matches the properties of an input device is known as an appropriate mapping. For force-sensing input devices, the transfer function should be a force-to-velocity function; for example, the force one exerts on an isometric joystick controls the speed at which the cursor moves. Other appropriate mappings include position-to-position and velocity-to-velocity functions, used with tablets and mice, respectively.

A common example of an inappropriate mapping is calculating a velocity based on the position of the mouse cursor, such as automatically scrolling a document when selecting a large region of text that extends beyond a single screen. The resulting input is difficult to control, and this inappropriate rate mapping is only necessary because the operating system clips the cursor to the screen edge. A better solution would be to ignore the cursor position and instead use the relative position information reported by the mouse to directly control the change of position within the document.

Self-centering devices: Rate mappings suit force-sensing devices or other devices that return to center when released (Zhai 1993; Zhai, Smith, and Selker 1997). This property allows a user to stop quickly by releasing the device. The formula for a nonlinear rate mapping is as follows:

$$\mathrm{d}x = Kx^a \tag{6.3}$$

Where x is the input signal, dx is the resulting rate, K is a gain factor, and a is a nonlinear parameter. The best values for K and a depend on the details of a device and application, and appropriate values must be identified by experimentation or optimal search (Zhai and Milgram 1993). Many commercial devices use more complex mappings (Rutledge and Selker 1990).

Motion-sensing devices: Desktop systems use an exponential transformation of mouse velocity, known as an acceleration function, to modify cursor response (Microsoft Corp. 2002). Acceleration functions do not directly improve pointing performance, although they do reduce the footprint required by a device (Jellinek and Card 1990), which may lead to greater comfort or less frequent clutching (Hinckley et al. 2002).

Absolute devices: Absolute devices offer a fixed, 1:1 control-to-display mapping. This is common in touch-screen and pen inputs. Relative transfer functions may also offer a 1:1 mapping of movements.

Mixed-mode absolute/relative mappings: It is possible to temporarily violate the 1:1 control-to-display mapping of absolute devices such as touch screens by damping small motions to provide fine adjustments; large motions revert to an absolute 1:1 mapping (Sears and Shneiderman 1991). A drawback of such techniques is that cursor feedback in the tracking state becomes the default behavior of the device rather than dragging (Buxton 1990); but researchers have demonstrated ways to overcome this problem by only adjusting cursor position beneath the finger, automatically escalating precise pointing interactions to indirect input, or providing means for a user to quickly switch between direct and indirect modes (Benko, Wilson, and Baudisch 2006; Vogel and Baudisch 2007; Forlines, Vogel, and Balakrishnan 2006). Other hybrids of direct and indirect devices, with mixed relative and absolute input mappings, have also been explored.

6.9 FEEDBACK: WHAT HAPPENS IN RESPONSE TO AN INPUT?

From the technology perspective, one can consider feedback as active or passive. Active feedback is under computer control; passive feedback is not and may result from internal sensations within a user's own body, such as muscle tension from holding down a button, or from the physical properties of a device, such as the feel of clicking its buttons.

Good industrial design guides a user to the appropriate affordances for a device as soon as he or she holds it and perhaps even suggests its intended uses before the user even touches it (Norman 1990; Buxton 2007). Mechanical sounds and vibrations produced by a device provide positive feedback for the user's actions (Lewis, Potosnak, and Magyar 1997). The shape of the device and the presence of tactile landmarks can help users acquire and orient a device without having to look at it (Hinckley et al. 1998).

6.9.1 Proprioceptive and Kinesthetic Feedback

Internal sensations of body posture, motion, and muscle tension (Burdea 1996; Gibson 1962) may allow users to feel how they are moving an input device without looking at the device or receiving visual feedback on a display. This is important when the user's attention is divided between multiple tasks and devices (Balakrishnan and Hinckley 1999; Fitzmaurice and Buxton 1997; Mine, Brooks, and Sequin 1997). Muscular tension can help to phrase together multiple related inputs (Buxton 1995) and may make mode transitions more salient to the user (Hinckley et al. 2006; Raskin 2000; Sellen, Kurtenbach, and Buxton 1992; Hinckley et al. 2010).

6.9.2 Kinesthetic Correspondence

With time, users can adapt to any consistent mapping (Cunningham and Welch 1994) so long as the mapping between input and display is a planar reorientation. Despite this ability, graphical feedback on the screen ideally should correspond with the direction in which a user moves an input device (Britton, Lipscomb, and Pique 1978). If the user moves a device to the left, then the object on the screen should likewise move to the left; however, users can easily adapt to certain kinds of noncorrespondences: When the user moves a mouse forward and backward, the cursor actually moves up and down on the screen; if the user drags a scrollbar downward, the text on the screen scrolls upward. Researchers have also found that the dimensions of an input device should match the perceptual structure of a task (Jacob et al. 1994).

6.9.3 To Cursor or Not to Cursor (with Direct Input)

The cursor serves as a proxy for the user when engaged in indirect input. When using direct input, a user's finger or a mechanical intermediary functions as its own indicator for a well-calibrated system (Potter, Weldon, and Shneiderman 1988). Despite this, there are uses for a cursor. In devices that can sense a hover state prior to the finger or stylus coming into contact with a digitizer (Buxton 1990), the cursor serves to indicate to the user which target will be selected before they commit by touching the surface of the device and it serves as a precise indicator of the contact location (Sutherland 1964). Further, iconic cursors serve as useful indicators of state (Tilbrook 1976). Finally, the presence of the cursor and its response to user input gives feedback to the user that the system is active, tracking, and ready to receive commands.

6.9.4 Echo Feedback versus Semantic Feedback

Input devices, through the lens of interaction techniques, process a stream of sensor values to yield a logical result. A choice can be made as to whether a system's feedback echoes unprocessed sensor data back to the user (here is what the system sees; Krueger 1991) or instead provides a semantic representation of the user's state (here is what the system knows) like the cursor (Sutherland 1964). Traditional systems have trended toward the latter. A mouse, for example, senses only movement, but the feedback given to the user is of a *cursor position*, which is a logical state maintained entirely for the purposes of enabling interactions between the computer and the user. In point-based interactions, the alternative (echoing back movement without showing a cursor) makes little sense. Richer input streams, meanwhile, might tempt designers to skew their feedback more toward unprocessed data, since it may represent a richer visualization (Buxton 1990; Freeman et al. 2009; Wilson and Benko 2010). Although richer, such a representation may not help the user understand cause and effect. Designs can also include both representations, as illustrated by the LucidTouch system (Wigdor, Forlines et al. 2007). LucidTouch shows raw camera data that makes a device appear transparent, but it also includes "touch cursors" to represent the system state. The echo feedback of raw hand images establishes the conceptual model of a device by leading the user to associate each touch cursor to the finger that controls it.

6.9.5 Impoverished Physicality

Modern input devices such as touch screens and in-air gesture systems lack some of the tactile and kinesthetic feedback inherently present in traditional input devices. Such feedback

TABLE 6.3
Potential Causes of Unexpected Behavior and the Source of Feedback That Users Receive to Refute the Causes in Representative Mouse versus Touch Input Systems

Cause of Unexpected Behavior	Feedback Refuting Cause	
	Mouse	Touch
System is nonresponsive	OS: pointer movement	Application
Hardware failed to detect input	HW: activation of button	Application
Input delivered to wrong location	OS: visible pointer	Application
Input does not map to expected function	Application	Application
System is in a particular mode	OS + application: pointer icon	Application
Maximum size reached	OS: pointer moves past edge	Application
Accidental input (arm brushing)	N/A	Application
Overconstrained (too many contacts)	N/A	Application
Stolen capture (second user captures control)	N/A	Application

Note: OS = provided by operating system, HW = provided by hardware.

is an essential element of user experience, especially when users are attempting to understand why a system's response is not as expected. Many commercial mobile devices use audio data to compensate for this problem, with phones that beep or click when a virtual key is pressed.

To understand the role played by feedback, consider Table 6.3, which describes various states of a system and the feedbacks that are provided by either the cursor or the hardware. As is immediately evident, most touch-based platforms shift a great deal of the feedback burden onto the application developer.

However, this difficulty can be addressed by introducing feedback visualizations that represent these specific states and that replace physical responses with visual ones. Such approaches can help to overcome issues of impoverished physicality and semantic feedback, while making touch devices appear more responsive to users (Wigdor et al. 2009).

6.9.6 Snapping Behaviors, Active Haptic Feedback, and Tactile Feedback

Software constraints, such as snapping (Baudisch et al. 2005), often suffice to support a user's tasks without resorting to exotic haptic or tactile feedback mechanisms. Active force or tactile feedback (Burdea 1996) can provide attractive forces for a target or additional feedback for the boundaries of a target, but when evaluated for indirect pointing devices such feedback typically yields little or no performance advantage even for isolated target selections (Akamatsu and Mackenzie 1996; MacKenzie 1995). Such techniques must evaluate selection among multiple targets, because haptic feedback or snapping behavior for one target may interfere with the selection of others (Grossman and Balakrishnan 2005; Oakley, Brewster, and Gray 2001). Visual dominance refers to the tendency of vision to dominate other modalities (Wickens 1992); haptic feedback typically must closely match visual feedback, which limits its utility as an independent modality (Campbell et al. 1999). One promising use of tactile feedback is to improve state transitions, particularly for direct-input devices (Poupyrev and Maruyama 2003; Snibbe and MacLean 2001; Bau et al. 2010).

6.10 KEYBOARDS AND TEXT ENTRY

Typewriters have been in use for over 140 years; the QWERTY key layout dates back to 1868 (Yamada 1980). Those who continue to predict the demise of keyboards would be wise to consider the resilience of this design in the face of the nearly unimaginable orders of magnitude of change that have vastly transformed nearly all other aspects of computing hardware.

Despite the antiquity of the design, QWERTY keyboards are extremely well suited to human performance and, at least for heavy text entry, mechanical keyboards are unlikely to be supplanted by new key layouts, speech recognition technologies, or other techniques any time soon.

Many factors influence typing performance, including key size, key shape, activation force, key travel distance, and the tactile and auditory feedback provided by striking the keys (Lewis, Potosnak, and Magyar 1997), but these well-established design details are not our focus here. We also discuss touch-screen "soft" keyboards, which have some commonality with mechanical keyboards but raise additional design issues, particularly because they demand so much visual attention.

6.10.1 Procedural Memory and the Power Law of Practice

Procedural memory facilitates human performance of complex sequences of practiced movements, such as riding a bike, seemingly without any cognitive effort (Anderson 1980). Procedural memory (which is sometimes informally referred to as muscle memory) is a distinct type of memory that resides below a person's conscious awareness. Procedural memory enables touch typing on a keyboard with minimal attention (Anderson 1980). As a result, users can focus their attention on mental composition and verification of the text appearing on the screen. Dedicated keys or chorded key presses for frequently used commands (hot keys) likewise allow rapid command invocation (McLoone, Hinckley, and Cutrell 2003). The automation of skills in procedural memory is described by the power law of practice:

$$T = aP^b \tag{6.4}$$

Here, T is the time to perform a task, P is the amount of practice, and multiplier a and exponent b are fit to the observed data (Anderson 1980). For a good example of applying the power law of practice to text entry research, see the study by MacKenzie et al. (2001).

Alternative keyboard layouts such as Dvorak offer perhaps a 5% performance gain (Lewis, Potosnak, and Magyar 1997), but the power law of practice suggests this small gain comes at a substantial cost for retraining time. Split-angle ergonomic QWERTY keyboards are close enough to the standard layout that they preserve much of a user's existing skill for typing. They have also been shown to help maintain neutral posture of the wrist and thus avoid ulnar deviation (Honan et al. 1995; Marklin, Simoneau, and Monroe 1997; Smutz et al. 1994), which has been associated with increased pressure in the carpal tunnel (Putz-Anderson 1988; Rempel et al. 1998).

6.10.2 Two-Thumb Mechanical Keyboards

Many designs for cell phones and other handheld devices, such as the RIM Blackberry, offer two-thumb keyboards with QWERTY key layouts. The principal virtue of QWERTY is that common pairs of letters tend to occur on opposite hands. This alternation is a very efficient movement pattern for both standard and two-thumb keyboards, since one hand completes a key press while the other hand moves to the next key (MacKenzie and Soukoreff 2002). A recent study found that two-thumb keyboards offer text entry rates approaching 60 wpm (wpm stands for words per minute) (Clarkson et al. 2005). This suggests that one-handed text entry rates are fundamentally limited due to the serial nature of character entry, despite novel improvements (MacKenzie et al. 2001; Wigdor and Balakrishnan 2003). Word prediction may help, but it also requires overhead for users to monitor and decide whether to use the predictions. Such techniques also require escape mechanisms to allow entry of out-of-vocabulary words.

6.10.3 Touch-Screen Keyboards

Modern multitouch screens enable text entry that is adequate for mobile interaction, thus bringing touch-screen keyboards to the mainstream. But the user experience with a graphical touch-screen keyboard still faces many challenges and shortcomings that may be addressed by future innovations and optimizations (Gunawardana, Paek, and Meek 2010). There have been many studies of touch-screen key sizes (Sears 1991) and of optimal target sizes in general (Vogel and Baudisch 2007), but in practice the key size is more or less dictated by screen dimensions. Graphical keyboards demand significant visual attention because the user must look at the screen to press the correct key. It therefore splits the user's visual attention between the workspace (where text is being inserted) and the graphical keyboard itself. This is particularly problematic on large form factors, such as slates, because the insertion point may be relatively far from the keyboard; if one brushes the screen by accident while typing, for example, one may not even notice that characters are being mistakenly inserted at a new and unintended location. The quality of tactile feedback is poor when compared with a physical keyboard because the user cannot feel the key boundaries. Many graphical keyboards add audible clicks to provide confirmatory feedback, but it is unclear if this actually benefits performance (Sears 1991; Lewis, Potosnak, and Magyar 1997). A graphical keyboard (as well as the user's hand) occludes a significant portion of a device's screen, resulting in less space for the document itself. Furthermore, because the user typically cannot rest his or her fingers in contact with the display (as one can with mechanical keys) and also because the user must carefully keep other fingers pulled back so as to not accidentally touch keys other than the intended ones, extended use of touch-screen keyboards can be fatiguing.

Innovative design hybrids that blend touch or stylus-based typing with stroke gestures have been shown to produce high rates of text entry once the user masters them (Kristensson and Zhai 2004; Zhai and Kristensson 2003; Zhai et al. 2009). It remains unclear if such approaches will achieve widespread adoption.

6.10.4 Handwriting and Character Recognition

Handwriting (even on paper, with no recognition involved) proceeds at about 15 wpm. Thus, a pen is a poor replacement for a keyboard; but, of course, a keyboard is an equally poor replacement for a pen. The specter of recognition arises as soon as one contemplates marking a virtual sheet of paper, but it is important to keep in mind that ink has significant value as a natural data type without recognition: It offers an expressive mix of writing, sketches, and diagrams, and when used to annotate a document concise pen marks or highlights implicitly emphasize the important points in context. Freeform pen input also may help users to generate a breadth of design concepts (Buxton 2007) as opposed to more rigid input mechanisms such as keyboard-based text entry.

Handwriting recognition technology on tablet personal computers has improved markedly over the past decade. Nonetheless, recognition of natural handwriting remains difficult and prone to error for computers, and it demands error correction input from the user. Handwriting recognition works well for short phrases such as search terms

(Hinckley et al. 2007) or for background tasks such as indexing handwritten documents for search, but converting lengthy handwritten passages to error-free text remains a tedious process. Hence, although handwriting recognition is an important enabling technology, in our view pen-operated devices can best avoid the graveyard by emphasizing those user experiences that make minimal demands for recognition and instead emphasize the virtues of ink as a uniquely expressive data type.

In order to make performance more predictable for users, some devices rely on character recognition, which is often implemented as single-stroke (unistroke) gestures (Goldberg and Richardson 1993). Unistroke alphabets attempt to strike a design balance such that each letter is easy for a computer to distinguish yet also straightforward for users to learn (MacKenzie and Zhang 1997). With the widespread adoption of touch-screen keyboards, coupled with the great strides made in handwriting recognition, such approaches have fallen out of favor in most contexts.

6.11 MODALITIES OF INTERACTION

In the search for designs that enhance interfaces and enable new usage scenarios, researchers have explored many input modalities and interaction strategies that transcend any specific type of device.

6.11.1 Bimanual Input

People use both hands to accomplish most real-world tasks (Guiard 1987), but computer interfaces make little use of the nonpreferred hand for tasks other than typing. Bimanual input enables compound input tasks such as navigation/selection tasks, where the user can scroll with the nonpreferred hand while handling the mouse using the preferred hand (Buxton and Myers 1986). This assignment of roles to the hands corresponds with Guiard's kinematic chain theory (Guiard 1987): The nonpreferred hand sets a frame of reference (scrolling to a location in the document) for the action of the preferred hand (selecting an item within the page using the mouse).

Interaction with handheld devices often requires two hands for some tasks. For example, users often hold a device with the nonpreferred hand while the preferred hand performs pinch-to-zoom gestures, taps on small targets, or punches out messages on a soft keyboard. Researchers have explored use of the nonpreferred hand for spatial manipulation by moving or tilting the device (Fitzmaurice and Buxton 1994; Hinckley and Song 2010). This approach leaves the preferred hand free to point at or sketch the content thus revealed.

Some example applications for bimanual input include command selection (Bier et al. 1993; Kabbash, Buxton, and Sellen 1994), drawing tools (Kurtenbach et al. 1997), and virtual camera control and manipulation (Balakrishnan and Kurtenbach 1999; Hinckley et al. 1998). Integrating additional buttons and controls with keyboards to encourage bimanual interaction can also improve the efficiency of some common tasks (MacKenzie and Guiard 2001; McLoone, Hinckley, and Cutrell 2003). Mode switching initiated by the nonpreferred hand, such as by holding down a mode button, has also been demonstrated to be a particularly effective means of changing mode in pen-based interfaces (Li et al. 2005).

6.11.2 Gesture Recognition versus Physics-Based Manipulation

As previously discussed in Section 6.2.1, researchers have found that there does not exist a universal set of natural gestures that users will perform without appropriate affordances (Wobbrock, Morris, and Wilson 2009). The sole exception is physical manipulation: moving an object from one place to another or otherwise changing its position or orientation. Physics-based systems extend this manipulation by mapping inputs to a virtual world governed by Newtonian physics, leading to user experiences described as natural (Agarawala and Balakrishnan 2006; Wilson et al. 2008; Wilson 2009). This approach has been characterized as "reality-based interaction," which advocates the use of naive physics combined with awareness of the body, surrounding environment, and social interaction as the base for successful user interfaces (Jacob et al. 2008). This is in contrast to an approach where gestures are specifically recognized to differentiate system responses, such as assigning functions to particular hand postures (Baudel and Beaudouin-Lafon 1993). Physics-based systems have the advantage that they "feel" like the real world, but they have not yet been demonstrated to scale to enable the range of functions expected of an interactive system. A hybrid model has also been demonstrated, in which shape-based information is used to manipulate a traditional WIMP GUI (Moscovich 2009). Taxonomies of gestures of touch-based computing are provided by Wobbrock, Morris, and Wilson (2009); and Freeman et al. (2009).

6.11.3 Pen and Pen-Based Gesture Input

Pens lend themselves to command gestures analogous to proofreader's marks, such as crossing out a word to delete it. Note that in this example, the gesture integrates the selection of a delete command with the selection of the word to be deleted. Another example is moving a paragraph by circling it and drawing a line to its new location. This integrates the verb, object, and indirect object by specifying the command, extent of text to be moved, and new location for the text (Hinckley, Baudisch et al. 2005; Kurtenbach and Buxton 1991). Marking menus use straight-line gestures along the primary compass directions for rapid command selection (Kurtenbach, Sellen, and Buxton 1993; Zhao and Balakrishnan 2004).

Pen interfaces must decide whether to treat pen strokes as ink content or as gesture commands. Some applications avoid this recognition problem by treating all strokes as commands (Kurtenbach and Buxton 1991), but for a free-form drawing or note-taking application, users need to interleave ink content and command input. The status quo solution presents commands in a toolbar or menu at the edge of the screen; however, this necessitates round-trips between the work area and the command area (Fitzmaurice, Khan, Piek et al. 2003), which become inconvenient in direct proportion to the display size. Pressing a button with the nonpreferred hand is a fast and robust means to switch between ink and gesture modes (Li et al. 2005).

Techniques that automatically distinguish ink and gestures have been proposed, although only for highly restricted gesture sets (Saund and Lank 2003). Punctuation (tapping) has also been explored as a way to both identify and delimit command phrases (LaViola and Zeleznik 2004). A fundamental problem with both these approaches is that the system cannot classify a set of strokes as a gesture or as ink until the user has finished drawing the entire command phrase. This makes it difficult to provide interactive feedback or to prompt the user with available commands before he or she commits to an operation.

Although moving the pen to toolbars at the edge of the screen seems slow on a tablet computer, in practice this round-trip strategy (Fitzmaurice, Khan, Piek et al. 2003) is difficult to improve upon. On a tablet the size of a standard 8.5 × 11–inch sheet of paper, a round-trip requires approximately 1.5 seconds; however, the user can mentally prepare for the next step of the interaction while moving the pen. A locally drawn gesture (such as a straight-line marking menu command) may take less time to articulate, but thinking about what command to select requires additional time unless the task is a routine one. Pressing a button for gesture mode also requires some overhead, as does lifting the pen at the end of the gesture. Also note that performing a sequence of gestures (e.g., tagging words in a document as key words by circling them) requires time to travel between screen locations. The round-trip strategy absorbs this travel time into the round-trip itself, but with gestures this is an extra cost that reduces the benefit of keeping the interaction localized.

Thus, on a tablet-sized device it is difficult to realize substantial time saving just by reducing round-trips. For our hypothetical task of tagging key words in a document, Figure 6.8 illustrates this predicament for average task times drawn from recent studies (Hinckley et al. 2006; Li et al. 2005). The chart shows two successive command selections and assumes that some mental preparation is required before issuing each command. Thus, the potential benefit of pen gestures depends on the sequence of operations as well as the elimination of multiple round-trips, which may be possible with techniques that integrate selection of verb, object, and indirect object (Hinckley, Baudisch et al. 2005; Kurtenbach and Buxton 1991). Localized interaction may also offer indirect benefits by reducing physical effort and by keeping users' visual attention focused on their work (Grossman et al. 2006; Kabbash, Buxton, and Sellen 1994).

6.11.4 Speech, Multimodal Input, and Situated Interaction

Speech has substantial value without recognition. Computers can augment human–human communication across both time and space by allowing users to record, edit, replay, or transmit digitized speech and sounds (Arons 1993; Stifelman 1996; Buxton 1995). Simultaneously recording speech and handwritten annotations is also a compelling combination for human–human communication and collaboration (Levine and Ehrlich 1991). Systems have used microphone input to detect ambient speech and employ this as a cue to optimize interaction with devices (Horvitz, Jacobs, and Hovel 1999; Sawhney

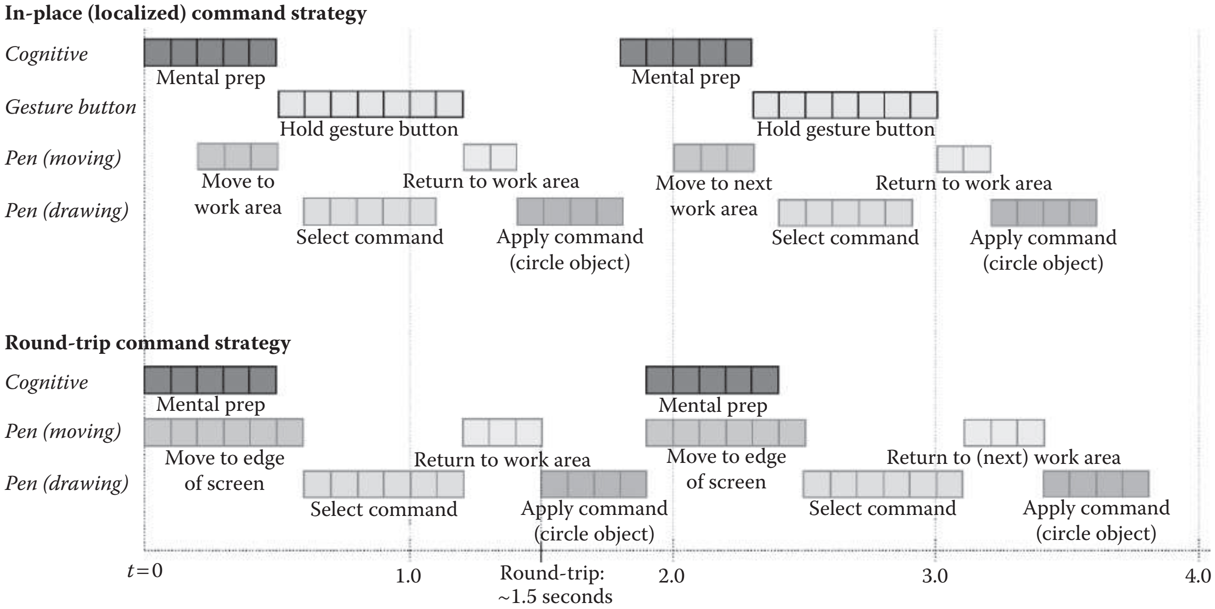

FIGURE 6.8 Time series contrasting the elements of command selection for in-place command selection versus a round-trip to the edge of the screen. These are approximate times for a tablet-sized device (of about 30-cm screen diagonal). (From Hinckley et al. 2006. In *Proceedings of the SIGCHI Conference on Human Factors in Computing Systems*. Montréal, QC: ACM. With permission.)

and Schmandt 2000; Schmandt et al. 2000) or to provide dual-purpose speech, which serves a communicative purpose while also cueing specific actions for a computer (Lyons et al. 2004).

Speech recognition can succeed for a limited vocabulary, such as speaking the name of a person from one's contact list to place a cell phone call; however, error rates increase as vocabulary grows and the complexity of grammar increases, if the quality of the audio signal from the microphone is not good enough, or if users employ out-of-vocabulary words. It is difficult to use speech to refer to spatial locations, so it cannot eliminate the need for pointing (Cohen et al. 1989; Oviatt, DeAngeli, and Kuhn 1997). Keyboard–mouse text entry for the English language is about twice as fast as automatic speech recognition (Karat et al. 1999); furthermore, speaking can sometimes interfere with one's ability to compose text and remember words (Karl, Pettey, and Shneiderman 1993). Finally, speech is inherently nonprivate in public situations. Thus, speech has an important role to play, but claims that speech will soon supplant manual input devices should be considered with skepticism.

Computer understanding of human speech does not enable users to talk to a computer as one would to another person. Doing spoken dialogue well entails *situated interaction*, which goes far beyond speech recognition itself. For computers to embed themselves naturally within the flow of human activities, they must be able to sense and reason about people and their intentions: In any given dialogue, multiple people may come and go; they may interact with the system or with each other, and they may interleave their interactions with other activities such that the computational system is not always in the foreground (Bohus and Horvitz 2010). Dealing with such challenges pushes existing technologies to their limits and, unfortunately, well beyond them at times as well.

6.11.5 Free-Space Gestures and Whole-Body Input

Humans naturally gesture and point using their hands during verbal communication, which has motivated research into freehand gestures, often in combination with speech recognition (Bolt 1980; Hauptmann 1989; Wilson and Oliver 2003; Tse et al. 2008). Cadoz (1994) categorizes hand gestures as semiotic, ergotic, or epistemic. Semiotic gestures, such as thumbs-up, communicate information (Cadoz 1994; Rime and Schiaratura 1991). Ergotic gestures manipulate physical objects. Epistemic gestures are exploratory motions that gather information (Kirsh 1995; Kirsh and Maglio 1994). The interaction literature often focuses on empty-handed semiotic gestures (Freeman and Weissman 1995; Jojic et al. 2000; Maes et al. 1997). A major challenge is to correctly identify when a gesture, as opposed to an incidental hand movement, starts and stops (Baudel and Beaudouin-Lafon 1993; Wilson and Oliver 2003). The lack of deterministic state transitions (Buxton 1990; Vogel and Balakrishnan 2005) can lead to errors of user intent or errors of computer interpretation (Bellotti et al. 2002). Other problems include fatigue from extending one's arms for long periods and the imprecision of pointing at a distance.

By contrast, tangible interaction techniques (Ishii and Ullmer 1997) and augmented devices (Harrison et al. 1998) sense ergotic gestures via a physical intermediary (Hinckley et al. 1998; Zhai, Milgram, and Buxton 1996). The emergence of cameras, cell phones, and tablets augmented with accelerometers, gyroscopes, and other sensors suggest this to be a promising design space.

Whole-body input is also possible, typically utilizing computer vision techniques (Krueger, Gionfriddo, and Hinrichsen 1985). Producing whole-body input by processing the imagery captured by a single camera significantly limits the vocabulary of input to those things that are clearly observable by that single camera, typically to 2D manipulations within the viewing plane (Krueger, Gionfriddo, and Hinrichsen 1985). More recent technologies have augmented this sensor stream with the distance of objects from the camera, enabling more subtle, three-dimensional (3D) interactions. This has been demonstrated by processing two camera images simultaneously and observing binocular disparity (Ko and Yang 1997; Matsushita and Rekimoto 1997). It has also been demonstrated with techniques such as time-of-flight cameras (Wilson 2007), as well as structured light techniques. Commercial products such as Microsoft Kinect provide in-depth information for each pixel, which has the potential to enable richer interaction, such as correcting a projected image to allow for consistently sized projection of objects onto moving surfaces (Wilson 2007).

6.11.6 Background Sensing Techniques

Sensors can enable a mobile device to sense when a user picks up, puts down, looks at, holds, or walks around with the device. These actions give the device information about the context of its use and represent a hidden vocabulary of naturally occurring gestures that people spontaneously exhibit in day-to-day activity. For example, many current smartphones and slate devices employ a tilt sensor to interactively switch the display between portrait and landscape formats, as well as to automatically save photographs in the correct orientation (Hinckley, Pierce et al. 2005; Hinckley et al. 2000). Here, the sensor allows the device to adapt its behavior to a user's needs rather than requiring the user to take extra steps to control the display format and photograph orientation (Buxton 1995).

Sensors can also be embedded in the environment. When one walks into a modern department store, no explicit command is required to open the doors: The doors sense motion and automatically open. Researchers are investigating new ways to leverage such contextual sensing to enrich and simplify human interaction with devices and digital environments (Abowd and Mynatt 2000; Schilit, Adams, and Want 1994).

6.11.7 Projector-Based Augmented Reality

Direct interaction can be extended beyond screens by projecting imagery onto real-world physical objects. Such a projection is normally coupled with a sensor that enables sensing of the movement of the object on which the imagery is projected, of users' hands within the projection area, or both. Such sensing has been enabled through projection of imagery onto input devices, thereby transforming indirect multitouch input devices into direct ones (Dietz and Leigh 2001). More typical is the use of a camera with a viewing area that overlaps the projection area (Ullmer and Ishii 1997; Matsushita and Rekimoto 1997; Klemmer et al. 2001). This has been envisioned as a lightbulb capable of high-resolution information display and of sensing user interaction with that display (Underkoffler and Ishii 1998). The technique has been used to augment physical objects with digital information, such as overlaying instructions for mechanical operations and augmenting data ports with network traffic information (Raskar et al. 2005). The technique has also been augmented by sensing manipulations of the projector itself, such as rolling the projector to zoom the user interface (UI) (Forlines et al. 2005; Cao and Balakrishnan 2006), and by allowing multiple projectors to overlap one another envisioning multiuser interaction scenarios such as sharing calendars (Cao, Forlines, and Balakrishnan 2007). Small projectors have also been mounted on other input devices, such as a stylus or a mouse, to augment those interactions (Song et al. 2009; Song et al. 2010).

6.11.8 Direct Muscle-Based Input and Brain–Computer Interfaces

Traditional input devices can be thought of as secondary sensors, in that they sense a physical action that is the consequence of cognition and muscle movements. An alternative approach is to attempt primary sensing by detecting brain activity and muscle movements directly. Muscle sensing is accomplished through electromyography, a technique previously employed for measuring muscular activity or controlling prosthetics. Saponas et al. (2009) demonstrated its use to enable sensing of muscle activation as fine-grained as detecting and identifying individual fingers, and used it in combination with touch-screen input to provide a richer data stream (Benko et al. 2009). Brain–computer interfaces (BCIs) typically employ electroencephalography (EEG) or functional near-infrared spectroscopy to detect input. Projects have used the technique to detect workload and user engagement (Hirshfield, Chauncey et al. 2009) in order to conduct usability studies, as well as to explore the possible dynamic adaptation of user interfaces based on such metrics (Hirshfield, Solovey et al. 2009). Such work remains in its infancy, but it appears to hold great promise (particularly as assistive technologies for users suffering from devastating injuries or significant physical limitations) with the improvement of sensing and signal-processing techniques.

6.12 FORM FACTORS FOR DIRECT (AND INDIRECT) INTERACTION

The form factor of a device is a function of both technology and the envisioned context of use of that device. This context extends, among other things, to the tasks a user is likely to want to perform, the physical environment in which the device is likely to be found, and the other devices that populate the surrounding ecosystem. Mobile phones and desktop computers enable some overlapping tasks and may even be put to complementary uses by the same user at the same time for some tasks, but for each device the focus of its design is on different usage contexts.

Here, we provide some example devices to sketch the terrain and show examples of how hardware form factor, input capabilities, and display size combine to create unique user experiences and how each of these classes of devices in turn offers unique interaction properties and hence new user experiences. In practice, these user experiences may be realized only if designers focus on the depth of an experience by designing for the context of use of a device, which perhaps necessitates foregoing breadth of solution.

6.12.1 Handheld Devices and Smartphones

Handheld devices promise quick access to information in many contexts, since they are easily carried in a pocket or purse. Early on, these were dubbed "personal digital assistants" (PDAs), whose purpose was to track contacts, make notes, and keep a calendar. Modern versions of PDAs are highly valued not only for the information they contain but also because they are persistently online, promising instant access to real-time data with e-mail, web browsing, and of course telephony as core functions. Their convenience of use often overcomes the limitations of these devices such as their tiny screens and inefficient text entry. A symptom of the success as well as the inadequacies of such devices is the caveat *sent from my mobile device* that pervades automatic e-mail signatures on smartphones, as if the messages were crafted by a carpenter who blames his tools for the shoddy construction.

One of the first real successes for handheld computing was the PalmPilot. The PalmPilot was designed to fit into a human being's shirt pocket. The screen was a resistive touch digitizer, enabling interaction using either a finger or a plastic stylus. Although one-handed interaction was possible in some situations, the form factor was primarily intended to be held in the nonpreferred hand while the preferred hand interacted with the screen via a finger or stylus. The PalmPilot's designers recognized that they could enable faster text entry and more precise pointing by using the stylus, which was sheathed in the bezel of the device.

Although the PalmPilot's form factor was ostensibly similar to that of the Apple iPhone, the iPhone replaced the PalmPilot's resistive screen with a highly sensitive capacitive touch screen enabling multitouch interactions such as the now ubiquitous pinch gesture (Krueger, Gionfriddo, and Hinrichsen 1985). Perhaps even more important than the multitouch capability was the soft-touch contact sensing afforded by the capacitive touch screen. Soft-touch sensing enabled more precise pointing as well as more pervasive use of dragging for interactive manipulations such as panning, zooming, and scrolling with inertia in a way that was difficult to support well on the prior generation of resistive touch screens. Of course, use of modern processors, graphics hardware, and well-designed animated feedback also made the interactions clear and rewarding for users to experience.

Many handheld devices are designed for use predominantly with a single hand, with the device secured by the palm while the thumb interacts with the screen. Because thumb input is significantly less precise than stylus input, a specialized user interface for the thumb should be considered (Karlson 2007). For example, zooming user interfaces enable interaction with large amounts of data on a small screen while using only the thumb (Karlson 2005). Ironically, however, the iPhone's iconic pinch-to-zoom gesture requires two hands (one hand to hold the device while the other hand articulates the pinch gesture itself). Touching the screen while tilting a handheld device offers an alternative for one-handed continuous zooming (Hinckley and Song 2010).

Both the PalmPilot and the iPhone do away with a physical keyboard in favor of a larger screen. As always, this is a trade-off supporting one use case (viewing a variety of data sources) over another (entering text for documents, e-mails, etc.). A variety of devices make the other choice, opting for a physical keyboard. A now classic form factor is the "clamshell"; it provides a physical keyboard attached to the bottom of a display, which affords use either by typing with two thumbs or by placing the device on a table. A noteworthy early device in this space is the Psion Series 5 device (Figure 6.9). The Psion included a physical keyboard, along with a resistive touch digitizer. Its hinging mechanism was a clever touch of its industrial design: The display slides forward as the device opens, such that the base of the device cantilevers the display. This enables the user to interact with the angled touch screen without it flopping around or toppling the device.

As digital devices become physically smaller, the displays and input mechanisms they offer shrink in size. Considerable effort was once devoted to supporting web browsing in limited screen space (e.g., Buyukkokten, Garcia-Molina, and Paepcke 2001; Trevor et al. 2001), but much of this effort now seems to have been obviated by pinch-to-zoom on touch-sensitive displays plus the emergence of mobile themes for many websites. Techniques to make small displays virtually larger include peephole displays (Fitzmaurice 1993; Yee 2003), transparent overlays (Harrison et al. 1995; Kamba et al. 1996), and use of on-screen visuals to suggest the location of off-screen objects (Baudisch and Rosenholtz 2003). The latter, for example, is one of the principal techniques embraced by the Windows Phone 7 Metro UI design, by having a typography and UI layout that suggests the presence of additional options beyond the periphery of the current view.

Physical manipulations such as tilting that use the device itself as an interface seem particularly well suited to small devices (Harrison et al. 1998; Hinckley et al. 2000; Rekimoto 1996). Tiny, bright, and inexpensive laser or light-emitting diode (LED) projectors lie just around the corner; progress on computer vision techniques suggests that interactive projection may allow small devices to project large displays and sensing surfaces (Raskar et al. 2004; Wilson 2005), but brightness and power consumption remain significant obstacles to the widespread adoption of projection displays. Ways to interact with even smaller devices, such as pendants, rings, watches, or even pointlike sensors/emitters, have also been considered (Ni and Baudisch 2009).

6.12.2 Slates and Tablets

A number of compelling direct-input devices are starting to populate the long-standing void between handheld devices

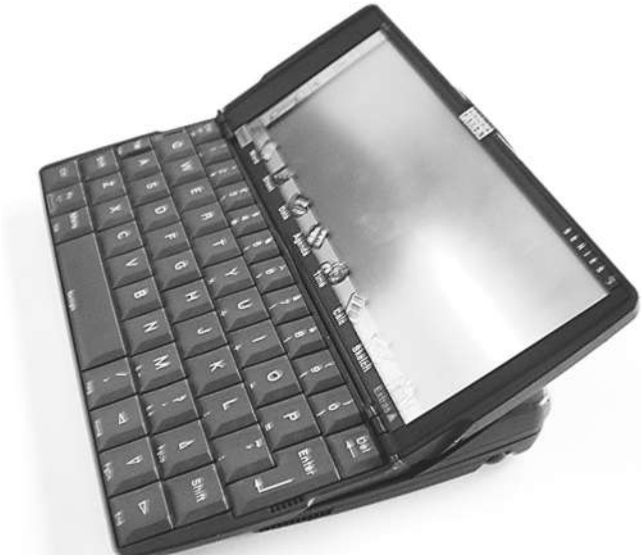

FIGURE 6.9 The Psion Series 5 handheld device, circa 1995. The resistive touch screen supports stylus or touch input. Note the counterweight on the bottom part of the clamshell that prevents the device from tipping over when one interacts with the screen.

and larger devices such as drafting boards, tabletop devices, and wall-mounted displays. Of course, laptops have existed in this category for many years, but these have essentially been caricatures of the traditional desktop interface.

Slates, e-readers, dual-screen booklets, and other emerging form factors such as flexible devices support new and specialized uses that stretch the boundaries of traditional computing experiences (Holman and Vertegaal 2008). The new usage contexts afforded by these devices, many of which emphasize direct interaction by touch or pen, or both, are placing new demands on input and interaction techniques, signaling an opportunity for innovation in both industry and academia. As our colleague Bill Buxton (www.billbuxton.com, accessed on September 1, 2010) writes, "Slate computers and e-readers represent a new class of digital appliance—one targeted for casual use. With the growth of this market will emerge a new and long overdue approach to interaction—one that is in keeping with the casual intent and context of such usage and which will complement, rather than replace, interfaces that support more formal and structured activities."

Even within this emerging category of devices, there remains much room for differentiation and specialization. Devices such as the Amazon Kindle focus on recreational reading. Devices such as the Apple iPad support reading as one of its many dedicated applications. Both have been successful in the marketplace. From the literature we also know that in many contexts, reading tends to occur in conjunction with writing, such as a student studying a textbook or an information worker bringing together documents to research a topic (O'Hara and Sellen 1997; Adler and van Doren 1972). Devices such as the iRex iLiad, which supports pen annotation on top of e-book content, and the Courier project (Microsoft Courier 2010), which explores a dual-screen booklet form factor supporting both pen and touch inputs, hint at further developments to come. Digital annotation (Price, Schilit, and Golovchinsky 1998) and dual-screen form factors (Chen et al. 2008; Hinckley et al. 2009) have also been explored in the research literature.

Such midsize devices place new demands on interaction design, even when they support similar or identical touch-screen interfaces to analogous handheld devices. For example, one reason that the Apple iPad must have such a wide bezel is that it would otherwise be unclear how to grasp the device without accidentally triggering operations on its touch screen. Our personal experience with touch-screen tablets of this sort suggests that one is nonetheless still far more likely to touch things by accident than on a corresponding handheld touch interface. This once again illustrates how even with a subtle shift in the underlying form factor a desirable property of an input modality—in this case, that one can just lightly touch the screen to initiate an action—can become a liability: If you just lightly touch the screen *by accident*, you will initiate some (undesired) action. New but related problems also crop up, such as the need to ameliorate accidental palm contact when writing on such a device with a pen, which do not manifest themselves on smaller handheld form factors.

6.12.3 Desktops

Rumors regarding the death of the desktop computer are greatly exaggerated. After 40 years of iterative design, the personal computer, driven by a mouse and keyboard and controlling a WIMP GUI, continues to evolve. Pointing continues to be the primary unit of interaction, where the mouse's fundamental properties make it difficult to beat (Balakrishnan et al. 1997). Another primitive of interaction, that is, scrolling, typically also has a dedicated input device in the form of the scroll wheel. Augmented desktops with additional peripheral displays for direct pen input on horizontal and vertical surfaces have also been explored (Morris, Brush, and Meyers 2008).

Desktops can be expanded with multiple monitors. Research has shown that users have a strong tendency to partition tasks between discrete physical displays; for example, users often dedicate monitors to particular tasks or types of applications (Grudin 2001). Monitor bezels influence the way in which users arrange application windows (Hutchings and Stasko 2004) and lead to discontinuities in information displays (Tan and Czerwinski 2003). Thus, the presence of a bezel between multiple monitors can be both a benefit and a hindrance depending on a user's task; but clearly, one large display is not necessarily superior to multiple smaller displays separated by bezels. Augmented desktops with additional peripheral displays for direct pen input on horizontal and vertical surfaces have also been explored (Morris, Brush, and Meyers 2008).

The potential negative consequences of having bezels between displays often can be mitigated by careful handling of inputs and appropriate display of graphical feedback. For example, researchers have explored applications that are aware of the seams and can adjust their layout accordingly (Mackinlay and Heer 2004), as well as windowing systems that reposition and duplicate dialog boxes (Hutchings and Stasko 2005). Interaction techniques have also been proposed to account for the physical layout of the monitors. These have included the mouse ether technique in which the physical gaps between monitors are echoed in a virtual motor space that the mouse cursor moves through, leading to better correspondence between input and output in accordance with users' expectations (Baudisch et al. 2004). Researchers have experimented with assigning each monitor its own mouse cursor (Benko and Feiner 2005) as well as the use of head tracking to facilitate jumps of the mouse cursor between distant monitors (Ashdown, Oka, and Sato 2005).

6.12.4 Multitouch Tables and Screens

Screen size is an obvious delimiter between different categories of devices. But so too is screen orientation: Research has demonstrated that large touch screens mounted horizontally afford uses distinct from screens mounted vertically.

Extensive study of tabletop interaction has unearthed many issues and techniques unique to the large horizontal form factor. Most relate to multiuser usage scenarios, which a large horizontal screen naturally affords because multiple users can sit while facing one another (Shen, Everitt, and Ryall 2003). Although conducive to multiuser interaction, such an arrangement creates issues of content orientation, since an on-screen object oriented correctly for one user is necessarily oriented incorrectly for other users (Shen et al. 2004). Systems can mitigate this problem by altering the view seen from each side of the table (Matsushita et al. 2004) by using head-worn displays as the sole display mechanism (Agrawala et al. 1997) or in combination with other information displays, such as projecting directly onto an input device (Benko, Ishak, and Feiner 2004).

Sharing a single tabletop also leads to issues. Users have been observed to implicitly and fluidly delineate a tabletop display into multiple territories, personal, shared, and storage (Scott et al. 2004), varying by the size of the table (Ryall et al. 2004). It is not clear how much of this separation is due simply to issues of comfort of reach, as described by anthropometricists as the *kinetosphere* (Toney and Bruce 2006), and how much is dictated by the mores of social distance as studied in the field of *proxemics* (Ballendat, Marquardt, and Greenberg 2010). Viewing information horizontally and from different sides has been shown to lead to perceptual differences (Wigdor, Shen et al. 2007) and to improve visual search efficiency (Forlines et al. 2006).

In addition to social and psychological factors, multiuser interaction with a single display breaks many existing UI paradigms, such as persistent modes, undo stacks, toolbars, and paint palettes that set a global mode in the interface when a user taps on the control. If your system is one of the many that does not offer user differentiation for its contacts and your interface design includes such elements, then your design is in trouble. Hence, cooperative tools for multiple users must often seek clever design solutions that avoid all global modes in an interface.

This is mitigated somewhat by technologies such as the DiamondTouch, which can identify users and thereby provide a specific mode for each distinct user (Dietz and Leigh 2001). Addressing these and other similar issues, researchers have designed many user interface elements specifically for shared horizontal form factors, such as shared versus individual controls (Morris et al. 2006), methods for supporting multiple off-axis viewpoints (Hancock and Carpendale 2007), multitouch content reorientation methods (Hancock et al. 2006), and text entry (Hinrichs et al. 2007). Researchers have also examined altering the form factor and have demonstrated differences in user behavior based on screen size (Ryall et al. 2004). Hartmann et al. (2009) demonstrated the augmentation of a large (4′ × 6′) tabletop with physical controls, such as multiple keyboards and mice, as well as other physical objects.

6.12.5 Vertical Displays and Very Large Displays

Mounting on a wall enables form factors, which include large screens. Large displays lend themselves to collaboration and the sharing of information with groups (Funkhouser and Li 2000; Swaminathan and Sato 1997), as well as giving a substantial physical presence to virtual activities (Buxton et al. 2000; Trimble, Wales, and Gossweiler 2003).

The digital whiteboard is a classic example of a large vertically oriented display (Elrod et al. 1992; Moran, Chiu, and Melle 1997; Pederson et al. 1993). Many digital whiteboards mix the physical and the digital by tracking the position of real markers as a user strokes on the board. Many boards are augmented with projection on the writing area, allowing users to interact with applications while still making digital or physical marker strokes. Many digital whiteboards' reliance on projectors limits their resolution, enabling a large but coarse information display.

Alternative technologies can enable large, high-resolution displays, although such displays typically require the tiling of either projectors or individual displays. Each of these technologies has inherent limitations. Tiled screens currently require a bezel (nondisplay area), which creates a grid of tiles that interferes with interactions such as direct-touch dragging of items across screens (Ball and North 2005). By contrast, in projected imagery, the lack of physical separation of the display area creates areas of nonuniform brightness and color even after careful calibration (Surati 1999). Despite these issues, large high-resolution displays have been demonstrated to aid spatial tasks (Tan et al. 2003), improve and reduce gender effects in navigation (Czerwinski, Tan, and Robertson 2002), provide utility in sense making (Andrews, Endert, and North 2010), and influence visual search and steering tasks (Bi, Bae, and Balakrishnan 2010).

Direct input on wall-mounted displays is commonplace, but the constant physical movement required can become burdensome. Hybrid approaches that mix absolute and relative direct pointing have been proposed (Forlines, Vogel, and Balakrishnan 2006), as have methods for bringing distant targets closer to the user (Baudisch, Bederson, and Zierlinger 2002; Bezerianos and Balakrishnan 2005; Collomb et al. 2005). Interaction-at-a-distance can be afforded via indirect interaction techniques, such as touch input on a nearby tablet device (Nacenta et al. 2005; Malik, Ranjan, and Balakrishnan 2005), eye tracking (Bolt 1981; Shell et al. 2004), or by pointing at the display using a physical device (Bolt 1980; Wilson and Shafer 2003) or the hand itself (Ko and Yang 1997; Nickel and Stiefelhagen 2003; Vogel and Balakrishnan 2005). Even when a user is close to a large display, interacting with portions of the display that are out of view or beyond arm's length raises challenges (Bezerianos and Balakrishnan 2005; Khan et al. 2005).

6.12.6 Federations of Form Factors: A Society of Devices

As form factors continue to evolve and multiple form factors per user become more affordable, each of us is likely to increasingly interact with our digital information and with one another through an ever-broadening array of devices, each suited to the contexts described till now. One early prediction of such an ecology of devices was Weiser's vision

(Weiser 1991) of ubiquitous computing, comprising tabs, pads, and boards, which foreshadowed the billion-dollar markets for smartphones, e-readers, and slate devices.

Displays of various sizes support different activities and social conventions; one of the principal challenges of ubiquitous computing is finding techniques that make it easy for users to work within a digital ecology that supports a range of tasks spanning multiple computers, displays, and interactive surfaces. Several projects have probed how to use small displays as adjuncts to large ones (Myers, Lie, and Yang 2000; Myers, Stiel, and Gargiulo 1998; Rekimoto 1998; Streitz et al. 1999), allowing simultaneous interaction with private information on a personal device and a shared or public context on a larger display.

What makes such federations of devices fascinating are not so much the individual devices themselves but rather the virtual bridges that span the spaces between them. Wireless networking is the technology that will perhaps most severely disrupt traditional approaches to HCI and computing in general in the coming years, because it breaks down barriers between devices and enables a new society of devices that fill specific roles and can still coordinate their activities (Fitzmaurice, Khan, Buxton et al. 2003; Want and Borriello 2000). Users need techniques that allow them to access and share information across the boundaries of individual devices, as well as to dynamically bind together multiple devices and displays to accomplish their tasks (Hinckley et al. 2004; Rekimoto et al. 2003). Such interaction techniques inherently involve multiple individuals, and thus they must also consider how people use physical proximity and relative body orientation (Deasy and Lasswell 1985; Hinckley et al. 2004; Sommer 1965).

Thus, the interaction designer must consider the full range of scale for display sizes and form factors that may embody an interaction task, as well as the interactions between different types of devices. How can interaction migrate from watches, cell phones, handheld devices, and tablets all the way up to desktop monitors, digital whiteboards, and interactive wall-sized displays? There is, as yet, no simple answer to such questions.

6.13 TRENDS AND OPPORTUNITIES FOR INPUT

The designer of an interactive system should take a broad view of input and consider not only traditional pointing techniques and GUI widgets but also issues such as search strategies to access information in the first place, sensor inputs that enable entirely new data types, and synthesis techniques to extract meaningful structure from data. Good search tools may reduce the many inputs needed to manually search and navigate file systems. Knowledge work requires integration of external information from web pages or databases (Yee et al. 2003) as well as reuse of personal information from documents, e-mails, and other content authored or viewed by a user (Dumais et al. 2003; Lansdale and Edmonds 1992). Unified full-text indexing allows users to quickly query their personal information across multiple information silos and can present information in the context of memory landmarks such as the date on which a message was sent or the application that was used to create a document (Cutrell et al. 2006).

Sensor inputs, such as those from accelerometers, gyroscopes, magnetometers, proximity sensors, and other sensors, are now widespread in mobile devices. Cell phones and low-power radios for wireless networking can sense their location or proximity to other devices via analyses of signal strengths (Bahl and Padmanabhan 2000; Krumm and Hinckley 2004). As another example, attempting to type a secure password on a mobile phone keypad quickly convinces one that biometric sensors or some other convenient means for establishing identity is essential to support secure interactions without completely frustrating users. Such sensors could make services such as personalization of interfaces much simpler. Research has already demonstrated how on-screen fingerprint sensing can also enable high-precision touch-screen interaction (Holz and Baudisch 2010).

The need to extract models and synthesize structure from large quantities of low-level inputs suggests that data mining and machine learning techniques will become important adjuncts to interaction (Fails and Olsen 2003; Fitzmaurice, Balakrisnan, and Kurtenbach 1999; Horvitz et al. 1998). Whenever a system considers automatic actions on behalf of a user, however, an important design principle in the face of uncertainty is to "do less, but do it well" (Horvitz 1999). A key challenge for input will be representation of these structures: As streams of sensors collect information, how to make this information available to applications so that their responses can be designed and customized is as yet unclear, but a probabilistic framework for handling input events may be the right general approach (Schwarz et al. 2010). Applying raw inputs to a physics engine is one extreme in the spectrum of possible approaches (Wilson et al. 2008). But we could argue that it is an equally extreme approach to reduce inputs to a lowest common denominator, as is common practice in modern toolkits. Somewhere in between, perhaps, lies a more nuanced solution to the breadth–depth dichotomy that carries a meaningful representation and framework that leverages the specific and deep aspects of individual platforms while also enabling broad solutions of very high quality that embrace the wide array of form factors comprising the modern society of devices.

We must make substantial progress in all these areas to advance human interaction with technology. The forms and capabilities of these and other technologies will continue to advance, but human senses and cognitive skills will not. We will continue to interact with computers using our hands and physical intermediaries, not necessarily because our technology requires us to do so but because touching, holding, and moving physical objects is the foundation of the long evolution of tool use in the human species (Wilson 1998).

Moore's law is often cited as an economic rule of technology, which states that the amount of processing power available at a given price will double every 18 months. A complement to and an expansion of this law is that all elements of device construction, design, electronics, and manufacture have been becoming and will continue to become less expensive over time. A natural consequence of this trend is the society of devices we have described, as more form factors become realizable at lower costs. Many predicted the end of the digital camera market as mobile phone cameras improved. Instead, the digital single-lens reflex camera market has grown significantly alongside the market for ever-improving camera-equipped phones. Likewise, the e-reader market, including slates such as the Amazon Kindle and the Apple iPad, has seen significant expansion despite the availability of Kindle and iBook software free of charge for smartphones and slates. As (bureaucrats? shapers? socialites? framers? founding fathers?) of this society of devices, designers will be well served to keep a broad perspective, taking into consideration many of the issues that we have addressed in this chapter, and thereby avoid the pitfalls of meaningless consistency, hopefully in favor of good design.

7 Sensor- and Recognition-Based Input for Interaction

Andrew D. Wilson

CONTENTS

7.1 INTRODUCTION

Sensors convert a physical signal into an electrical signal that may be manipulated symbolically on a computer. A wide variety of sensors have been developed for aerospace, automotive, and robotics applications (Fraden 2003). Continual innovations in manufacturing and reductions in cost have allowed many sensing technologies to find application in consumer products. An interesting example is the development of the ubiquitous computer mouse. Douglas Engelbart's original mouse, so named because its wire "tail" came out of its end, used two metal wheels and a pair of potentiometers to sense the wheels rolling over a desk surface. Soon, mice used a ball and a pair of optical encoders to convert the movement of the hand into digital signals indicating precise relative motion. Now, even the most inexpensive mice use a specialized camera and image-processing algorithms to sense motions at the scale of one one-thousandth of an inch several thousand times per second. Accelerometers, devices that sense acceleration due to motion and the constant acceleration due to gravity, are another interesting example. Today's tiny accelerometers were originally developed for application in automotive air-bag systems. Digital cameras now incorporate accelerometers to sense whether a picture is taken in landscape or portrait mode, and save the digital photo appropriately. Many laptops with built-in hard disks also include accelerometers to detect when the laptop has been dropped, and park the hard drive before impact. Meanwhile, mobile phone manufacturers are experimenting with phones that use accelerometers to sense motion for use in interaction, such as in-the-air dialing, scrolling, and detecting the user's walking pattern.

Research in human–computer interaction (HCI) explores the application of sensing to enhance interaction. The motivation of this work is varied. Some researchers seek to either expand the array of desktop input options or build completely new computing form factors such as mobile devices that know where they are pointed and intelligent environments that are aware of their inhabitants. Other researchers are interested in using sensors to make our machines behave more like we do, or alternatively to make them complement human abilities. Entertainment, surveillance, safety, productivity, mobile computing, and affective computing are all active areas in which researchers are applying sensors in interesting ways.

Although a wide array of sensors is available to researchers, rarely does a sensor address exactly the needs of a given application. Consider building into a computer the capability to sense when its user is frustrated. Detection of user frustration would allow a computer to respond by adopting a new strategy of interaction, playing soothing music, or even calling technical support; however, today, no "frustration meter" may be purchased at the local electronics store. What are the alternatives? A microphone could be used to sense when the user mutters or yells at the machine. A pressure sensor in the mouse and keyboard could detect whether the user is typing harder or squeezing the mouse in frustration (Klein, Moon, and Picard 2002; Reynolds 2001). A webcam might detect scowling or furrowing of the eyebrows. Sensors in the chair could detect user agitation (Tan, Slivovsky, and Pentland 2001). Ultimately, the system chosen should probably exploit a consistent, predictable relationship between the output of one of these sensors and the user's frustration level; for example, if the mouse is squeezed at a level exceeding some set threshold, the computer may conclude that the user is frustrated.

In our effort to build a frustration detector, we may find a number of issues confounding the relationship between the sensors and the state to be detected:

- There is no easy a priori mapping between the output of the sensors and the presumed state of frustration in the user. Implementation of a pressure sensor on the mouse requires observation of the user over time to determine how much pressure reliably indicates frustration. Implementation of the more complex approach of detecting furrowed brows by computer vision requires an elaborate image-processing algorithm.
- The output of the sensors is noisy and often accompanied by a degree of uncertainty.
- Initial experimentation reveals that while no single sensor seems satisfactory, it sometimes may suffice to combine the output of multiple sensors.
- Our preconceived notions of frustration may not correspond to what the sensors observe. This may cause us to revisit our understanding of how people express frustration, which, in turn, may lead us to a different choice of sensors.
- The manner in which the user expresses frustration depends greatly on the user's current task and other contextual factors, such as the time of day and level of arousal. Exploiting knowledge of the user's current application may address many cases where our algorithm for detecting frustration fails.
- After realizing that our frustration detector does not perform flawlessly, we struggle to balance the cost of our system making mistakes with the benefit the system provides.

These are just some of the considerations that are typical in a nontrivial application of sensors to recognition in HCI. Although this chapter does not propose to solve the problem of detecting and responding to user frustration, it will survey aspects of sensor-based recognition highlighted by this example. In particular, this chapter presents the variety of available sensors and how they are often used in interactive systems. Signal processing, recognition techniques, and further considerations in designing sensor and recognition-based interactive systems are briefly addressed.

7.2 SENSORS AND SENSING MODES

This chapter focuses only on those sensors relevant to interactive applications and their typical modes of use. Experimenting with such sensors has never been easier. Microcontrollers such as the Microchip PIC and BasicStamp can interface sensors to PCs and other devices, and can be programmed using high-level languages such as C and BASIC. The Phidgets hardware toolkit (Greenberg and Fitchett 2001) enables effortless "plug and play" prototyping with modular sensors and actuators that are plugged into a base interface board, and provides software application programing interfaces (APIs). The Berkeley and Intel Mote projects also offer wireless sensor packages useful in data collection and sensor networks (Kahn, Katz, and Pister 2000; Nachman et al. 2005). Another source for inexpensive sensors and sensor interface kits is the hobbyist robotics community.

7.2.1 Occupancy and Motion

Probably owing to the importance of sensing technology in security applications, many devices and techniques exist to sense either motion or a person's presence (occupancy). Among these are the following:

- Air pressure sensors that detect changes in air pressure resulting from the opening of doors and windows
- Capacitive sensors that detect capacitance changes induced by the body

- Acoustic sensors
- Photoelectric and laser-based sensors that detect disruption of light
- Optoelectric sensors that detect variations in illumination
- Pressure mat switches and strain gauges
- Contact and noncontact (magnetic) switches
- Vibration detectors
- Infrared motion detectors
- Active microwave and ultrasonic detectors
- Triboelectric detectors that detect the static electric charge of a moving object (Fraden 2003)

Perhaps one of the most familiar motion detectors is the passive infrared detector, which is sensitive to small changes in the pattern of infrared radiation within the spectral range of 4–20 μm (far infrared). Passive infrared detectors sense heat changes over a small duration of time, indicating the presence of a person moving through the room. These devices often control lights in office buildings and can be useful in office-awareness applications when combined with other sensors.

More selective motion and occupancy detection can be obtained with video cameras and simple computer vision techniques. For example, a computer vision system allows for the definition of multiple regions of interest that allow fine distinctions regarding the location of motion. Such a system may thus be able to ignore distracting motion.

7.2.2 Range Sensing

Range sensors calculate the distance to a given object. Such detectors can be used as occupancy detectors, and they are also useful in motion- and gesture-driven interfaces.

Many range and proximity sensors triangulate the position of the nearest object. For example, the Sharp IR Ranger emits a controlled burst of near infrared light from a light-emitting diode (LED). This light is reflected by any object within a few feet and is focused onto a small, linear, charge-coupled devices-array that is displaced slightly from the emitter. The position of the reflection on the sensor can be related with the distance to the object by trigonometry. Similar approaches can be used over a longer effective distance with the use of lasers rather than LEDs.

Stereo computer vision systems similarly use triangulation to calculate depth. If the same object is detected in two displaced views, the difference in their sensed two-dimensional (2D) positions, called “disparity,” can be related to the depth of the object (Forsyth and Ponce 2002; Horn 1986). Stereo vision techniques may be used to determine the depth of a discrete object in the scene, or to compute depth at each point in the image to arrive at a full range image.

A second approach to calculating range is based on measuring the time of flight of an emitted signal. The Polaroid ultrasonic ranging device, for example, was originally developed for autofocus cameras, and subsequently became popular in robotics. Such sensors emit a narrow ultrasonic “chirp” and later detect the chirp’s reflection. The duration in time between the chirp and the detection of the reflection is used to calculate the distance to the object. Ultrasonic range finders can sometimes be confused by multiple reflections of the same chirp; such difficulties are eliminated by measuring the time of flight of emitted light rather than sound, but such sensors are still comparatively exotic.

7.2.3 Position

Designers of sensing-based interactive systems would probably most like a low-power, wireless, inexpensive three-dimensional (3D) position sensor that does not rely on the installation of complicated infrastructure. Originally designed for military application, global positioning satellite (GPS) devices are useful for sensing street-level movement but are limited to outdoor application. Unfortunately, no indoor tracking standard has gained the popularity of GPS.

The position of a wireless RF receiver can be determined by measuring signal strengths to RF transmitters of known position using Wi-Fi, Bluetooth, and Global System for Mobile communications (GSM) standards (LaMarca et al. 2005). Under the assumption that signal strength approximates distance, position may be determined by triangulation, but often interference from buildings, walls, furniture, and even people can be troublesome. Another approach is to treat the pattern of signal strengths as a “signature” which, when recognized later, indicates the position associated with the signature (Krumm and Horvitz 2004). Using Wi-Fi transceivers and a number of Wi-Fi access points, position can be calculated within several feet of accuracy under ideal laboratory conditions using a combination of approaches (Letchner, Fox, and LaMarca 2005). Finally, the Ubisense location system achieves accuracy on the order of 15 cm indoors by using arrival time and angle of RF signals in ultrawideband frequencies.

Commercially available motion capture systems use a variety of strategies to track the position and orientation of multiple points. These systems are generally used to record human motions for applications such as video game character animation. Most require the performer to wear several small tracking devices. For example, when precisely calibrated, the Polhemus and Ascension magnetic tracking devices achieve millimeter accurate, six degrees of freedom (position and orientation) tracking of multiple points, but rely on technology that connects each tracking device to a base station with wires. Such products have been very useful in prototyping gesture-based interactions that require accurate 3D position and orientation (Fitzmaurice, Ishii, and Buxton 1995; Hinckley et al. 1998; Ware 1990; Ware and Jessome 1988), but often are too expensive for widespread use.

Much research in computer vision focuses on accurate and reliable object tracking. Where multiple cameras are available, it is possible to compute the 3D position of a tracked object using triangulation. To recover 3D position useful for interactive applications in a typical room setting, such cameras require careful calibration. Several prototype interactive systems use vision techniques to track the hands, head, and body of a user. Often, a model of shape and appearance that includes typical skin color is used to track the head and hands. The ALIVE system, for example, determines the 2D position of the head and hands of a user by first extracting the user's silhouette against a controlled (static) background. Point of high curvature along this contour are then extracted and tracked as hands or head. Later variants exploit color information as well. Depth is computed by assuming the user is standing on a flat floor (Maes et al. 1995; Wren et al. 1995).

Computer vision-based tracking systems often suffer from poor tracking reliability and sensitivity to variations in background illumination. Tracking reliability can be enhanced by controlling the appearance of the object so that it can be tracked unambiguously. A number of professional motion capture systems, such as the Vicon Peak system, rely on passive, wireless, infrared-reflective pieces, but also require a powerful infrared light source and multiple, redundant sensors (cameras) to minimize missing data resulting from occlusion. Alternatively, cameras sensitive in the infrared domain can be used to track an infrared LED (IR-LED). The position sensitive device, for example, is an inexpensive, camera-like device that reports the brightest spot on its imaging array and is thus suitable for inexpensive IR-LED-based tracking systems. Multiple IR-LEDs can be tracked using a position sensitive device by carefully controlling when each is illuminated. Gross room-level location can be determined using the simplest infrared detectors and IR-LEDs that transmit the identity of the user by blinking specific patterns over time, much like a television remote control (Want et al. 1992).

Acoustic tracking systems are able to triangulate position using time-of-flight measurements. One approach is to equip the room with multiple detectors that are able to hear a mobile tracking device equipped to emit a sound at a known frequency. This configuration can also be inverted, with the detector on the tracked device and the emitters in the environment (Smith et al. 2004; Ward, Jones, and Hopper 1997). Related signal-processing algorithms can combine the output of two or more microphones to triangulate the position of an arbitrary sound source (Rui and Florencio 2003). This approach can be particularly effective when combined with other techniques such as computer vision-based face tracking (Zhang and Hershey 2005).

7.2.4 Movement and Orientation

Unlike most tracking technologies, a number of movement and orientation sensors do not rely on external infrastructure. Inertial sensors, for example, sense spatial and angular motion (translation and rotation). They can be used for activity recognition as well as gesture and body motion-based interactive applications where it is acceptable to wear or hold a small wireless sensor package (Bao and Intille 2004; Hinckley et al. 2000; Lee and Mase 2002).

Very simple tilt sensors such as mercury switches have been used for years to sense gross orientation. More recently, inexpensive accelerometer devices using micro-electromechanical systems (MEMS) technology were developed for application in automotive airbag systems (Kovacs 1998). MEMS accelerometers feature a tiny proof mass or cantilever beam and deflection sensing circuitry to sense both varying accelerations due to movement as well as the constant acceleration due to gravity. Two-axis MEMS accelerometers can be applied to sensing tilt (pitch and roll) and have been used in gaming controllers. But nonmilitary accelerometers are not sufficiently precise to support the double integration of acceleration necessary to calculate position information for more than a few seconds. In such applications, it may suffice to add a coarse position sensor to combat the effects of drift.

MEMS technology has also allowed the development of gyroscope devices that sense angular acceleration rather than absolute orientation. These devices have been used in stabilizing handheld cameras and in the GyroMouse product, which maps relative change in gyroscope orientation to the relative motion of the mouse cursor.

Magnetometers are compact, solid-state devices able to detect the strength of the earth's magnetic field along its principle axis, and so are useful in determining absolute orientation information. The output of a pair of orthogonally mounted magnetometers held level may be combined to find magnetic north. It is common to combine a two-axis accelerator with a two-axis magnetometer to "correct" the output of the magnetometer when it is not held level (Caruso 1997). Three-axis magnetometers are available, but alone do not give a true 3D orientation (e.g., a magnetometer's reading does not change when it is rotated about magnetic north).

7.2.5 Touch

The microswitch typical of today's mouse requires a certain amount of force to activate, thus allowing a user to comfortably rest their forefinger on the button without accidentally clicking. Pressure sensors, however, sense a continuous range of pressure states. Historically, these have been useful in robotics, where they play an important role in designing control systems for manipulators. Polyvinylidene fluoride films and force sensitive resistors are two inexpensive types of pressure sensors with good dynamic range and form factors useful for small devices and interactive systems. Flexible strain gauges utilizing the piezoresistive effect have a resistance related to the amount of deformation (bend) applied to the sensor. Such gauges have been used as the basis for inexpensive glove devices that sense the deflection of each of the fingers of the hand.

Capacitive sensing is based on the property that nearly any object is capable of storing electric charge, and that charge will flow between two objects when touching or in close proximity. A zero-force touch sensor can be implemented with a charge transfer technique, whereby the capacitance of an electrode is estimated by measuring the time taken for an electrode to discharge a small applied charge (Hinckley and Sinclair 1999). This time drops dramatically when the user places a finger on the electrode, since the user's body takes on much of the charge. Other capacitive sensing techniques can sense an object before it touches the electrode, making them suitable as proximity sensors for a wide variety of interactive applications (Baxter 1996; Smith 1999; Vranish, McConnell, and Mahalingam 1991). Multiple electrodes can be used to implement position sensitive sliders, such as the wheel on the Apple iPod.

Most common touch screens report the single 2D position of the user's finger touching or pressing the screen (Sears, Plaisant, and Shneiderman 1992). Resistive touch screens use two large transparent conductive overlays that vary in resistance over their length. When the user presses on the screen, the overlays are brought into contact, and a voltage applied to one or the other overlay is used to detect the horizontal or vertical position of the finger. Capacitive touch screens use capacitive sensing to sense touch, and the relative difference in the charge sensed at each corner of the screen to determine position. Recently, the ability to more precisely sense the touch location and also sense the area and shape of the touching object has been enabled by embedding multiple capacitive sensors in the display surface (Dietz and Leigh 2001; Rekimoto 2002). Finally, surface acoustic wave systems rely on sensing the finger's disruption of surface acoustic waves applied to a screen surface (Pickering 1986).

Finally, computer vision techniques have been applied to sense touch (Fails and Olsen 2002; Han 2005; Matsushita and Rekimoto 1997; Smart Technologies, Inc., 2007; Tomasi, Rafii, and Torunoglu 2003; Wellner 1993; Wilson 2005). Using computer vision to sense touch over an area has a number of advantages: First, these techniques usually do not require a special instrumented surface as do most touch screens. Second, vision techniques naturally support multiple touch points. Finally, vision techniques enable the ability to detect and recognize a variety of objects besides fingers. For example, barcode-like visual codes may be applied to uniquely identify objects such as game pieces placed on a surface.

7.2.6 Gaze and Eyetracking

Gaze detection refers to determining where a person is looking and is principally the domain of computer vision. It is possible to very coarsely determine head orientation using techniques related to face detection (Wu, Toyama, and Huang 2000), but head orientation is often a poor indicator of where someone is looking. The goal of eyetracking systems is to precisely determine where the user is looking, or foveating. Usually, these techniques are based on precise tracking of multiple reflections of an infrared illuminant off the eye's cornea. For good performance, however, eyetracking systems require careful per-user calibration, and so have seen limited general application in interactive systems (Beymer and Flickner 2003; Jacob 1993; Tobii 2005; Zhai, Morimoto, and Ihde 1999).

Rather than determining gaze in a general fashion only to later match the gaze direction to one of several known objects, an alternative is to determine only whether user is looking at the object. The detector can then be embedded in the object itself. Furthermore, the reflection of an infrared illuminant by the cornea and retina can be detected by simple image-processing techniques when the camera and infrared illuminant are colocated (Haro, Flicker, and Essa 2000; Shell et al. 2004).

7.2.7 Speech

The long history of research on speech recognition techniques has resulted in commodity systems that bring modern speech recognition to anyone with a PC and an inexpensive microphone (Rabiner and Juang 1993). New interactive systems, however, highlight the need for further work. Current systems, for example, function poorly without a "close-talk" microphone and in noisy environments, and so are unsuited for use in such contexts as intelligent rooms and mobile scenarios.

The array microphone combines audio from multiple microphones to address the problems of multiple sound sources and noisy environments. Through the process of beamforming, the outputs of the multiple microphones of an array are combined to form a single audio signal in which all but the dominant speaker's signal has been removed. Beamforming can also reveal information about the position of the speaker (Tashev and Malvar 2005).

To achieve robustness, speech may also be combined with other input modalities such as pen gestures (Oviatt 2002). Such approaches usually require a sophisticated model of the user's interaction. Perhaps inspired by HAL in *2001: A Space Odyssey*, some researchers have proposed incorporating computer vision-based lip-reading techniques into the speech interpretation process (Stork 1998). Finally, information such as intonation, prosody, and conversational turn taking can be valuable in interactive systems (Bilmes et al. 2005; Choudhury and Pentland 2003; Pentland 2004).

7.2.8 Gesture

Many notions of gesture exist in interactive systems, and thus, many sensor systems are applicable. A gesture can be thought of as a specific hand pose, a spatial trajectory of the hands or stylus, pointing or other motion to indicate an object, or the quality of a motion of almost any body part as it relates to a given application context (McNeill 1992).

Many of the earlier-mentioned tracking and movement sensing technologies have been applied to sense and recognize gestures. For example, a wireless sensor package with multiple accelerometers or gyros can capture motion information useful in recognizing many gestures. Computer vision techniques also can be used to track body parts such as the hands and head, as well as overall motion qualities that can be interpreted as gesture. Often such systems ease the sensing task by requiring the user to wear brightly colored gloves, or by training precise models of skin color (Brashear et al. 2003).

Pen gestures are often studied on the tablet computer, a form factor that often uses the Wacom electromagnetic positioning technology. This system uses coils embedded in the pen and under the display to find pen position, limited height (hover) above the surface, tilt, pressure, and button state. It can also support multiple simultaneous inputs. The gestures themselves are usually modeled as simple "flick" gestures or spatial trajectories.

Although computer vision techniques have been explored to recover detailed hand pose information, gloves with built-in sensors are more commonly worn for this purpose (Baudel and Beaudouin-Lafon 1993). Early virtual reality systems, for example, used magnetic trackers attached to gloves equipped with bend sensors to recover the position, orientation, and pose of the hands. More recently, vision-based professional motion capture systems that track infrared retro-reflective balls have been used in a similar fashion. With such precise hand shape information, it is possible to point at an object with the index finger, and then make a motion similar to pulling the trigger of a gun to effect an action (Vogel and Balakrishnan 2005).

7.2.9 Identity

In interactive systems, it is often useful to know the identity of an object or user, and a variety of sensing systems are designed to recognize known objects. Object recognition is an active research area in computer vision. There are practical techniques for quickly recognizing one of many known flat objects such as photos or book covers, for example (Lowe 2004). Computer vision-based face recognition techniques have also been shown to work in fairly controlled settings (Li and Jain 2005). However, general object recognition and face recognition in uncontrolled settings is still difficult.

Beyond face recognition, biometrics uses a variety of sensing technologies. Fingerprint recognition hardware, for example, uses optical scanning technology, or an array of tiny capacitive sensors, to construct an overall picture of the fingerprint. Since Johansen's early experiments demonstrating an ability to recognize human motion from point-light displays (Johansson 1973), researchers have worked on gait recognition techniques from video (Boyd and Little 2005). Iris, retina, hand geometry, vascular pattern, handwritten signature, and voice dynamics are other biometric techniques using sensing technology (Sugiura and Koseki 1997; Wayman et al. 2004).

In the absence of reliable techniques to recognize an object by its natural properties, it is often useful to "tag" an object with a standard, easily recognizable marker that reveals the object's identity. Visual codes such as the ubiquitous UPC bar code symbols, for example, are read by laser scanning systems, which are now small enough to be incorporated into mobile devices. Two-dimensional "matrix codes" such as the Quick Response (QR) code pack more bits into the same space, and they have been used in a variety of interactive systems that recognize them by image analysis (Kato et al. 2000; Rekimoto and Ayatsuka 2000).

Recently, radio frequency identification (RFID) tags have gained in popularity. RFID tags themselves are usually passive, can be made small and unobtrusive, are cheap to manufacture, and can be read at a distance. A scanning antenna that emits an RF signal reads the tags; this signal, in turn, powers the tags with enough energy to respond with an identification code. RFID systems vary in terms of range, power requirements, antenna and tag form factors, bit depth, and so on (Garfinkel and Rosenberg 2005). They are thus particularly attractive for commercial inventory management applications and have been applied to interactive systems (Want et al. 1999).

7.2.10 Context

Sensors can provide important information about the context of the user or device. For example, a computer may listen in on an office to determine whether a meeting is in progress, and if so withhold noncritical notifications (Oliver and Horvitz 2005). A later section explores the role of context in interpreting the output of sensors.

Simple context sensors are especially useful in mobile applications. Environmental sensors that detect such information as air temperature, lighting quality, and air pressure may be more directly relevant to the application than the absolute location given by a GPS sensor (Lester, Choudhury, and Borriello 2006; Schmidt, Beigl, and Gellersen 1999). Context sensors may be used to determine the user's activity, or what the user is currently doing. In mobile applications, an inertial sensor may be used to determine the current transportation mode of the user, while a microphone may be used to conclude that the user is engaged in a conversation. An array of simple switches placed throughout a household environment, such as on kitchen cabinets and drawers, may be all that is needed to reliably determine the activities of its inhabitants (Tapia, Intille, and Larson 2004; Wilson and Atkeson 2005).

7.2.11 Affect

In psychology, affect refers to an emotion or subjective feeling. Recently, there has been interest in applying sensing technology to allow interactive systems to respond appropriately to (and perhaps influence) the user's affect (Picard 2000). A system might respond to the user's boredom, interest, pleasure, stress, or frustration (as in the example in the introduction) by changing aspects of the interaction.

Like other multimodal systems, an affective computing system is likely to integrate a variety of conventional sensors. There is an emphasis, however, on the use of physiological sensors to recover physical data that may be related to the user's affective state. For example, the galvanic skin response sensor measures the skin's conductivity, which increases quickly when the user is startled or experiences anxiety. The blood volume pulse sensor measures blood pressure over a local region by measuring the reflectance of a bright infrared light, and can detect certain states of arousal when applied to the fingertips. Respiration rate can be sensed by measuring the amount of stretch in an elastic band worn around the chest. The electromyogram sensor measures the amount of electrical activity produced when the muscle it is placed over contracts, and is useful in detecting jaw clenching, and contraction of various muscles related to facial expressions. Finally, the electrocardiogram measures heart rate.

In designing affective computing systems, it is often difficult to determine the mapping of sensor outputs to application-specific quantities, such as emotional state. Particularly challenging is the task of identifying specific physical correlates for broadly defined emotional states such as "frustration." Finally, physiological sensors are unsuitable for many applications because of the difficulty in deploying them: many must be placed on particular locations on the body, may require good contact with the skin, and are susceptible to differences among individual users or even the same user from day to day.

7.2.12 Brain Interfaces

Advances in cognitive neuroscience and brain imaging technology have spurred initial explorations into interfacing computers directly with a user's brain activity. Much of the work is motivated by a desire to help individuals who have lost the motor skills necessary to use traditional interfaces. Thus, the goal of brain–computer interfaces (BCI) is often to enable users to explicitly manipulate brain activity in order to provide input to a system. Such interfaces typically emulate traditional interfaces by triggering keystrokes and cursor control. However, future applications will likely take advantage of the unique abilities of BCI systems to enable completely new styles of interaction (Hjelm and Browall 2000).

BCI is generally limited to brain imaging techniques that are noninvasive and do not require bulky, expensive equipment. The electroencephalograph (EEG) measures electrical activity at local parts of the brain using electrodes placed carefully on the scalp. EEG has low-spatial resolution compared with other brain imaging techniques, but has relatively good temporal resolution. Functional near infrared imaging measures blood flow in local regions of the brain by calculating the absorption of infrared light directed into the scalp. The technology suffers, however, from low-temporal resolution, but obtains higher spatial resolution than EEG and generates results that are similar to more impractical blood flow–related imaging techniques such as functional magnetic resonance imaging.

With today's BCI systems, users must learn how to manipulate their brain activity effectively for a given application, either through operant conditioning or by executing certain predetermined cognitive tasks that are distinguishable to the sensors. Imagining the performance of a motor skill, for example, exercises specific parts of the brain (Curran and Stokes 2003). This specific activity may be detectable by an imaging technique of coarse resolution. Alternatively, applications can be specifically designed to take advantage of naturally occurring brain activity, such as that associated with a flashing light. Under carefully controlled conditions, it is possible to classify the user's engagement in cognitive tasks, such as rest, mental arithmetic, and mental rotation (Kiern and Aunon 1990).

7.3 SIGNAL PROCESSING

It is rare to find a sensor precisely suited to a given sensing task. Often, sensor output must be manipulated or combined with other sensors to fit the needs of the application. This section surveys signal-processing techniques useful in applying sensors to input and recognition tasks.

7.3.1 Preprocessing

Preprocessing refers to the earliest stage of processing sensor signals. It is at this stage that noise may be removed from raw sensor signals, or signals may be reduced to make them more compact and otherwise easier to use in later processing stages.

The performance of a sensor relevant to preprocessing can be characterized in several ways. Accuracy refers to the degree to which the sensor readings represent the true value of what is measured. Precision, or resolution, by contrast, refers to the extent to which successive readings of the same physical phenomenon agree in value. It is important to realize that while a device's resolution is often measured in bits, this number is often distinct from the number of bits used to represent or store the sensor's readings.

In general, accuracy and precision can be estimated by collecting several successive measurements (samples or observations) of the same input, and computing the resultant mean and scatter (covariance). An accurate sensor will put the mean near the true value, and a precise sensor will have a small amount of scatter about the mean. An accurate but noisy sensor will have low precision (high scatter), but can still be useful by the Central Limit Theorem from statistics: If we make some assumptions about the noise and average a sufficient number of successive values, then we will derive a good estimate of the true value (Hoel, Port, and Stone 1971).

Averaging of successive sensors readings is but one simple way to smooth noisy data to obtain a noise-free estimate of what is measured. Of course, the input in a real application is likely to be changing over time, and the manner in which this average is computed can vary. For example, the boxcar filter is simply the average of the last *n* samples, and is thus easy to implement; however, the boxcar filter suffers because it requires a buffer of samples over which the average is computed, and the resulting estimate will lag the true value in the case of a changing signal. Related to the boxcar filter is a technique whereby the estimate is obtained as a weighted average of new observation and previous estimate. This filter is even easier to implement and requires no buffer of previous samples. In this technique, however, each estimate depends on previous estimates as the Poisson distribution over time, such that a very quickly moving signal or a signal with many outliers will result in erratic changes in the smoothed signal.

The Kalman filter is a popular technique for filtering time-varying signals and can be used to both smooth and predict a signal. It is the optimal linear filter in the sense that it minimizes the difference between the estimate and the true value, assuming a linear model of the input's changing signal and

Gaussian noise (Welch and Bishop 2004). The most common Kalman filter for estimating the position of a moving object models the object's state as a linear function of both velocity and the position estimate in the previous time step. The Kalman filter models uncertainty in two ways. First, there is some uncertainty in the linear model (how much do we believe that the linear model is correct?). Second, there is uncertainty resulting from instantaneous noise that corrupts the observation (how precise is the sensor?). A properly tuned Kalman filter balances these uncertainties appropriately and suffers fewer problems with lag than, for example, a boxcar filter. When the changing signal is actually linear, it can completely defeat lag due to filtering. An improperly tuned Kalman filter, however, can impart unnecessary lag and overshoot, such that the estimate runs past the input before correcting itself.

Often, rather than obtaining a continuous estimate of a sensed quantity, we are interested only in obtaining a binary result: Is the switch on or off? When a user throws on a switch in a real system, the output state of the switch can change very rapidly from off to on and back several times before settling to a single stable state. Debouncing techniques combat this effect; one simple technique is to ignore the switch for some small, fixed time after seeing the first change in switch state (e.g., 40 milliseconds).

More difficult is the situation in which a truly continuous quantity must be transformed into a binary signal. This is commonly done by choosing a threshold below which we report the output as "zero," and otherwise, "one." For example, in using a continuous-valued tilt sensor such as an accelerometer to determine whether a tablet PC is being used in "portrait" or "landscape" mode, it is necessary to transform the tilt information into a binary quantity indicating "portrait" or "landscape." An alternative to a single threshold is a scheme with two thresholds and a region between (a deadband) in which no change to the output is made. Similar to debouncing, this approach can prevent fluctuation of the output around a single threshold.

Choosing threshold values is generally challenging, and poorly designed complex systems are frequently awash in thresholds that require modification to achieve acceptable performance. Ultimately, the thresholding process destroys information; depending on the nature of subsequent processing, this loss can be detrimental to a system's overall performance. This is particularly true for borderline cases where a system is likely to make erroneous decisions as the result of either an improperly chosen threshold or a noisy input. Such concerns may be eased by adopting a "soft" threshold that reports intermediate results around the "hard" threshold; the logistic function (Bishop 1995) can be useful in this approach.

The signal's effective range of output, or dynamic range, must be often be considered both in thresholding and subsequent processing. The relevant range of the property to be sensed must of course lie within the dynamic range of the sensor. If the dynamic range changes—as a consequence, for example, of temperature change, lighting change, or even variations in installation—it may be necessary to calibrate the signal to achieve a normative range. One strategy is to find the sensor's minimum and maximum output during normal use and to map these to some canonical range. For example, the output of a photodetector may be mapped to a range from zero to one by recording the value of the sensor in the darkest and brightest conditions of regular use. Another strategy is to calibrate the sensor to ground truth values that are collected by some other more trusted sensor. Both of these approaches require care if the sensor is not linear in its response; it may then be necessary to fit a curve (e.g., polynomial) to map the sensor to normal values. Characteristics such as dynamic range, linearity of the response, and variation due to temperature are often detailed in a sensor's "data sheet," available from the manufacturer.

In time-varying systems, we are often concerned with the frequency with which we receive new samples from the sensor. An overly high sampling rate can result in too much data to process, and can be reduced by downsampling. By contrast, many interactive systems will seem to lose their responsiveness if the overall latency is greater than 100 milliseconds. Latency or lag refers to any delay present in the sensor's response to a change in the sensed property of the world, and can limit the responsiveness of an interactive system built on the sensor (MacKenzie and Ware 1993). A low-sampling rate imparts latency, which may be remedied by predictive techniques such as the Kalman filter.

Finally, it is important to consider the true distribution of any noise in filtering and many subsequent processing techniques. Many techniques—including the simplest averaging, Kalman filters, and many probabilistic approaches—assume a Gaussian or uniform distribution of noise. Outliers violating this assumption can be troublesome and should be removed by ad hoc means or techniques from the field of robust statistics (Fischler and Bolles 1981; Huber 1981). For example, the median filter, in which values of a sequence are replaced by the median value, is easy to implement, yet more robust than simple averaging.

7.3.2 Feature Selection

In the context of recognition, a feature can refer to a particular sensor or a piece of information derived from one or more sensors, or even derived from other features. Often thought of as a preprocessing step, feature selection refers to the process of determining which features are to be computed from the raw inputs and passed to the next level of processing. Appropriate feature selection can sometimes make difficult recognition problems easy. For example, one somewhat unusual approach to detecting faces in video is to detect eye-blinking patterns. Blinking provides a signal that is easily detected by simple image-processing operations, and is further supported by the fact that both eyes blink together and are arranged in a symmetric spatial configuration on the face. Blinking thus may be highly diagnostic for faces (Crowley and Berard 1997).

Feature selection begins by determining a set of sensors relevant to the task at hand often with knowledge of the task or domain. In the course of development of a new sensing-based system, it can be beneficial to incorporate as many physical sensors as possible, with the idea that subsequent feature selection processes will indicate which sensors are necessary and sufficient. Furthermore, a number of sensors taken in combination may provide the best overall performance.

Having selected a number of sensors, often the next step is to compute derived features from the raw sensor inputs. For example, when an unimportant and unpredictable offset is present in the sensor inputs raw levels, it may be easier to work with its derivative instead. Again, these features are determined in an ad hoc fashion, in light of special domain or application knowledge. For example, early stylus gesture recognition algorithms relied on simple derived features such as the (a) initial angle of the stroke, (b) maximum speed obtained, (c) size of the containing bounding box, (d) duration of the stroke, (e) amount of change in curvature along the gesture, and so on (Rubine 1991). Early face recognition approaches relied on features such as the distances between facial features such as the eyes, nose, and mouth (Zhao et al. 2003). In the domain of audio, the linear predictive coding and the Fourier transform are useful derived feature spaces. The Fourier transform in particular has general applicability to signals with periodicity. For example, the Fourier transform of a body-worn accelerometer may reveal patterns of the user's walking (Hinckley et al. 2000).

Often, it is desirable to put spatial features in a local coordinate system. For example, a gesture recognition system may begin with the position of the head and hands of the user. To remove the effects of the person moving about the room, the head position may be subtracted from the position of each hand, yielding a "head-centric" coordinate system. In the spirit of asymmetric bimanual models of gesture, we might also consider a coordinate system centered on the non-dominant hand (Guiard 1987; Hinckley et al. 1998). In many cases, switching to a local coordinate system eliminates a large source of the irrelevant variation present in the raw signal, thus easing subsequent modeling, and it can be superior to using only derivative information.

If there is a large number of sensors, or if each sensor is of high dimension (e.g., images taken from video cameras), each sensor's value is unlikely to be statistically independent from one another. To remove redundancy and make the input a more manageable size, some form of dimensionality reduction may be used to transform each observation into one of lower dimension. One broad class of techniques involves approximating each sample as the linear combination of a small number of basis functions; the coefficients in this linear combination form the corresponding sample in the new, smaller feature space. Principle components analysis (PCA) is a popular technique and is the optimal linear technique in the mean-square error sense. PCA finds orthogonal vectors ("principle components," or eigenvectors) in the input space as basis vectors, each vector reducing variance (scatter) in the data set. PCA has been used in a wide variety of recognition systems, such as face recognition from images, where often less than 50 components are necessary to perform recognition (Pentland, Moghaddam, and Starner 1994). Today, there are numerous techniques related to PCA, many of which are more suited to classification (Fodor 2002).

Where the number of input features is not large, automatic feature selection techniques may be used to determine the subset of features that matter. Although the topic is an active area of research, one technique of general applicability is cross validation (Bishop 1995; Mitchell 1997). The simplest form of cross validation is the holdout method, which begins by dividing the data set into two halves. Several variations of the model are then trained on one half of the data and tested on the other. The variation with the best performance on the test set is selected as the best model. In the case of feature selection, each variation uses a particular subset of the original input features; after trying all such subsets, we are left with the best performing subset of features. For more than a handful of original features this approach will be impractical, so various greedy approximations are often used, such as starting with the full set and eliminating one at a time, or successively adding features from a small set.

7.3.3 Classification and Modeling

Classification refers to the process of determining which of several known classes a given sample or observation is drawn from, and is typically the means by which a novel input is recognized. A classifier can be used, for example, to recognize which of several known gestures the user has performed by the motion of the pen on a tablet. Detection refers to determining the presence of an observation drawn from a known class against a background of many other observations. The distinction between classification and detection is often rather semantic. For example, a face detection system will determine if there is any face present in an image, while a face recognition system will determine the identity of the detected face. Although both operations can be thought of as classification, often they call for different techniques.

When simple thresholding or feature selection operations are not enough to transform a group of sensor readings into a signal that is readily consumed by the application, it is often necessary to exploit more sophisticated classification and modeling techniques. These techniques are particularly useful in cases where it is necessary to use many sensors together, and when there are dependencies among them that are difficult to untangle by simple inspection. Modeling refers to the choices in representation of sensor values, their dependencies, and the computations performed on them.

There are many ways to classify a new sensor observation as belonging to one of several known classes. Approaches in which a model is trained automatically from a set of training examples are the most relevant to sensor-based systems. These techniques are typically the domain of machine learning. The canonical introductory technique is Fisher's linear discriminant (Bishop 1995) in which a closed-form training procedure determines a line in the feature space that optimally divides two classes of training data. A new, unseen sample may then be classified by determining which side of the line the sample lies. Beyond the two-class case, samples are often classified by computing the likelihood that the sample was drawn from each class, and choosing the class with the largest likelihood. Assuming a new observation x, and classes C_i we choose C* as the maximum value $P(C_i)P(xfC_i)$. The prior $P(C_i)$ indicates our belief that a sample is drawn from a class before we even record it, and is often ignored. There are a variety of techniques to derive such probabilistic models from a set of examples.

Common to all these approaches is the ability to characterize the quality of a recognition result. A sample that is correctly classified as belonging to a given class is a true positive. A sample that is incorrectly classified as belonging to the class is a false positive. A sample that is correctly classified as not belonging to a given class is true negative, while a sample that is incorrectly classified as not belonging is a false negative. In the context of interactive systems, a false negative might correspond to when the user provides an input and the system fails to recognize it. A high false-negative rate can lead to an overall impression of unresponsiveness, or a sense on the part of the user that they are doing something wrong. False positives, however, may correspond to when the system takes an action when the user had no such intention, and can lead to an impression that the system is erratic or overly sensitive (Zhai and Bellotti 2005).

In most situations, a clear trade-off exists between the rate of true positives and false positives. Lower the bar for acceptance to increase the true positive rate, and the rate of false positives is likely to increase. In the context of interactive systems, this tradeoff is especially important to consider when developing criteria for when the system takes action as the result of a recognition process. The receiver operator characteristic (ROC) curve plots true-positive rate against false-positive rate and best characterizes this trade-off (see Figure 7.1). The ROC curve is also an established method to compare the performance of recognition techniques, without regard to any application-specific choice on how tolerant we are to false positives.

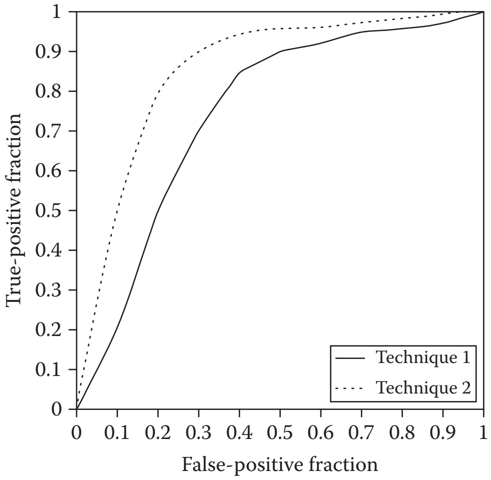

FIGURE 7.1 Receiver operator characteristic curves illustrate the trade-off between the rate of true positives and false positives, and can be useful in comparing recognition techniques. Here we see that for a given tolerable rate of false positives, Technique 2 yields better recognition performance than Technique 1.

In a given application, it is also instructive to break out classification performance by each class. The confusion matrix summarizes how a labeled test set is classified by each class, and may reveal that much of the overall classification error can be traced to errors classifying observations from a small number of classes. This can thus inform design of the classifier or the set of application-relevant categories. Boosting is one technique in which misclassified samples are emphasized in subsequent training of the model to reduce the overall error rate (Schapire 2003).

The naïve Bayes classifier assumes that the value of a given feature is independent of all the others. This property of conditional independence may not actually apply to the data set, but its assumption simplifies computation and often may not matter in practice (hence the label "naïve"). Assuming observations of the form x 5 ^x_1, x_2, …, x_n&, the posterior probability of a class C is $P(Cfx)$ 5 $P(C)\ P(xfC)$ by the Bayes rule. Naïve Bayes treats each feature as independent: $P(Cfx)$ 5 $P(C)P_iP(x_ifC)$. Because each feature is modeled independently, naïve Bayes is particularly suited to high-dimensional feature spaces and large data sets. Each feature can be continuous or discrete. Discrete variables are often modeled as a histogram (or probability mass function), while continuous variables can be quantized or binned to discrete values, or modeled as a Gaussian or other parametric distribution.

A number of other popular classification techniques do not have obvious probabilistic interpretations. The neural network, for example, is best thought of as a function approximation technique. Often, as applied to classification, the input of the approximated function is the observation itself, and the output is a vector whose *i*th component indicates belief that the observation belongs to the *i*th class.

Decision trees can be a powerful classification technique that leads to very compact representations for some problems. Each node of a decision tree corresponds to an assertion about the value of a feature in the observation, and yields a split in the data set. The leaves of the tree then indicate the class to which the observation belongs. Classification of a new sample is then rather like the children's game of "twenty questions." Training the model involves determining how to make the splits to optimize classification performance, and possibly, the size of the tree (Breiman et al. 1984).

The support vector machine (SVM) is a powerful modern alternative to the Fisher linear discriminant (Cristianini and Shawe-Taylor 2000). SVMs determine the split between the two classes to maximize performance on unseen data. Furthermore, SVMs gain much of their power by allowing nonlinear splits of the feature space, but are often thought of as being computational intensive (though, see [Platt 1999]).

Where the conditional independence assumption of naïve Bayes is too strong, other techniques that directly model the joint probabilities are applicable. For example, a mixture of Gaussians uses a sum of multiple Gaussian distributions to model arbitrarily complex joint distributions: $P(xfC)$

5 $S_iP(v_i)$ $P(xfv_i)$, where $P(xfv_i)$ is Gaussian with mean m_i and covariance S_i. Such mixture models may be trained by the expectation maximization algorithm (Mitchell 1997; Neal and Hinton 1999). The expectation maximization algorithm is very similar to clustering approaches such as k-means, in which k points in the feature space are chosen as representative of the overall set of samples.

Often, there are advantages in treating some subset of the variables as conditionally independent from others. For example, a full joint probability distribution can require a lot of data to train; there may be clear constraints from the application that imply conditional independence, and there may be some subset of the variables that are most effectively modeled with one technique while the rest are best modeled with another. In this case, it may be helpful to selectively apply conditional independence to break the problem into smaller pieces. For example, we might take $P(xfC)$ 5 $P(x_1,x_2fC)$ $P(x_3fC)$ for a 3D feature space, model $P(x_1,x_2fC)$ with a mixture of Gaussians, and $P(x_3fC)$ as a histogram. This overall model amounts to an assertion of condition independence between x_3 and the joint space of x_1 and x_2.

This modularity afforded by assumptions of conditional independence is taken to its logical conclusion in the Bayesian network, which is commonly represented as a directed acyclic graph, where each node corresponds to a random variable x_1 with probability distribution $P(x_if\text{parents}(x_i))$, and each variable is conditionally independent of all variables except its parents (Jensen 2001). Nodes in a Bayesian network for which we have observations are called evidence nodes, whereas others are considered hidden. Observations may be entered into network, and through an inference procedure, the likelihood of the observation may be calculated, as well as posterior distributions over any hidden nodes. With Bayesian networks, designers may craft complex probability models without becoming mired in mathematical notation, and software packages allow graphical manipulation of the networks directly (Kadie, Hovel, and Horvitz 2001).

The dynamic Bayesian network (DBN) models time-varying sequences, and thus is relevant to systems in which interactions take place over durations of time. A DBN can be thought of as a Bayesian network where certain nodes depend on the same Bayesian network instantiated on the previous time slice. Dependencies can be within a time slice, or across the time slice. For example, a state variable may depend on its past value as $P(x_tfx_{t21})$. Such relationships with past values of the same variable can encode a probabilistic finite state machine or Markov model, where the distribution $P(x_tfx_{t21})$ is considered a transition matrix. With this dependency on random variables in the past DBNs can effectively encode a time-varying state or "memory" that may be relevant for an interactive application. For example, it can be useful in modeling interactions composed of a sequence of steps, or where application state itself can be modeled as a finite state machine. Finally, by making a strong dependency on the immediate past, the model can be given some inertia or "smoothed."

One popular special case of the DBN is the Hidden Markov Model (HMM), often used to model time-varying signals such as speech, gesture, pen strokes, and so on. HMMs model observations y_t conditioned on a state variable x_t, which evolves over time as $P(x_tfx_{t21})$. As with many probabilistic models, HMMs are generative in nature, meaning one of the ways we can understand them is to consider "running them forward" to generate new observations: an HMM can be thought of as a stochastic finite state machine (Markov model) that generates observations drawn from a distribution associated with each state. With each time step, the Markov model takes a transition to a new state. In the inference (recognition) process, the posterior distribution over the hidden state variable x_t is computed from the observation sequence y_t (Rabiner 1989). HMMs have been applied many types of observation sequences, including hand gestures, handwriting recognition, speech recognition, and so on. In the simplest application paradigm, a separate HMM is trained for each class.

Much of the attraction of Bayesian networks is because of their flexibility to implement complex probabilistic dependencies. Many probability models may be thought of as particular Bayesian networks. Naïve Bayes, mixture of Gaussians, HMMs, and Kalman filters, are among the models that have been shown to be special cases of the Bayesian network (Jordan 1999). The structure of the Bayesian network is often determined by hand using application-specific knowledge, while the various distributions may be tuned by training from data. Parts of a Bayesian network may be completely handcrafted, derived from domain knowledge in the same manner as expert systems. Other sections of the network may in fact be HMMs, Kalman filters, mixtures of Gaussians and various hybrids, such as a mixture of Kalman filters. The automatic learning of the structure of the network itself is active area of research (Heckerman, Geiger, and Chickering 1994).

Many of the techniques outlined in Section 7.3.3 can be applied to the more generic task of modeling, where we are interested in more than classification results. For example, a Bayesian network that fully models the user's interactions with a mobile device might include a variable representing the user's location. The value of this variable will be hidden (unknown) if there is no sensor to directly observe the user's location. We may, however, compute the posterior distribution of the variable after several other kinds of observations are entered in the network and find that the user's location is sometimes known with some precision (e.g., the device recognizes the nearest wireless access point with a known location). Not only is this model useful in deducing the user's location, but also enables other parts of the model to exploit this knowledge even if we are not ultimately interested in location information.

Finally, sometimes the signal-processing task for an application is better thought of as approximating a function that directly maps a set of inputs to outputs. Techniques such as neural networks, radial basis function networks, and other manifold learning techniques can be useful in learning mappings from sensor inputs to application-specific quantities.

Such techniques can be particularly useful in transforming raw, high-dimensional, nonlinear sensor readings into simple calibrated outputs useful in an application. For example, in carefully controlled circumstances, it is possible to map images of a face to gaze angle by providing a number of face image and gaze-angle pairs. A function approximation approach can interpolate over these examples to map new images to gaze angle (Beymer and Poggio 1996).

7.4 EXAMPLE SYSTEM

The following example demonstrates a number of the techniques described in Section 7.3.3 in a working, interactive, sensor-based system. After motivating the overall design of the system, a number of aspects of hardware design are illustrated. Also described are subsequent signal-processing steps such as sensor fusion, the application of Bayesian networks for modeling, and gesture and speech recognition.

In the design of intelligent rooms, the issue of how the room's inhabitants might best interact with the room often arises. The traditional notions of desktop computing or the multiple, incompatible, button-laden remote controls typical of consumer electronics are perhaps antithetical to the seamless and untethered experience that is a main feature of the vision of intelligent environments. One popular notion of how users could control an intelligent room is borrowed directly from *Star Trek*: The user of the room merely speaks to it, as in, "Computer, turn on the lights."

In the development of one intelligent room (Brumitt et al. 2000), a user study was conducted to determine how real users might want to control multiple lights throughout the space (Brumitt and Cadiz 2001). A *Wizard of Oz* paradigm was adopted so that the study would not be limited to designs already implemented. The experimenter, seated behind one-way mirrored glass, operated the lighting controls manually in response to user actions. The users were then exposed to multiple ways of controlling the lights: (a) a traditional graphical user interface (GUI) list box, (b) a graphical touch screen display depicting a plan view of the room with lights, (c) two speech only-based systems, and (d) a speech and gesture-based system. The study concluded that, like Captain Kirk, users preferred to use speech to control the lights, but that the vocabulary used to indicate which light to control was highly unpredictable. This variance in speech chosen poses a problem for the pure speech-based interface.

Interestingly, the majority of subjects looked at the light they were trying to control while speaking. This observation suggests that an intelligent room could resolve ambiguity in spoken commands (e.g., which light to control) by using computer vision techniques to determine the user's gaze, at least where the device under control is within sight. There are a number of general approaches to computing gaze, but each has serious drawbacks. For example, it is possible to roughly compute gaze from a small number of cameras throughout the room (Wu, Toyama, and Huang 2000), but such systems presently lack accuracy and reliability, or require a large number of cameras to cover a useful space. Wearing a special device such as glasses solves some problems, but may not be acceptable to casual users. Another approach is to embed a camera in the device to determine whether the user is looking at it, rather than computing general gaze (Shell et al. 2004). This technique can be effective, but presently scales poorly to a large number of devices.

In light of the difficulties of determining gaze reliably, we reasoned that pointing gestures may play a similar role as gaze in indicating objects. While few subjects in the lighting study spontaneously used gestures, this may be partially explained by the near perfect performance of the *Wizard of Oz* speech recognizer (the experimenter). Furthermore, pointing may have certain advantages over gaze. For example, pointing is typically the result of a conscious decision to take action, whereas changes in eye gaze direction may be more involuntary (Zhai, Morimoto, and Ihde 1999). However, pointing may be no easier to detect by computer vision techniques than gaze (Jojic et al. 2000).

To demonstrate the utility of the combination of pointing and speech as an interface modality in an intelligent environment, we built a hardware device to sense pointing gestures and developed associated signal-processing algorithms to combine speech and gesture (Wilson and Shafer 2003). At the center of the XWand system is a handheld device that may be used to select objects in the room by pointing, and a speech recognition system for a simple command and control grammar. To turn on a light in the room, the user may point the wand at a light and say, "Turn on." Because the pointing gesture serves to limit the context of the interaction (the light), the speech recognition task is reduced to recognizing the few operations available on lights: "Turn on" or "Turn off." Alternatively, the user may perform a simple gesture in place of speech to effect the same command. The user may, for example, point at a media player device, hold the button down, and roll the device to adjust the volume. The XWand system illustrates a number of points related to sensor and recognition-based input, including the hardware design of a composite inertial sensor, sensor fusion, DBNs, and a host of design considerations.

The original XWand system is based on a 3D model of a room and the controllable devices within it. Using onboard sensors, the XWand device can determine its own absolute orientation, while a computer vision system mounted in the environment finds the position of the wand. Given the size and 3D position of an object in the room, it is a simple trigonometric calculation to determine whether the XWand is currently pointing at the object.

The original XWand hardware device contains an Analog Devices ADXL202 two-axis MEMS accelerometer, a Honeywell HMC1023 three-axis magnetometer, a Murata ENC-03 one-axis piezoelectric gyroscope, a 418-MHz FM transceiver, a PIC 16F873 microcontroller, an IR-LED, and a pushbutton mounted on a custom printed circuit board (see Figure 7.2). Although the accelerometer is useful in detecting pitch and

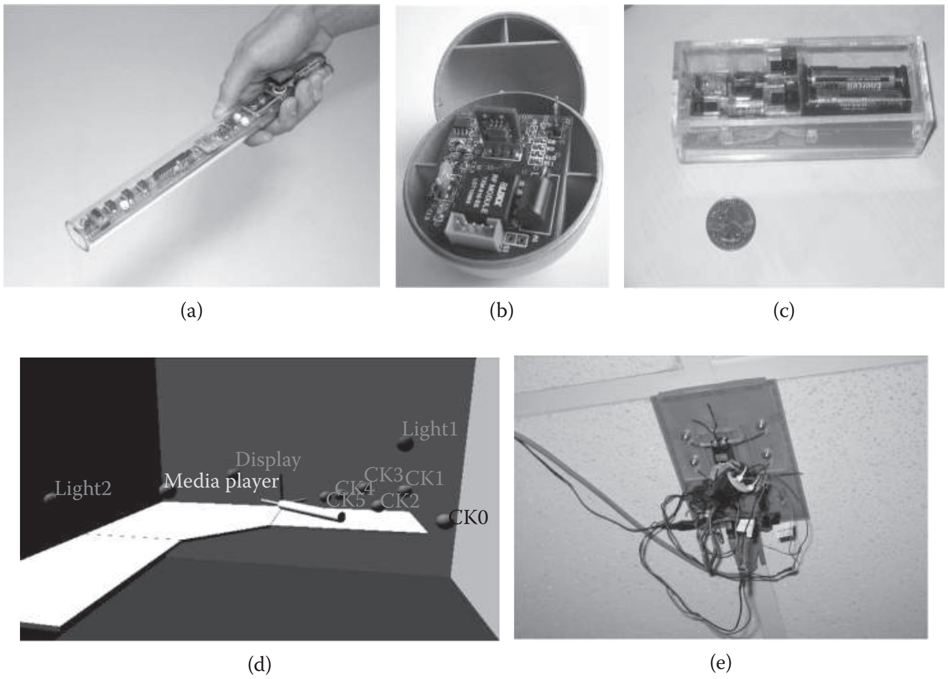

FIGURE 7.2 (a) The first XWand prototype includes accelerometers, magnetometers, gyro, radio, etc. (Image © 2003 ACM.) (b) The Orb device repackaged much of the XWand. (c) The WarpPointer updates most of the components and uses Bluetooth. (d) The XWand three-dimensional geometry model includes the three-dimensional position of all interactive devices in a room. (Image © 2003 ACM.) (e) The WorldCursor teleoperated laser pointer is driven by the XWand.

roll (recall that gravity is an acceleration), it cannot detect the yaw attitude of the device. The three-axis magnetometer reports direction cosines against magnetic north, from which yaw can be determined only if the device is held flat (some GPS devices are equipped with two-axis magnetometers that give heading when the device is held flat). Fortunately, pitch and roll information from the accelerometers may be used to "correct" the output of the three-axis magnetometer to yield a full 3D orientation with respect to magnetic north.

To compute the 3D position of wand, the XWand system uses a pair of FireWire cameras mounted in the corners of the room, which are used to track the IR-LED on the device. Each camera uses an IR-pass filter so that in a typical office environment, only the IR-LED is visible in the image. Furthermore, the IR-LED is programmed to flash at 15 Hz. When the host takes the video output of each camera at 30 Hz, consecutive images may be subtracted pixelwise so that only objects blinking at 15 Hz remain. The IR-LED can thus be located easily in both views. Furthermore, the cameras are calibrated to the geometry of the room so that the 3D position of the IR-LED is obtained from its 2D position in both views. Note that this arrangement assumes a line of sight to the IR-LED from both cameras.

To support speech recognition, an open microphone (low impedance) is placed in the environment. Ultimately, this microphone should be placed on the device, perhaps with the audio encoded and relayed off-board for recognition. The speech recognition engine is programmed with simple command and control grammar based on a simple command-referent pattern, where a referent can be a device in the environment (e.g., a light) and the command refers to one of a number of permitted actions on the device (e.g., "turn on").

Simple gestures made with the wand—such as flicking left, right, up, down, and roll—are recognized by simple routines that measure the change in attitude of the wand from the attitude recorded when the button on the device is first pressed. We have also experimented with using HMMs to recognize more complex gestures, but have chosen instead to exploit a small set of simple, memorable, and reusable gestures in conjunction with other contextual information such as pointing and possibly speech information. This approach allows for a very simple and robust gesture recognition process, and avoids training users on a gesture set of greater complexity.

A DBN fuses the various quantities to arrive at a multimodal interpretation of the user's interaction. It models the combination of the output of the speech recognition, the object at which the wand is currently pointing, any gesture performed, the known state of the devices under control, and the state of the interpretation in the previous time steps (see Figure 7.3). The network bases this combination on the command-referent pattern outlined in the previous paragraph, where the referent may be determined by speech or pointing gesture, and the command may be determined by speech, gesture, button click, or any combination thereof. The ultimate action to be taken (e.g., "turn on light #2") depends on the command and referent, as well as the state of the device itself (e.g., "turn on light #2" is only permitted if the light is off). Finally, both the command and referent at the current time step depend heavily on the command and

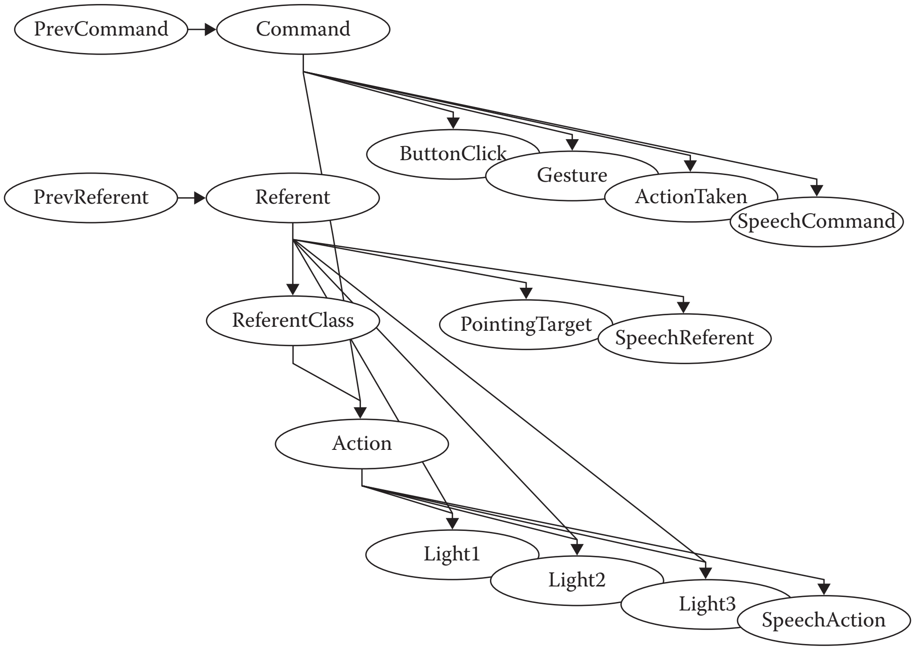

FIGURE 7.3 The XWand Dynamic Bayesian Network models multimodal interaction. It combines wand input (PointingTarget, Gesture, ButtonClick), speech input (SpeechReferent, SpeechCommand, SpeechAction), and world state (Light1, Light2, Light3) to determine the next action (Action) as a combination of command (Command) and referent (Referent) and past beliefs (PrevCommand, PrevReferent). (Image © 2003 ACM.)

referent from the previous time step, such that either quantity can be specified at slightly different moments in time.

The multimodal fusion Bayes network offers a number of interesting capabilities for the XWand system. For example, when the state of each controlled device is represented in the network itself, distributions over related quantities change in appropriate ways. For example, if the user points at a device that is currently turned off, speech and gesture recognition results inconsistent with that state are ignored, such that the phrase "turn off" is removed from the speech recognition grammar. In future work, it may also be possible to infer vocabulary by training the network dynamically (e.g., point at a light and label it as a "light," or point several times at a point in space to train the position of a known light while saying, "Light."

We have continued to develop the XWand prototype in various ways. A typical objection to the camera-based tracking system is the lengthy setup and calibration procedures such systems require. We therefore explored an alternative configuration that eliminates cameras in favor of a single teleoperated laser pointer mounted in the ceiling (Wilson and Pham 2003). The WorldCursor laser (see Figure 7.2) is programmed to match the motion of the wand, in a manner similar to how the standard mouse controls a cursor with relative motion. Because the set of objects the laser can reach is limited by line of sight, the original 3D model of the system is eliminated in favor of a simpler spherical coordinate system with an arbitrary origin, thus simplifying setup.

The most recent iteration includes a three-axis accelerometer that can be combined with a magnetometer to arrive at a true 3D orientation by a simple cross-product calculation (see Figure 7.2). The device has also been applied to cursor control with very large displays, where the mixture of sensors enables a variety of cursor control mechanisms including absolute, orientation-based pointing (position and orientation), relative angular motion similar to the Gyromouse, and pure absolute position only. This flexibility allows exploration of several new modes of interaction. The relative, gyro-based mode of pointing allows very fine control with clutching over a small area. With very large (wall-sized) displays, however, it is easy to lose the cursor among the many onscreen objects. With the current device, it is possible to momentarily adopt one of the more absolute pointing modes to "warp" the cursor to a point directly in front of the user.

7.5 CONSIDERATIONS IN DESIGNING RECOGNITION-BASED SYSTEMS

Section 7.4 touches on issues common to complex sensing-based interactive systems, from hardware design to modeling and sensor fusion. Overall, the strategy in the example is to avoid complex recognition problems whenever possible through thoughtful choice of hardware sensors, design of the interaction, and strong modeling of context. In Section 7.5, we expand upon the motivations behind these design choices. Many of these considerations must be considered in the design of recognition-based interactive systems. While many involve difficult problems with no easy answer, it is best to be aware of these issues when designing a sensing-based interactive system.

7.5.1 Computational Cost, Utility, and the Cost of Failure

A number of challenges exist in designing an interactive system that uses sensors and recognition techniques. First, although Moore's Law continually pushes forward the frontier of practical signal-processing techniques, many of these algorithms are still computationally intensive. Only in the last six years or so have real-time computer vision techniques become practical on commodity hardware. Furthermore, many of the machine learning and pattern recognition techniques are data-driven, thus requiring large amounts of storage, memory, and training. In the case of mobile devices, where computational power lags desktop computing power by several years, many of these algorithms are impractical, and developers are often forced to make hard choices and take shortcuts. These concerns are often magnified in interactive systems that entirely remake the user interface and use multiple recognition-based techniques.

Second, recognition-based systems often face serious challenges achieving and guaranteeing the level of robustness required in real applications. In the case of developing consumer products, for example, it is one thing to demonstrate a technique in a laboratory setting; it is quite another to show that the same technique will work in the variety of circumstances in which customers will expect it to work. Unit testing even simple recognition-based interactive systems can be daunting. Computer vision techniques, for example, are often susceptible to variations in lighting, while audio-based techniques may fail in the presence of background noise. Some effort has been devoted to developing signal-processing techniques that adapt to both the current circumstances and user. Adaptive speech recognition and handwriting recognition techniques, for example, have become commonplace. Even in these cases, however, it is important that the systems have good functionality out of the box or else the user may not use the system long enough for an adaptive algorithm to improve performance.

In the development of a recognition-based interactive system, it may become impractical to seek more improvement in recognition performance. At this point, it is important to consider the cost of recognition failure: Often the cost of repairing a false-positive recognition can overwhelm any advantage in the use of the system. In speech recognition, for example, the repair of the errors can be awkward, slow, and disruptive to the task (Karat et al. 1999). Only users that are unable to use a regular keyboard may accept a dictation system that fails three times out of 100 words, for example (Feng, Karat, and Sears 2005). Another consideration is whether the system returns a result similar to the desired result when it fails (graceful degradation), in which case repair is likely to be easier (Horvitz 1999). If a recognition failure is too costly to consider repair (for example, control of an air lock on a spacecraft, or more mundanely, closing a window on a desktop GUI), the cost of making a mistake may be incorporated directly in the model so that false positives are more likely to be avoided. This can be done either by seeking some kind of deliberate confirmation from the user, or more simply by moving thresholds up the ROC curve. In the latter approach, it is important to be aware that often users modify their behavior on successive attempts such that their input is no longer modeled by the usual training corpus; in speech, this is known as the Lombard effect (Junqua 1993), but this phenomenon can be observed in other modalities as well.

Considerations of computational cost, robustness, and cost of errors should play prominent roles in the end-to-end design of recognition-based systems. Ultimately, the designer may be forced to recast the interaction and possibly the application altogether. An example of a system in which one can find many of these issues played out is the Sony EyeToy, an add-on camera for the Sony Playstation 2. The EyeToy allows the player to interact with a game through gesture and body motion, rather than through the usual game controller. It also appears to use very simple image-processing techniques to determine the player's motion. These techniques are computationally cheap and generally quite robust to varying light levels and other factors that are likely to be encountered in a residential application. Furthermore, the EyeToy works with a small number of games written specifically for use with this device. These games take advantage of the strengths of the EyeToy, rather than risk providing a poor emulation of the regular game controller.

7.5.2 Role of Feedback

Feedback is important in any interactive application, but may be even more so where sensing and recognition are used (Bellotti et al. 2002). We can characterize some kinds of feedback as "tight" or not, where a "tight" feedback loop provides feedback in a frequent, timely, and informative fashion.

Usually, if there is any chance of recognition failure, the system should provide feedback on all recognition results, errors, or otherwise. If possible, the system should provide some indication of the nature of any failure so that the user can modify his or her own behavior to meet the system's expectations. If the system can provide some indication of the quality of the interpretation as it is happening, then it may be possible to allow the user to cancel or modify the interaction on the fly, so as to avoid costly errors or cumbersome confirmation routines (Vogel and Balakrishnan 2004).

The right feedback can often influence the design of the sensing and recognition algorithm itself. For example, because the onscreen cursor is updated so quickly (a tight feedback loop), a naïve user might not ever realize or care that the mouse provides rapid, small, successive bits of relative movement information rather than true position information, which would be much harder to sense. This trick is used in the WorldCursor system to avoid the use of cameras required by the original XWand system.

Considering the EyeToy again, it is interesting to note that the image of the player is often incorporated into the onscreen presentation. By watching themselves onscreen, players are able to interact with onscreen elements without relying on sophisticated, yet more failure prone and computationally intense, hand-tracking algorithms. This feedback also cleverly ensures that the player stays in the camera's field of view; the flow of the game does not have to be broken to alert a player who has left the field of view.

7.5.3 Implicit and Explicit Interaction

In the previous discussion regarding feedback and cost of failure, we assume that interaction is structured in such a way that the user takes action and expects a timely response from the system—that is, the user's actions and the system's responses are explicit. Most interactive systems can be characterized in this way.

In contrast to explicit interactions, implicit interactions are based not on explicit action by the user, but more commonly on users' existing patterns of behavior (Schmidt 2000). For example, with the frustration-sensing system outlined in the introduction, the state of frustration is not explicitly entered by the user in order to elicit some behavior from the system. Instead, the state arises naturally and perhaps involuntarily, and upon detection, the system should take appropriate action.

Implicit interactions may take place over a long duration, and may not exhibit an obvious pattern of cause and effect. For example, systems that adapt to perceived user preferences, as indicated by the history of user behavior, might eventually make a recommendation to the user, or even take actions so subtle that the user may not notice them. Such systems can be complex in terms of sensing and modeling, and often tend toward automating or refining aspects of the user's original task (Horvitz et al. 1998). For example, a smart home may observe its inhabitants' daily patterns of coming and going to determine an optimal schedule to control the thermostat automatically, balancing comfort and economy (Mozer 2005). One potential difficulty is that, unless the output of the system is designed very carefully, users may feel unable to correct a mistake made by the system or exert more explicit control in the face of exceptional circumstances (e.g., a party). Designers should consider providing functionality that allows the user to query the system for why it took a given action, provide simple mechanisms to redress errors, and finally, revert to a manual control mode.

Implicit interaction systems driven by patterns of ongoing user behavior are often not as critically dependent on sensing and recognition reliability and the nature of feedback. Rather, it is more important that interpretation processes are more correct than incorrect over time; accordingly, modeling techniques that integrate noisy sensor values over time are often appropriate. The automatic thermostat, for example, should probably incorporate many observations of the users' behavior—including presence and manual thermostat control—and model weekends, weekdays, and holidays differently. Sophisticated modeling techniques in hand, designers of such systems have the opportunity to exploit powerful, though sometimes unreliable, sensing techniques.

7.5.4 Importance of Context

Notions of context can play an important role in sensing-based interaction (Dey et al. 2001). "Context" refers to the overall environment the interaction or device finds itself in, rather than the objects obviously and directly relevant to the task at hand. What constitutes context often depends on point of view; after studying the application in detail, factors that once may have seemed external and tangentially relevant (context) may be central to the model after all.

Note the purposeful vagueness in the definition of "context"; with respect to sensing, "environment" can refer to the actual physical surroundings. The addition of sensors to a system may give it awareness of its environment, and thereby enable interesting "context-dependent" behavior. For example, a mobile device equipped with GPS or other localization technology might bring up web search results corresponding to the nearest points of interest (Abowd et al. 1997; Davies et al. 2001; Hariharan, Krumm, and Horvitz 2005). Beyond the physical environment, context can refer to more abstract states, such as the user's current activity (e.g., working or not), the history of their interactions, and their preferences. It may also refer to momentary information, such as the action of the nondominant hand, or anaphoric references that provide scope for an ongoing interaction.

Often our activities follow preestablished patterns, either by design or by accident. These patterns can provide strong contextual information for interpreting the user's interactions. For example, entertainment-based scenarios may have a narrative structure that constrains the interaction (Galyean 1995). The KidsRoom interactive experience, for example, was structured according to a narrative progression involving the fantastical transformation of a children's room (Bobick et al. 1999; Bobick et al. 2000) (see Figure 7.4). This structure in turn guided the selection of recognition at any given moment.

Modeling context explicitly can be a powerful way to solve difficult recognition problems. The more context can be brought to bear, often the easier and more robust the recognition. Although counterintuitive at first, by exploiting context, the combination of multiple sensors with simple signal-processing techniques may result in better performance than the use of fewer sensors with more complex signal-processing techniques. Recall how in the XWand system, the speech recognition process is constrained by the knowledge of what the user is currently pointing at with the wand, the current state of the device indicated, and so forth. In fact, the interaction can be so constrained that, often, the system only needs some indication that the user said anything. Similarly, it suffices to use simple, learnable, and reusable gestures when the interaction has been contextualized by pointing, speech, or both. Our frustration detection system may be more robust if it incorporates the knowledge of the application currently in focus. For example, it may be easier to write one frustration detector for office applications and a separate one for use while playing video games, rather than one detector that works in both contexts. In the end, the two detectors may only differ in terms of how some threshold is set.

FIGURE 7.4 The KidsRoom engaged children to participate in an interactive journey. Computer vision and projection technologies were used to transform an ordinary room into a variety of settings including a forest and river. (Courtesy of the Massachusetts Institute of Technology, © 1999.)

7.5.5 Importance of *A Priori* Knowledge

The development of a model for a sensing, interactive system can benefit from specific knowledge of the domain in which the interaction is situated. Such a priori knowledge can lead to insights as to how to determine meaningful categories from raw sensor data. Higher level rules taken from the domain can then be brought to bear. For example, in the case of a pen-based system that automatically parses and manipulates mathematical equations, the rules of how mathematical expressions are combined can be a powerful constraint that drives the correct interpretation of the sloppiest drawings (LaViola and Zeleznik 2004). Similarly, knowledge of chemistry can guide the transformation of sketches of molecules to a full 3D model (Tenneson and Becker 2005). Providing a kind of context, strong assumptions taken from the domain can limit the applicability of a model but can often dramatically improve performance.

Many domains of human behavior have been categorized and described in terms of detailed taxonomies and ontologies. For example, music, gesture, dance, and spoken language each have detailed ontologies, notation schemes, and so on. It can be beneficial to draw from such knowledge when developing a model, but some aspects of a categorization scheme may not be fully supported by the available sensors. For example, there may be some aspect of the domain not covered by the model, or a single category may "alias" to several distinct classes as perceived by the sensors. A detailed analysis of the sensing system output may lead to insights on the original domain model.

One of the advantages of incorporating bits of domain knowledge representation directly into the model itself is that it becomes more transparent to its designers and users, and thus, more reusable. If there is a problem with the system, the designer may directly inspect semantically relevant quantities from the model. Approaches that do not rely on such informed representations, such as neural networks, are often so difficult to inspect that upon discovery of a problem, it may be easier to retrain the model from scratch than to troubleshoot what the network really learned. A good compromise is to use the more data-driven techniques (such as neural networks or probabilistic modeling techniques) to map the raw input signals onto semantically meaningful mid-level primitives. Such choices in representation can support modularity and explorative research.

It is interesting to note, however, that initial research on a given complex sensing problem often draws heavily from domain knowledge, only to be eclipsed later by more purely data-driven approaches. Early approaches to speech recognition, for example, transformed the audio signal into a string of symbols representing phoneme categories developed by linguists; today, one is more likely to see approaches in which subword acoustic unit categories are trained from audio signals directly in a purely data-driven approach. Early face detection and recognition approaches similarly relied on prescriptive or ad hoc features, whereas more recent approaches are more purely data-driven (Li and Jain 2005; Zhao et al. 2003).

7.5.6 Generalize or Specialize?

The incorporation of a priori and context information leads to potentially complex, yet powerful, modeling techniques. One of the drawbacks of adding more and more detail into a model, however, is that the resulting system may be so tailored to a particular domain or set of contextual circumstances that it fails to generalize to new applications. It seems as if engineering best practices, including modularity and device independence, run counter to models that are optimized for a given situation.

For example, consider the problem of delivering various location-based services to inhabitants of an indoor space. A good, familiar choice for the representation of each person's location might be 2D Cartesian coordinates on a full map of the environment. A person-tracking system is installed in the environment; it is charged with determining where everyone is on the map. This information is then passed onto another part of the system that delivers services to each user based on the knowledge of where everyone is at any given moment.

Such a choice of representation has many desirable features. We can consider a multitude of person-tracking technologies—as long as each reports 2D Cartesian coordinates we can incorporate its output into our map (device independence), and we can consider merging the results of multiple such systems in a simple probabilistic framework where we model the location of each person as a distribution over space rather than simple 2D coordinates. Furthermore, we can exploit familiar rules of geometry to calculate interesting properties such as whether a display is within sight of a particular user. Most importantly, we need not concern ourselves with the particular application services that our ultimate system will provide: As long as each service expects only our generic representation, we can expect the service to work properly. The system is general in its applicability.

Contrast this approach to one in which we have no unifying geometric model or map, but instead, install proximity sensors at each of the devices of interest, each sensor detecting someone as they approach the device. Perhaps we install special sensors on some of the doors to detect when someone walks through (Abowd, Battestini, and O'Connell 2003), and maybe a sensor on seats to detect when someone sits down (Brumitt et al. 2000). Often, proximity information is enough and requires no calibration step (Krumm and Hinckley 2004). For our location-based services, we note that in some cases, it is important to know who is at a given location, but in many cases, this information is not necessary. We place various simple sensors throughout the environment in locations that we think will provide the information needed to support the specific location-based services we currently have in mind. The solution we come up with is quite specialized.

It is unclear which approach is superior. The geometric model-based approach depends heavily on the performance of the person-tracking system. When it fails, it may return no useful position information, even when the given circumstances do not require precise position information, and even while the sensor and the underlying signal-processing algorithms may produce relevant intermediate results that could be used at a subsequent level of processing. The assumption of device independence ignores the fact that different sensing technologies typically have very different failure modes. The resulting application may perform poorly because of its design around modeling choices that follow the lowest common denominator. However, it could work very well and provide the utmost in flexibility if the person-tracking is very reliable.

The specialized approach of course suffers in all the ways that the general approach excels; each installation of the system may require significant innovation on the part of the designer. However, because it is tailored to the application, the system is more likely to gracefully handle sensing failure modes, and furthermore, is more likely to be less wasteful of resources, both physical and computational. Not surprisingly, the specialized approach is likely to exhibit better performance for a given application than the generalized approach.

The consideration of generalized versus specialized designs is a common engineering problem that is especially relevant in the realm of sensor and recognition-based systems. As our example illustrates, the two approaches may demand completely different sensors, representations, and modeling choices.

7.5.7 Traditional versus Nontraditional Interfaces

A question that naturally arises in the application of sensing and recognition to interactive systems is whether the design should emulate, augment, or completely replace the interfaces we already have.

It is probably not surprising that so many interactive sensor-based systems emulate the mouse. After all, once this functionality is achieved, the system is now relevant to the vast majority of the world's software. It is interesting to note, however, the degree to which the original development of the GUI hinged on the development of the mouse itself, and how to this day, the mouse is still the favored input device. This suggests that unless the new interactive system offers significant new functionality over the mouse, it will not be adopted, and that instead of forcing the new techniques on today's interfaces, designers should think about what changes in the interface are implied by new sensing systems.

Another approach is to augment or complement today's interfaces. For example, it is relatively simple to add an accelerometer to a mobile device that allows the user to position the cursor or scroll by tilting the device, and it is not hard to imagine how users could easily pick up this interaction (Hinckley et al. 2000).

Still another approach is to completely reinvent the interface. The risks are that the user is required to learn a completely new way of working, the designer is faced with developing the entire system, and the utility of the system will inevitably be compared with more established techniques. Again, unless there is a significant improvement to be had, users are unlikely to adopt the new approach.

Many of these issues are illustrated by recent research into interactive table systems. In its simplest form, an interactive table system might be no more than a large flat-panel touch screen turned horizontal to function as a table surface.

This simple change in orientation enables new applications that exploit the collaborative nature of multiple users gathering around a table (Shen et al. 2004). Furthermore, sensing techniques have been developed to support multiple points of contact on the surface, and to support bimanual interaction, or the multiple hands of multiple users. Distinct from wall displays, tables are able to hold objects, and accordingly, some interactive tables use sensing techniques to recognize objects placed upon them. This ability can be used to support various tangible user interface scenarios. For example, a puck placed on the table can enable a feature of the application; the user might rotate the puck to adjust an associated parameter, or it might call up a group of photos (Fitzmaurice, Ishii, and Buxton 1995; Ullmer, Ishii, and Glas 1998; see also Ishii and Ullmer, Chapter 21, this volume).

Clearly, in order to exploit the unique affordances and sensing capabilities of an interactive table, we must be willing to let go of many of today's GUI interfaces. For example, the multiple-touch and multiple-user aspect cannot be supported by the single-focus model of the GUI, and even the assumption that the display has a natural reading orientation (an "up" direction) may no longer be valid (Kruger et al. 2004; Shen, Lesh, and Vernier 2003). Finally, today's GUI model has no role for tangible user interfaces (UIs).

The designers of interactive table systems tend to follow a few guiding principles to innovate without alienating the user. First, there is a desire to leave the overburdened widgets of the modern GUI behind and instead rely on more of a direct manipulation style of interaction. For example, to rotate a virtual object on the screen, it may suffice to place two fingers anywhere on the object and move one finger about the other, much in the same way that one might rotate a piece of paper sitting on a desk. By using the multiple touch capability, we avoid the clumsy widget-heavy and mode-heavy rotation techniques typical of many drawing packages. The addition of pucks and other tangle UIs extends this approach; for example, while the puck is on the table, it may behave as knob (Patten, Ishii, and Pangaro 2001). Second, there is a trend to add widget-based interaction back into the direct manipulation framework, perhaps mainly to address the need to perform a variety of actions on the digital representation of the object. For example, e-mailing, printing, and contrast and color adjustment are just a few things that the user might want to do with their photos; these operations are outside of the scope of direct manipulation. These widget-based interactions can draw upon the advantages a multiple touch table interface provides. For example, putting two fingers down near an object may trigger a scrollbar-like widget in which bringing the two fingers closer or further apart adjusts a parameter (Wu and Balakrishnan 2003).

7.5.8 Evaluating Novel Interfaces

Determining whether the novel sensing and interaction model actually works is the domain of usability testing. No research into sensor and recognition-based input is complete without an evaluation showing its effectiveness. Unfortunately, the technical difficulty of getting such systems to work at all often leaves little time to quantify performance on a standard task. Furthermore, when the new work is in a preliminary state, it may not be instructive to compare the new technique against one that has had decades to evolve.

Many times, user study subjects are often so impressed by the "magic" of sensor-based systems that the sheer novelty of the interface can skew study results. Subjective surveys are likely to show bias in favor of the novel design (Nielsen 1994). This is a very difficult problem without an easy solution, particularly in the case of tangible UIs, tabletop interactive systems, and perceptual user interface systems. Longitudinal studies, which involve repeated sessions spread out over multiple days, can be used to minimize this effect, but such studies are expensive and time-consuming. As a result, many interactive sensing-based systems come with few convincing quantitative user studies that prove their utility. In the case of a system that uses tracking or detection to select an object, Fitts's Law studies can be an effective technique to compare pointing performance across very different systems (MacKenzie 1992).

Of course, often the point of the work is not to show a decrease in task completion time, a reduction in errors, or other more conventional metrics from the field of HCI. Rather, the goal may be to highlight completely new ways of conceptualizing the relationship between users and their machines, and to demonstrate that such innovations are technically feasible. There is often more of an emphasis on invention and design than on evaluation. The novelty that can sabotage a user study may even be a desirable effect, compelling users to engaging experiences they may not have otherwise had. Furthermore, traditional evaluation methods seem at odds with the goals of surprising, delighting, and entertaining the user. The field has only recently begun to recognize the need to develop ways to objectively evaluate interactive systems along these dimensions that are basic to the quality of life (Blythe et al. 2004; Norman 2003).

A fantastic example where simple sensing techniques were used to great effect to surprise and delight the user is the PingPongPlus system (Ishii et al. 1999). In this research prototype, the usual ping-pong table was augmented with sound effects and a top–down video projection onto the table surface, and electronics to sense where the ping-pong ball hits the surface during game play (see Figure 7.5). This sensing system used eight microphones mounted under the table, and custom electronics to triangulate where the ball hit the surface. The sound effects and video presentation reacted to each strike of the ball, in ways calculated to amuse the players and augment the game play in dramatic ways. For example, in one mode, the ball produces ripples on the table, while in another, thunderstorm audio and video effects build up as the length of the volley increases.

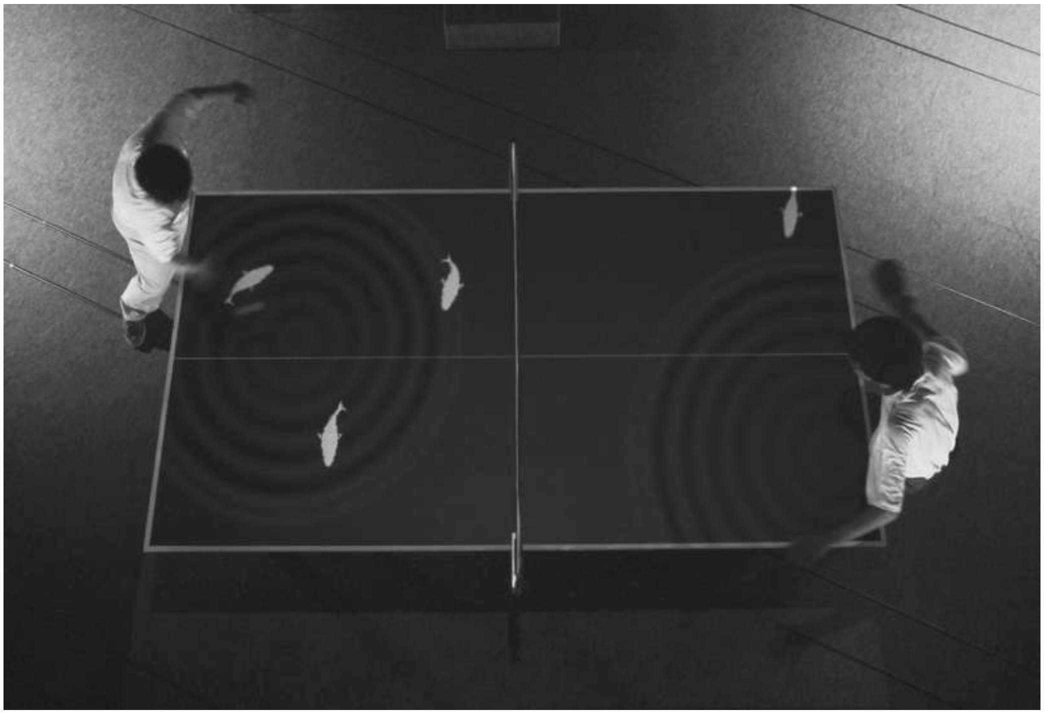

FIGURE 7.5 The PingPongPlus system uses a series of microphones to triangulate where the ping-pong ball strikes the surface of the table. This position information is used to drive a variety of interactive graphics displayed on the table by an overhead projector. (Courtesy of Tangible Media Group, MIT Media Laboratory, © 2006.)

7.6 CONCLUSION

In this chapter, we explored a variety of sensing technologies available today, outlined a number of signal-processing techniques common to using these sensing technologies in sensor and recognition-based input for interactive systems, and discussed further issues related to designing such systems.

Although much of the discussion highlighted difficulties in designing systems that rely on sensors, the future of interactive sensing systems is bright. Advances in MEMS and nanotechnology will continue to drive innovations in the sensors themselves, while the relentless increase in commodity CPU power and storage capabilities will continue to enable more sophisticated modeling techniques used in interpreting sensor outputs.

Another powerful driver in the development of sensing-based interactive systems is the growth of the computing form factor beyond the traditional desktop computer. The proliferation of cell phones, personal digital assistants, portable gaming devices, music players, tablet PCs, and living room-centric PCs shows a trend toward the vision of ubiquitous computing, in which computing is situated throughout our environment and daily life. Individual computing devices will be tailored in deep ways to the task at hand, away from the "one size fits all" mentality of desktop computing. The use of sensors and recognition techniques will play an important role in enabling this diversity, and will naturally support and demand a variety of interaction styles. As interactive systems become more tailored to a given activity, the opportunity to leverage the techniques described in this chapter increases, in turn enabling the application of the sensors themselves. Such a virtuous cycle may speed the development and adoption of sensing-based systems in ways that are hard to imagine today.

ACKNOWLEDGMENTS

The XWand and Orb prototypes were developed with the assistance of Mike Sinclair and Steven Bathiche. Thanks to Ken Hinckley, John Krumm, Steven Bathiche, and Ewa Davison for comments.

8 Visual Displays

Christopher M. Schlick, Carsten Winkelholz, Martina Ziefle, and Alexander Mertens

CONTENTS

8.1 INTRODUCTION

Since the dawn of humankind, people have been inventing and building tools to make life easier and more comfortable. One of mankind's first tools with a visual display was the sundial, built more than 3000 years ago in Babylon. Due to its basic physical principle though, one of its significant disadvantages was that it could not show the time during the night or when the weather was cloudy. Moreover, the first sundials were in public places, so people had to make the effort to go there to check the time. Later developments of clocks (also in public places) eliminated the disadvantages of the sundial. Church clocks could show the time in almost any type of weather and at any time of day or night, and they could also display the time acoustically and therefore bridge distances of up to a few miles. The following developments are well known—from the grandfather clock and the fob watch to the first analog and digital wristwatches to today's powerful wrist computers with high-resolution active-matrix organic light-emitting diode displays (AMOLED) (Vogel et al. 2008). These displays not only show the time and date ergonomically under different ambient light intensities, but also present complex information in full color with short response times. This means user interface designers can chart a person's precise location on earth using the Global Positioning System, visualize individual heart rate profiles, and even present high-dynamic range video images.

8.2 BASIC PRINCIPLES AND CONCEPTS

8.2.1 Image Generation

Visual displays rely on different physical principles to generate an image, including light emission, transmission, and reflection. Examples from noncomputer displays can be helpful to explain these basic principles and point out relevant advantages and limitations.

Writing on a piece of paper alters the reflective properties of the paper from a highly reflective white to a less reflective blue or black. Ambient light is needed to read what is written on the paper, but the contrast ratio between the text and the background remains the same in different intensity conditions. A similar principle holds true for reflectance-based displays such as classic reflective liquid crystal displays (LCDs) or electrophoretic displays (see Sections 8.4.3 and 8.4.8).

Examples of transmission include transparency film used with an overhead projector and slides used with a projector. Different parts of the transparency or slide transmit light of different wavelengths (i.e., color) with different intensity. Transmission is used as a basic principle in many electronic information displays, such as the popular thin film transistor (TFT) LCDs. It is also often combined with other physical principles. For instance, a simple front projection display (see Section 8.4.1) consists of a light source, a TFT LCD that forms the image by transmitting the rays of light through a matrix of liquid crystals picture elements, and finally a projection surface that reflects the light into the eye of the observer.

An example of emission would be a lighthouse. Its light can be easily seen at night, but it is barely visible in bright sunlight. Examples of emission-based displays are cathode ray tubes (CRTs) (see Section 8.4.2), electroluminescent displays (see Section 8.4.5) and cathodoluminescent displays (see Section 8.4.6). Like a lighthouse, these displays need to be brighter than the ambient light to be perceived properly.

8.2.2 Electronic Information Displays

The development of advanced display technologies began with CRT, which was invented in the nineteenth century, though the observation of a glow from the electronic excitation of gas in an evacuated tube may go back as early as the seventeenth century. The invention of the device itself is generally attributed to Karl Ferdinand Braun. The "Braun tube" reportedly first built in Strasbourg, Germany in 1897, used an evacuated tube, deflection plates, and a fluorescent material for the screen. It was probably the first use of an electronic information display in the natural sciences (Castellano 1992).

Over the last decade, flat-panel displays based on LCD technology have been becoming increasingly popular for human–computer interfaces, gradually replacing the CRT displays that have dominated the market since the 1960s. Yet increasing quality demands from consumers have also led to rapid developments in alternative technologies for electronic information displays, such as the above-mentioned AMOLED displays. Today, a large variety of display technologies are competing over image quality, screen size, costs, power consumption, 3D imaging, and novel information input features for mobile applications (see Section 8.7.3).

There are two basic methods for displaying information visually: digital and analog. A digital display uses a discrete spatial structure (typically a square or rectangular grid of picture elements) to display symbols such as characters and icons, whereas an analog system uses a spatially continuous instrument panel for information presentation. If an instant impression is required, analog displays often present information better. Many people glance quickly at their analog watch and know roughly what the time is or at the analog speed indicator of their automobile dashboard and know that they are driving too fast. Analog displays translate a value of a continuous variable into an angle or a distance. Analog displays used for control devices consist of a scale and an indicator. Either the scale or the indicator moves. There are a number of guidelines for designing analog displays (Woodson 1987; Baumann and Lanz 1998).

When accuracy is a critical issue, however, digital displays are preferred. Reading analog meters quickly and accurately requires time and cognitive skills, whereas writing down the value from a digital display is merely a case of copying down the digits. In cases where both accuracy and quick reckoning are required, hybrid displays are often used.

A computer is a digital device, so all symbols it displays are encoded into binary numbers and drawn as matrices of picture elements. Therefore, all commonly used electronic information displays are digital displays. Nevertheless, some application programs mimic indicator devices for their ergonomic advantages. If the spatial resolution and the response time of a digital display are sufficiently high and the covered color space is sufficiently large, there will be no significant differences in visual performance versus an analog display (see Section 8.3).

8.2.3 Display Segmentation

Standard PC monitors have a sufficiently high resolution to display a virtually unlimited set of characters, icons, and graphics. Conversely, a wide variety of displays with

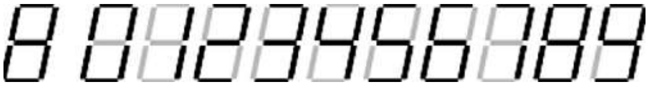

FIGURE 8.1 Seven-segment display.

lower spatial resolution can be found on other kinds of computerized technical devices such as low cost mobile phones or music players. Here, the set of displayable tokens is often far more restricted.

Basic display elements are binary, being either on or off. A ternary display element can be built from a two-color light-emitting diode (LED). To transmit more information, display elements with more states are needed. These could use different colors or luminance levels.

A common way to increase the amount of displayable information is by grouping a number of binary display elements into a unit. The classical seven-segment display (Figure 8.1) and many custom displays are examples of this approach.

If multiple display elements that have the same shape are arranged in matrix form and the elements are explicitly addressed to display multiple colors or different luminance levels, the basic concept of the common direct-view and projection displays can be derived. The shape of picture elements (pixels) in current electronic information displays is typically square or rectangular. For two-dimensional (2D) image data, the position of each pixel is addressed in horizontal rows and vertical columns called pixel matrices or pixel formats. In 3D space, volume elements are called voxels (volumetric pixels). Their positions are normally addressed in Cartesian space.

8.2.4 Display Dimensionality

Visual displays can be differentiated by means of the spatial dimensionality of the image generated. The simplest way to display information is to rely on only one spatial dimension. However, the notion of "1D display" is not strictly correct because human perception requires the picture elements to have two spatial dimensions; the secondary dimension of such displays does not provide information and is simply a function of the primary dimension. 1D displays represent a bare-minimum approach to presenting information, which is encoded by either discrete or continuous variables in 1D-state space. Still, a simple source of light such as a LED can convey a binary message of arbitrary length. Most current systems show the status of devices as "on" or "off" with LEDs. LEDs give off light radiation when biased in the forward direction. When displaying a continuous state variable in one dimension, an indicator bar value usually indicates the actual discretized value being measured or controlled. The volume level of a speaker or the temperature in a room can be indicated using a simple row of LEDs or an indicator bar on a linear scale.

To display more complex information that can only be shown using two independent spatial dimensions (length and width), 2D displays are used. This category of displays occupies the biggest segment in the market by far. 2D displays are suitable for displaying all kinds of visual information. Images are formed by activating pixels, each of these elements has a unique location (x,y) on a 2D plane, and a color scale or gray scale value can be assigned to each one. Although these displays have only two dimensions, depth perception is also achievable by using depth cues such as relative size, height relative to the horizon, interposition or occlusion, shadows and shading, spatial perspective, linear perspective, and texture gradients. Even more realistic three-dimensional (3D) scenes can be viewed on 2D screens by applying special viewing devices such as shutter glasses or polarizing glasses.

8.2.5 Human-Related Display Functionality

The wearable computing paradigm requires visual displays to be worn on the human body (Azuma 1997; Amft and Lukowicz 2009). A popular approach is to mount the display on a user's head. Thus the user can work hands-free and is always able to perceive information in his or her field of view. These displays are commonly referred to as head-mounted displays (HMDs). From a technological point of view, HMDs can roughly be divided into three main categories based on the way the image is provided to the user (Figure 8.2).

The first category, screen-based HMDs, comprises all HMDs whose picture elements are arranged in a spatially adjacent way. Ocular image forming displays use technologies such as LCD, digital mirror devices (DMDs), or organic light-emitting diodes (OLEDs). Most of the HMDs on the market today, however, are based on transmissive or reflective liquid crystal minidisplays (LCD) (Holzel 1999). Miniature LCDs are available at a relatively low price, provide suitable resolution (SXGA resolution of up to 1280 × 1024 pixels) and are lightweight (von Waldkirch 2004). With the retinal projection method, the image is projected directly onto the retina the same way a slide is projected onto a screen. Retinal projection displays are normally designed in the form of a Maxwellian-view optical system (Bass 1995), where the screen plane is optically conjugated to the retina and the illumination source is conjugated to the eye's pupil plane. Consequently, such displays can only be implemented on the basis of illuminated screens (like LCD and DMD) and not with self-emitting technologies like OLED and CRT (von Waldkirch 2004).

Scanning displays, where the image is scanned pixel-by-pixel directly onto a surface, are an alternative to screen-based displays. A retinal scanning display (RSD), also referred to as virtual retinal displays (VRDs), is the most important in this category. VRD technology was first proposed in 1992 by Sony. Since 1992, researchers at the Human Interface Technology Lab (Washington, DC) have been developing this technology to obtain a commercial product. In 2003, they presented the first commercial VRD (called Nomad) in collaboration with the U.S. company Microvision. This technology scans an image directly onto a viewer's retina using low-power red, green, and blue light sources such as lasers or LEDs (see Section 8.4.7). The VRD system has superior brightness and contrast compared with LCDs and CRTs because it typically uses spectrally pure lasers as a

light source (Stanney and Zyda 2002; Urey, Wine, and Lewis 2002). Recent developments use microelectromechanical systems scanner technology to present an ultrawide image of up to an estimated 100° horizontal by 90° vertical field of view at the pupil of each eye (Hilton 2008). Finally, there is the option of combining a scanning technology and a screen-based system (Fruehauf et al. 2000; Lippert 2006).

Besides technological categorization, HMDs can be classified according to visual perception (Figure 8.3, von Waldkirch 2004). Here, HMDs are usually divided into monocular, biocular, and binocular displays. In addition, all these types can provide the image in closed-view or see-through mode, and the monocular also in look-around mode.

See-through displays are usually problematic because visual information appears a specific distance away from the observer within the natural environment. To perceive the displayed information clearly, a user's eyes need to accommodate to that distance. This can be a problem if a user needs to attend to objects within the natural environment and to objects on the display simultaneously, provided the virtual distance to the displayed information and the distance to the real objects are not equal. According to von Waldkirch (2004), images displayed by different technologies have a different depth of focus. In an ideal case, the displayed image would be accommodation-insensitive. However, candidate technologies promising to increase depth of focus have a drawback: The sharpness of the image also in focus decreases (Winkelholz 2008).

Monocular displays have a single display source and provide the image to one eye only. Compared with binocular HMDs, monocular displays are lighter and cheaper. However, in a monocular HMD, the view seen by the eye not blocked by a screen may produce binocular rivalry with the image seen through the HMD. Biocular HMDs have two displays with separate screens and optical paths, enabling both eyes to see the same images simultaneously. Users only perceive a 2D image, like when using a computer screen. Binocular displays allow stereoscopic viewing with 3D depth perception. To produce the stereoscopic view, two spatially slightly incongruent images are presented to the left and to the right eye (binocular parallax, see Section 8.3.7).

Popular application areas for HMDs include defense, security, and technical services, where they can provide stereoscopic views of 3D CAD models for maintenance, overhaul, and repair of complex mechanical systems. An HMD can enable technicians to effectively "see through" a metal housing to view critical safety components such as valves (Schlick et al. 2009).

In addition to HMDs, electronic information displays that users hold in their hand must also be considered. Smartphones are one area where these types of displays are used. In recent years, mobile phones and personal digital assistants have merged into smartphones to provide integrated functionalities like calling, keeping an agenda, sending and receiving messages, playing games, music, and video, and surfing the Internet in one device (Wiley et al. 2008). For the latter applications especially, sufficient screen size, display resolution, and luminance are important requirements to ensure usability under different ambient light conditions and for users with different perceptual abilities (see Section 8.6.3). TFT LCD technology (see Section 8.4.3) and more recently AMOLED technology (see Section 8.4.5) are the primary display types used in handheld devices. An additional important requirement is that the electronic information display can be used as an input device by touching the plastic or glass cover of the screen (see Section 8.4.9). Satisfying all functional and ergonomic requirements is very challenging because displays often consume more than 50% of the total power available and therefore cannot simply be enlarged (Zehner 2008).

Advances in electronics have recently brought affordable, truly “wearable” visual displays to the consumer market. Researchers incorporated LEDs into textiles and called them “photonic textiles.” A flexible array of LEDs (see Section 8.4.5) and attached optical fibers are integrated into the textiles and connected to a battery power supply. Using the provided control unit, messages can be created and distributed wirelessly to several pieces of cloth (Graham-Rowe 2007). The location on the human body is critical for usability and acceptance because the information not only needs to be accessible for direct manipulation, located in a socially acceptable spot and comfortable to use, but it must also be transmitted effectively. Research in this field can roughly be divided into three areas (Tumler et al. 2008): (1) research that focuses on technological aspects, (2) research into areas of application such as military and industry, and (3) research concerned with ergonomic and medical aspects.

The cave automatic virtual environment (CAVE) is an “accessible” display in the truest meaning of the word. The CAVE creates an immersive virtual reality (VR) environment (see Section 8.7.1) around the user by aiming several projectors at the ambient walls. The walls of the CAVE are usually made up of rear-projection screens, and the floor is made of a down-projection screen. The first CAVE was developed in 1992 at the University of Illinois at Chicago in response to a challenge to demonstrate the manifold application areas of very large projection displays. Today CAVEs are used to design vehicle interiors and the layout of entire factory facilities, long before large investments in physical mock-ups or prototypes become necessary (DeFanti et al. 2009).

8.3 QUALITY CRITERIA

8.3.1 Colors

The retina of the human eye is covered with photoreceptors that transform the energy distribution of incoming light into neural activity. There are three main classes of photoreceptors: cones, rods, and photosensitive ganglion cells. Under normal-light conditions only three photoreceptors, known as cone cells, play a role in color perception. They differ in their spectral sensitivity. There are different types of cone cells for short (420–440 nm), medium (530–540 nm), and long (560–580 nm) wavelengths. Cone cells generate electrochemical impulses proportional to the inner product of their corresponding spectral sensitivities and the spectral distribution of the incoming light. Thus, in principle, color sensation can be described by three parameters, called tristimulus values. For an objective description of colors the Commission International de l’Eclairage (CIE) has defined three color matching functions, which can be thought of as the spectral sensitivity curves of three linear light detectors that yield the tristimulus values X, Y, and Z. However, these color-matching functions do not directly correspond to the spectral sensitivity curves of the cone types, and because it is not absolutely clear how the actual tristimulus values of the cone cells are processed, many different sets of color-matching functions can be specified to represent color sensations unambiguously. Figure 8.4 depicts the process of color perception from red, green, and blue (RGB) pixels. The RGB color model is an additive color model in which RGB light are mixed together in various ways to produce a broad range of colors. If any two of the RGB color channels are mixed in equal proportions, new colors are created: blue and green create cyan (bright, light blue); red and blue make magenta (a bright pink); and red and green create yellow. If all three colors are mixed together equally, the result is white light.

The color-matching functions of the CIE-XYZ system were defined to have some useful properties. For example, whenever equal amounts of XYZ values are combined, they match white light. Furthermore, the $\bar{y}(\lambda)$ color matching function was chosen to be exactly equal to the photopic luminous efficiency function $V(\lambda)$ for the “CIE standard photopic observer,” which describes the variation of perceived brightness with wavelength.

Because XYZ values scale with light intensity, they also encode the brightness of the color. To describe the actual color sensation, relative amounts denoted by lower case letters are used. Because x, y, and z are relative amounts, it is true that $x + y + z = 1$. Consequently, when x and y are

FIGURE 8.4 Generation of color and modeling of perception of color by color matching functions of the standard XYZ system. The curves $\bar{x}(\lambda)$, $\bar{y}(\lambda)$, and $\bar{z}(\lambda)$ represent the relative amounts of the X, Y, and Z primaries needed to match the color of the wavelength of light.

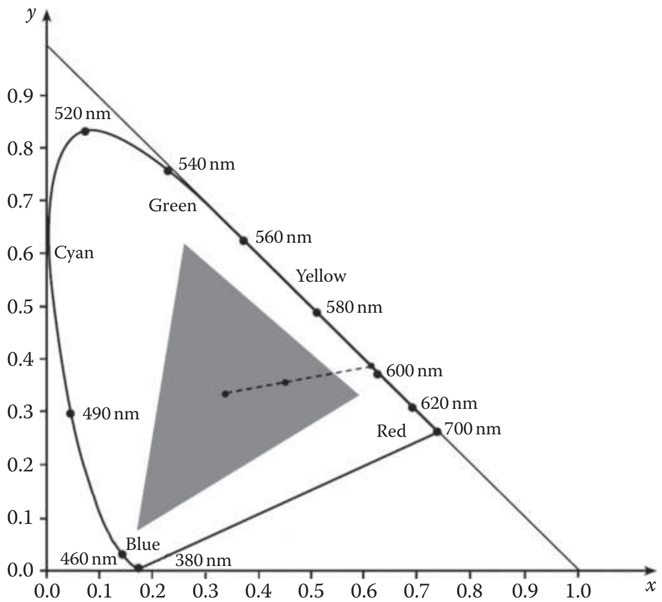

FIGURE 8.5 The Commission International de l'Eclairage chromaticity diagram. The curve, the locus of spectral colors, represents the *x*, *y*, and *z* values for all of the spectral colors between 380 nm and 770 nm. The triangle depicts the colors that can be presented by a display that uses the three primary colors at the corners of the triangle. The hue of any color within the curved line can be determined by drawing a line from pure white ($x = 0.33$ and $y = 0.33$) through the color of interest to the locus line. The saturation is given by the relative length of the dashed line between white and the color of interest and white and the intersection of this line with the locus. (Adapted from Schmidt, N. S. 2009. *Professionelle Videotechnik*. Berlin: Springer.)

known, *z* is known as well, because $z = 1 - (x + y)$. Therefore all colors can be represented within a *xy*-chromaticity diagram, which is shown in Figure 8.5. Pure white (i.e., achromatic light) is represented at the intersection of $x = 0.33$ and $y = 0.33$. The curved line, the locus of spectral colors, represents the *x* and *y* values for all of the spectral colors (see Figure 8.5). It is convenient to incorporate the Y-component for luminance into the description of a color and keep the *x*, *y* values as a description for chromaticity. This system of color characterization is referred to as the "xyY-system."

All visible colors can be encoded within the CIE-xyY system. Most luminous visual displays produce colors by using subpixels of the primary colors red, green, and blue. By controlling the luminance of the subpixels, different spectral distributions for each pixel can be generated, enabling different colors to be displayed for one pixel. Because of the (near) linearity of human color perception as expressed by Grassmann's Law, the resulting color in the XYZ system can be expressed by a linear combination of the intensities of the primary colors used. Because intensities can only be added and are bounded by an upper limit, a display is only able to produce colors that lie within a triangle in the *xy*- chromaticity diagram whose corners are defined by the primary colors used (see Figure 8.5). Computer systems encode the intensities of the primary colors of one pixel as RGB values. The representation of this information in the computer's hardware and software places a further restriction on the variety of colors. Popular configurations devote 4 to 32 bit to the representation of color information, yielding 16 to 16,777,216 colors with different chromaticity and luminance. For a device-independent representation, these values need to be interpreted by a transformation into the CIE-XYZ system. This transformation assumes definite primary colors and scales the RGB values using a power-law to increase resolution in regions of the color space where the human eye is highly sensitive. Different transformations define different RGB color spaces. The standard RGB color space is sRGB. One can generally assume, in the absence of embedded profiles and any other information, that any 8-bit-per-channel image can be considered to be in the sRGB color space. However, every display has its own unique color signature, displaying a certain color according to manufacturing tolerances and material deterioration through use and age. Thus, displays offer an opportunity to adjust the mapping of the RGB values to the luminance of the RGB subpixels. Using a spectrophotometer, a correction matrix can be determined in a way the RGB values are displayed within a target RGB color space. RGB systems also include a reference white, considering that the human color perception system is able to adapt to varying illumination conditions. For instance, a white sheet of paper looks white in sunlight and in artificial light, but the XYZ values are different. A different light source causes a shift in the whole color space, to which the visual system is able to adapt. The CIE Standard Illuminant D65 is the reference white for the sRGB color space. The CIE 1931 color space chromaticity coordinates of D65 are $x = 0.31271$, $y = 0.32902$.

Although the CIE chromaticity diagram is a widely accepted standard to represent the color space, additional models are also popular in the context of human–computer interaction. One of them specifies hue, saturation, and brightness (sometimes the terms "luminance" or "lightness" are used instead of "brightness"). This model uses an upside-down cone to represent the color space (see Figure 8.6). On the edge of the cone's base, the visible light spectrum is arranged in a circle by joining red and violet. Hue is the actual color; it can be specified in percent, in angular degrees around the cone starting and ending at red (0° or 360°), or in 8-bit values (0–255). Saturation is the purity of the color, measured in percent or 8-bit values from the center of the cone (min.) to the surface (max.). At 0% saturation, hue is meaningless. Brightness is measured in percent or 8-bit values from black (min.) to white (max.). At 0% brightness, both hue and saturation are meaningless.

The CMYK model defines cyan, magenta, yellow, and black as main colors. This model is used to specify colors on the monitor for printing. In printing, colors are mixed subtractively and, using RGB, it would not be possible to produce many colors. By choosing cyan, magenta, and yellow as basic colors, many other colors, including RGB, can be produced. Theoretically, when all three basic colors are printed over each other, the resulting color should be black. In practice, however, this is not the case, and a fourth printing

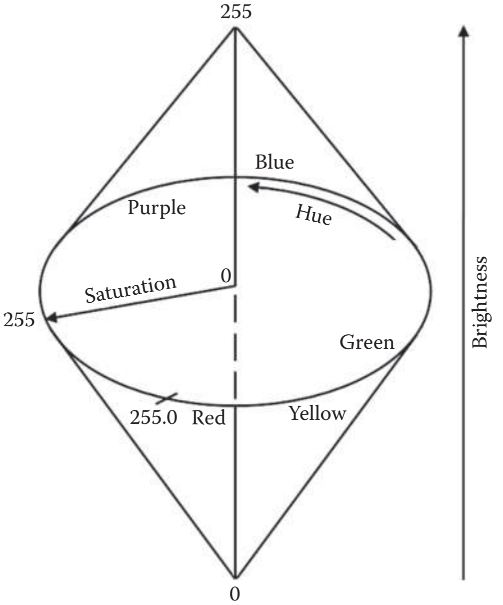

FIGURE 8.6 Hue, saturation, and brightness system for specifying color.

process with black ink must also be used. Values for CMYK are often specified as percentages.

8.3.2 Brightness

The brightness of a visual display depends not only on the optical power generated, transmitted, or reflected by the display but also on the response of the human eye at certain wavelengths. An adequate photometric measure is the photopic luminosity $K(\lambda) = 683.002$ lm/$W^*V(\lambda)$, which relates optical power in watts at a given wavelength to its effect on the human visual system. This luminosity can be considered as the optical spectral response of the eye of a "standard observer" (Nelson and Wullert 1997). Luminous flux Φ can be computed on the basis of $K(\lambda)$ and the spectral distribution of optical power $P(\lambda)$ by integrating the spectral response over the range of visible wavelengths (Macadam 1982):

$$\Phi = \int_{\lambda=380}^{\lambda=770} K(\lambda)P(\lambda)\mathrm{d}\lambda \tag{8.1}$$

The SI unit of luminous flux is the lumen (lm). The emitted luminous flux per unit solid angle Ω is called luminous intensity (I) (or radiant intensity) and is defined by

$$I = \frac{\mathrm{d}\Phi}{\mathrm{d}\Omega} \tag{8.2}$$

Luminous intensity is measured in candela (cd); the unit is lumen per steradian.

The human eye cannot collect all of the light that is radiated or reflected from a source. Brightness also depends on the size of the surface that the light is emanating from. Figure 8.7 shows how the brightness of a surface is actually given by the luminous flux per unit of the projected area of the emitting surface per unit solid angle depending on the viewing angle.

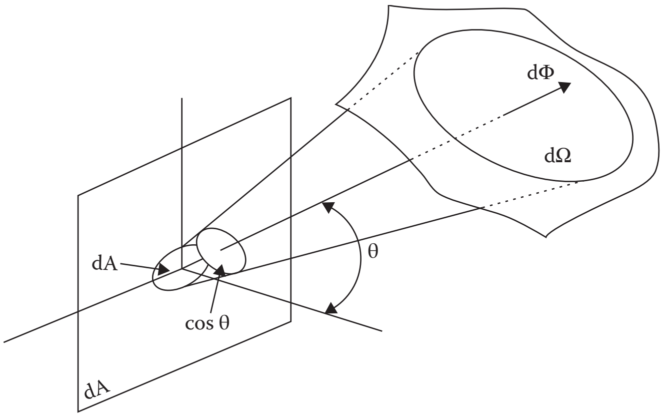

FIGURE 8.7 Definition of the brightness of a surface as a function of the direction from which the surface is observed. (Adapted from Nelson, T. J., and J. R. Wullert. 1997. *Electronic Information Display Technologies*. River Edge, NJ: World Scientific.)

Some displays such as LCDs appear dimmer from an oblique angle than from the normal viewing angle, whereas most emissive displays, such as CRTs, emit light in such a way that the angular luminous intensity approximately follows Lambert's cosine law (Lambertian surface), resulting in approximately constant luminance across all viewing angles.

Brightness of a visual display can be defined as the perceived amount of light traveling in a certain direction and specified by the photometric measure called luminance (L). Luminance is the luminous intensity of light (I) emitted from a light source per unit surface area (A) normal to the direction of the light flux (Çakir, Hart, and Stewart 1979). In this context, θ is the angle between the perpendicular from the surface and the direction of measurement (Boff and Lincoln 1988). It holds

$$L = \frac{\mathrm{d}I}{\mathrm{d}A\cos\theta} \tag{8.3}$$

The unit of luminance is lumen per steradian per square meter or candela per square meter (cd/m^2). In some cases, the unit foot-lambert (fL) is used to describe luminance (1 fL = 3426 cd/m^2).

8.3.3 Contrast and Gray Scales

Strictly speaking, contrast is not a physiologic unit, but it is nevertheless one of the most important photometry quantities. It is related to numerous visual performance criteria such as visual acuity or contrast sensitivity. There are different definitions of contrast.

For a luminance increment or decrement relative to background luminance (such as a single point), the contrast ratio C_r is used (Boff and Lincoln 1988):

$$C_r = \frac{L_{\text{object}}}{L_{\text{background}}} \tag{8.4}$$

The contrast ratio represents the factor by which one pixel is brighter than another pixel. For electronic information displays, maximum contrast ratio is used to determine the range of gray levels that can be displayed. Modern LCDs have a contrast ratio of 500:1 or more. Because LCDs do not emit light, the luminance in Equation 8.4 for contrast refers to the luminance of light either passing through the display (for a backlit transmissive type) or the luminance of the light that is reflected off the display's surface (for a reflective LCD). In multiplexed LCDs, the contrast is affected by the viewing angle. Therefore, the contrast should be indicated by referring to the solid angle, known as the "viewing cone" (Castellano 1992).

Large contrast ratios are also needed to satisfy current gray scale requirements. Following from the idea that the brightest areas are white and the darkest areas are black, levels of brightness in between the two extremes are referred to as gray levels or gray shades, and the ability to display them as gray scale (Nelson and Wullert 1997). Technically, gray scale is a term that should be applied only to monochrome or "gray" displays. However, the term is often applied to color displays where intermediate brightness controls are required by the system (Castellano 1992). The number of gray scales is determined both by the contrast level and the ability of the human visual system to distinguish between the different brightness levels. Our visual system reacts to changes in brightness level as a logarithmic function, so it may not perceive very small differences in brightness (Theis 1999). The acceptable difference in brightness levels between scales is 1.414 (the square root of 2). In order to obtain five levels of gray scale above background, a display must have a contrast ratio of at least 5.6:1.0 (1.00, 1.41, 2.00, 2.82, 4.00, and 5.65:1.00) (Castellano 1992). Full-color displays have about 128 to 256 linear gray levels. The number of gray shades (G) that can be displayed can be defined as a logarithmic function based on contrast ratio (Nelson and Wullert 1997):

$$G = 1 + \frac{1}{\log\sqrt{2}} \log\left(\frac{L_{\max}}{L_{\min}}\right) \tag{8.5}$$

$L_{\max}$ and $L_{\min}$ are maximum and minimum luminance. TFT LCDs improve contrast ratio by dimming the backlight for dark images. The contrast ratio of a black pixel displayed with dimmed backlight and a white pixel displayed at full backlight is called the dynamic contrast.

Different contrasts measures are used to quantify overall contrast within an image. In cases where small features are present on a large uniform background, the Weber Contrast C_w (luminance contrast) is used. The International Lighting Commission defines as follows:

$$C_w = \frac{L_{\text{object}} - L_{\text{background}}}{L_{\text{background}}} \tag{8.6}$$

The *Michelson Contrast* C_m (also called modulation contrast, depth of modulation, or relative contrast about the mean luminance) is generally used for periodic stimuli that deviate symmetrically above and below a mean luminance value, such as gratings or bar patterns. It is computed as follows (Boff and Lincoln 1988):

$$C_m = \frac{L_{\max} - L_{\min}}{L_{\max} + L_{\min}} \tag{8.7}$$

The Michelson Contrast will take on a value between 0 and 1. The minimum modulation threshold, meaning the smallest detectable brightness modulation, occurs at a brightness modulation of approximately 0.003 at about three cycles per degree of the visual field (Nelson and Wullert 1997).

Sanders and McCormick (1993) specify another possibility for defining contrast (called luminous contrast) as the difference between maximum and minimum luminance in relation to maximum luminance:

$$C_l = \frac{L_{\max} - L_{\min}}{L_{\max}} \tag{8.8}$$

These contrast measures can be converted from one to another. For example, given the contrast ratio C_r and knowledge of positive contrast conditions ($L_{\max} = L_{\text{object}}$; $L_{\min} = L_{\text{background}}$), the other visual contrasts can be calculated as follows:

Weber Contrast:

$$C_w = C_r - 1 \tag{8.9}$$

Michelson Contrast:

$$C_m = \frac{C_r - 1}{C_r + 1} \tag{8.10}$$

Luminous Contrast:

$$C_l = \frac{C_r - 1}{C_r} \tag{8.11}$$

8.3.4 Glare and Light Reflection

High-luminance levels in the field of view cause glare discomfort. Glare caused by light sources in the field of view is called direct glare; glare caused by light being reflected by a surface in the field of view is called reflected glare (Figure 8.8).

Reflected glare can occur from specular (smooth, polished, or mirror-like) surfaces, spread (brushed, etched, or pebbled) surfaces, diffuse (flat or matte) surfaces, or as a combination of the above three (compound) (Sanders and McCormick 1993). Glare sources are more disturbing when they have higher luminance and when they are closer to the fixation point (Sheedy 2005). Experiments also show that visibility is decreased by glare, and the decrease is greatest when the source of the glare is in the direct line-of-sight (Boff and Lincoln 1988).

To avoid glare, it is advisable to position the display at a right angle to the window (so that the line of vision is parallel to the window). The display can be protected with curtains, blinds, or movable walls. Lamps that can be reflected in the monitor must not have a mean luminance of more than 200 cd/m^2, and the maximum luminance must be less than 400 cd/m^2 according to German standard DIN 5035-7. An example of good workplace design is shown in Figure 8.9.

8.3.5 Resolution

The arrangement of pixels into rows and columns is defined as the pixel format. It is often referred to as a resolution; however, this is not a resolution parameter by itself. For instance, the resolution of a flat-panel display mainly depends on its screen diagonal and its dot pitch (stripe pitch, SP). When set to lower resolutions, a pixel encompasses multiple dots. Thus, the resolution in terms of pixel density, or the number of pixels per linear distance (pixels per inch or pixels per centimeter). This parameter indicates how close the pixels are.

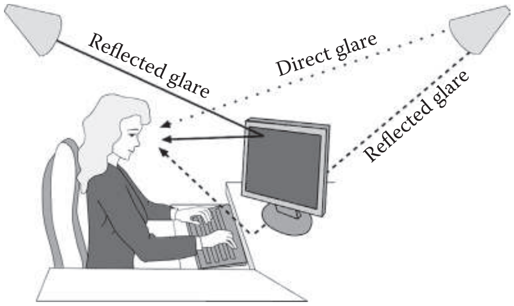

FIGURE 8.8 Direct and reflected glare.

As a picture element, a pixel is the basic unit of programmable color on a display. In classic color displays, the pixel is usually formed from a number of dots and it may consist of a number of triads, which are composed of red, green, and blue dots. The dot pitch in a CRT display with a shadow mask is defined as the distance between the holes in the shadow mask, measured in millimeters (mm). In matrix-driven, flat-panel displays every single pixel is composed of a red, a green, and a blue phosphor dot or filter element, and dot pitch is defined as the center-to-center distance between adjacent green phosphor or filter element dots. Thus, the pixel density is the reciprocal of pixel pitch, which is equal to the dot pitch. Resolution quality levels are defined as follows (Castellano 1992):

- Low resolution: <50 pixels per inch
- Medium resolution: 51–70 pixels per inch
- High resolution: 71–120 pixels per inch
- Ultrahigh resolution: >120 pixels per inch

Obviously, ergonomic resolution requirements depend on the viewing distance to the display. The visual acuity of a person with normal vision and under normal ambient light intensity is frequently considered to be what was defined by Snellen as the ability to recognize a standardized symbol (optotype) when it is subtended 5 minutes of arc. Therefore, if the distance from the display to the eye of the observer is 50 cm, he or she will be able to distinguish approximately 175 pixels per inch. The quality levels mentioned above refer to displays on a desktop. For handheld displays, viewing distances are typically closer, up to 20–25 cm. Therefore, the resolution of current handheld displays often far exceeds the level for ultrahigh resolution. For HMDs specifying the

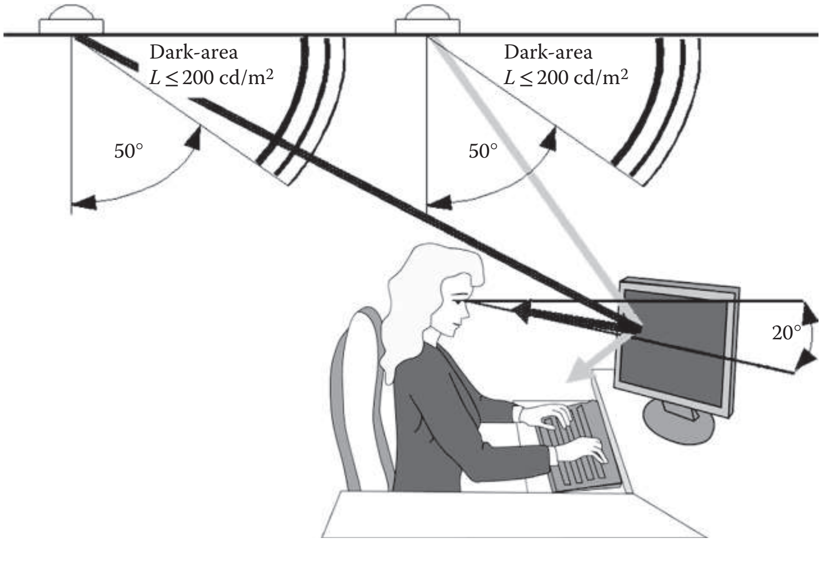

FIGURE 8.9 Glare can be avoided by limiting lamp luminance and by positioning the display correctly.

resolution in pixels per inch is often not meaningful because optics magnify the physical screen to appear at a predefined distance from the observer and to cover a specific field of view. For this reason, HMD resolution is usually specified as the number of pixels per degree of arc. HMDs typically offer 10–20 pixels/°, though advances in microdisplays will significantly increase this ratio in the near future. A higher resolution can also be reached at the cost of the width or height of the field of view. Human visual acuity is reached at approximately 60 pixels/°.

8.3.6 Refresh Rate and Response Times

The number of times that the image on the display is drawn per second is called the display refresh rate (also called vertical scanning rate on CRTs). The unit of measurement is hertz (Hz). On CRTs, a high-display refresh rate prevents a flickering image because there is only a small amount of time between two successive stimulations of a single dot, where luminance fades away after several milliseconds. Because the retina retains a precise image of an object for about 10–20 milliseconds after an object has disappeared, this temporary disappearance of the dot will not be noticed if the dot is stimulated at a fast enough rate. On CRTs, a refresh rate of between 70 and 80 Hz is needed to ensure a flicker-free image on the display (meaning the flicker is not perceivable) (Bosman 1989).

The effects of the "refresh rate" on human vision are different for other display types in which the color and luminance brightness of the pixels is constant until the state of the pixels is explicitly updated. One example is a classic LCD, whose shutters remain at the opacity level last addressed. Another example is an electrophoretic display, whose charged pigment particles stay in a stable configuration to form a visible image. For these kinds of displays, the response time needed by the pixels to transition to a new visible state is a more appropriate quality metric. Long response times will cause motion blur when displaying scenes with a high-dynamic range. But motion blur is also an issue if response times are short and the frame rate at which the dynamic scene is rendered is low. There is a simple reason for this effect: If an object has moved in two sequential frames and it disappears at one position on the display to appear at another position, the retina keeps the imprint of the object at the old position for 10 milliseconds, and the user perceives both pictures simultaneously. At a low frame rate of about 30 frames per second, the visual system will perceive the images of two frames with an interval of about 33 milliseconds. These pictures differ substantially for dynamic scenes and therefore blur perception. At higher frame rates, the two images differ less and the impression of motion blur is reduced. Interestingly, motion blur is not that critical on CRTs if the refresh rate is set to 60–80 Hz. This is because the pixels on CRTs turn black before they are re-lit, so the imprint of the old picture is reduced. Manufacturers of LCDs attempt to simulate CRTs by using a strobing backlight. If the refresh rate is high, CRTs also tend to show motion blur at low frame rates. Some displays that run at 100 Hz or more add additional functions to avoid motion blur. Motion interpolation can cut the amount of blur by inserting extra synthesized in between frames.

8.3.7 Depth in 3D Displays

Depth perception depends on physiological sensations that are addressed differently by different display technologies. Monocular depth cues like perspective, occlusion, motion parallax, and comparison of familiar size can also be displayed on standard displays and refer to the structure of the image. Binocular depth cues provide depth information when viewing a scene with both eyes. Because they cannot be addressed by standard displays, new technologies need to be considered. Both eyes see a real scene from two different observation points, which are fused by the brain into a single visual impression that includes depth information. The two additional types of depth information achieved with binocular vision are convergence and retinal disparity. Convergence is a binocular oculomotor cue referring to the orientation of the eyes. If visual attention is focused upon an object, both eyes will adjust their orientation to perceive the image of the object on the fovea of the retina. The gaze direction of both eyes crosses at the depth of the object's location. Retinal disparity refers to the effect that if both eyes focus on the same object, the images they see are from a slight different perspective. The visual system determines corresponding points of the two images by pattern matching. Two pairs of corresponding points on the retina relate to two different visual features of objects in the physical space. The different offsets of the two pairs of corresponding points can be utilized by the visual system to determine the relative depth of two visual features. In general, display technology must be capable of showing two independent pictures to each eye of a user to produce binocular depth cues. This can be achieved by using common displays with optics that inverse multiplex two images for the left and the right eye (see Section 8.4.10). Depending on the technology, inverse multiplexing may not be perfect, in which case each eye will tend to catch a glimpse of the picture addressed to the other eye. This effect is called ghosting, and it deters visual impression. The acuity of binocular depth cues is closely related to the visual acuity of the single images for each eye. If the resolution of each single image exceeds the limits of human vision, the acuity of disparity cannot be further improved. However, there are individual differences in how well binocular depth cues could be resolved. A small group of people (about 2%) are not able to see 3D using stereo vision. One might expect that if both eyes were presented with two pictures that are arranged in such a way that each eye sees the picture it would have seen in a real scene, depth perception would also be close to reality. But one must consider that in reality the eyes also need to change the optical power of their lenses to perceive a clear image of objects at different distances. As long as both images are displayed on a display surface at a distinct distance, accommodation stays constant while convergence changes to focus on objects with a different parallax (different depth) in the two displayed images. This mismatch causes eyestrain and limits the range of parallax that can be used in a pair of stereo images to encode depth (Lambooij, IJsselsteijn, and Heynderickx 2007). Therefore, when using simple stereoscopic displays, objects cannot be displayed to appear at arbitrary distances to the given display screen. Furthermore, this mismatch causes distorted depth perception (Armbrüster et al. 2008; Kleiber and Winkelholz 2008; Patterson, Moe, and Hewitt 1992). To overcome these limitations, other technologies are needed that exactly reproduce the lightfield of real 3D objects. Holographic and volumetric displays are two promising approaches (see Section 8.4.10). Volumetric displays are able to address single points as voxels in a 3D display space and make them emit or transmit light as small diffusive point sources. The resolution of a volumetric display is then given by the number of voxels that can be addressed and the display volume. Volumetric displays can also cope with motion parallax if the user moves his or her head. Virtual objects can be seen from different viewpoints just by moving the head as if the virtual objects were real. However, human performance in perceiving and processing depth information from a visual field is also limited in reality (Winkelholz, Kleiber, and Schlick 2010a,b). Acuity in depth perception is far lower than visual acuity in lateral dimensions (Norman et al. 1996).

8.4 TECHNOLOGIES

8.4.1 Taxonomy of Electronic Information Display Technologies

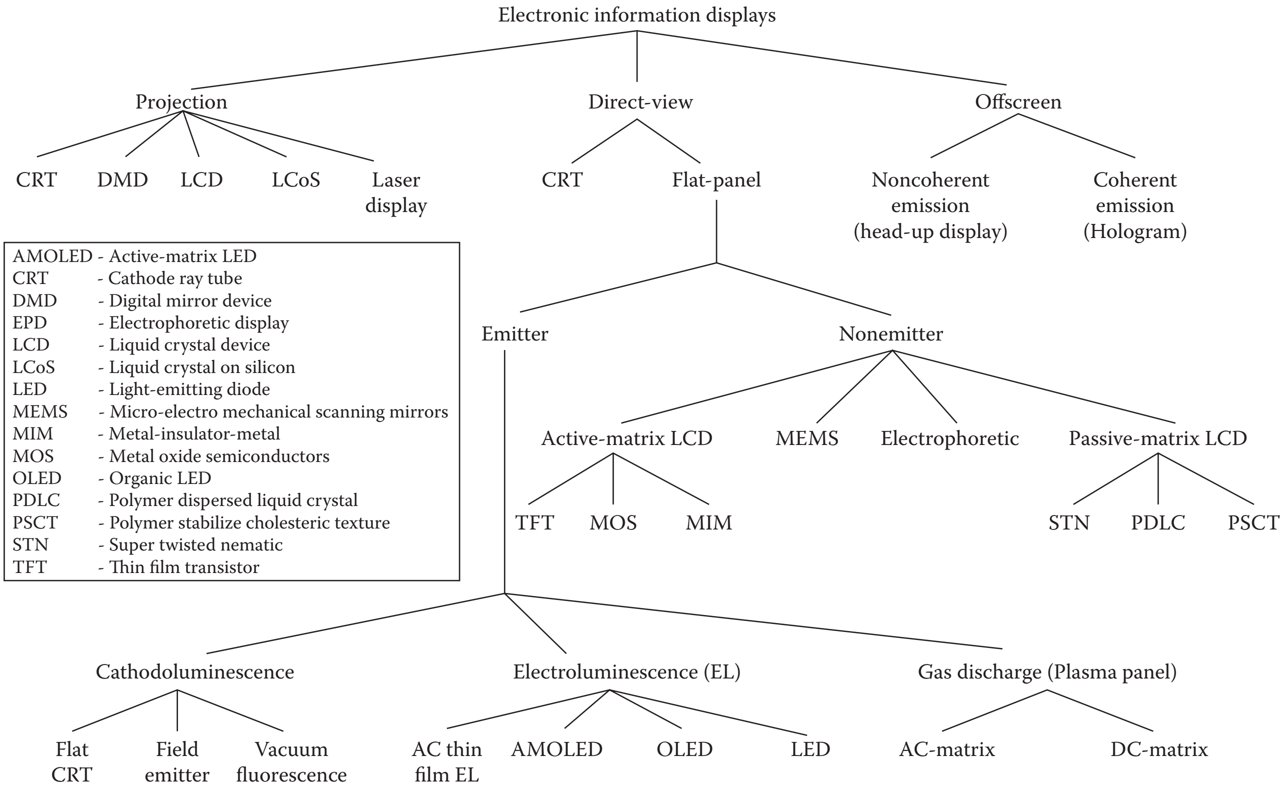
Figure 8.10 provides a systematic overview of display technologies (Theis 1999). All of these technologies can be assigned to one of the three basic display concepts: direct-view, projection, and offscreen.

8.4.1.1 Direct-View Displays

These are electronic information displays in which the image produced by a display device is viewed directly without first bouncing off a screen. All plasma televisions and TFT LCD computer monitors are direct-view displays. These displays tend to work well in bright light conditions and have greater luminance than projection displays.

8.4.1.2 Projection Displays

Unlike direct-view systems, a projection display relies on the projection of an image onto a screen. There are front and rear projection systems, which mainly differ with regard to screen technology. Front projection utilizes a reflective screen surface, whereas rear projection uses a transmissive screen material, typically transparent plastic sheets. Projection displays work best in dimly lit environments. In particular, a front projection setup requires a darkened room for optimal viewing quality.



Electronic information displays
Projection
Direct-view
Offscreen
CRT
DMD
LCD
LCoS
Laser display
CRT
Flat-panel
Noncoherent emission (head-up display)
Coherent emission (Hologram)
AMOLED - Active-matrix LED
CRT - Cathode ray tube
DMD - Digital mirror device
EPD - Electrophoretic display
LCD - Liquid crystal device
LCoS - Liquid crystal on silicon
LED - Light-emitting diode
MEMS - Micro-electro mechanical scanning mirrors
MIM - Metal-insulator-metal
MOS - Metal oxide semiconductors
OLED - Organic LED
PDLC - Polymer dispersed liquid crystal
PSCT - Polymer stabilize cholesteric texture
STN - Super twisted nematic
TFT - Thin film transistor

In *Vom Arbeitsplatzrechner zum ubiquitären Computer [From the Desktop PC to the ubiquitous Computer]*, ed. C. Müller-Schloer and B. Schallenberger, 205–38. Berlin: VDE.)

8.4.1.3 Offscreen Display Systems

These display systems do not use a projection screen. Instead, a natural medium like windshield made of laminated safety glass or even the retina can be used for image projection. Offscreen systems are based either on coherent or noncoherent light emission. Coherence is a property of waves that measures the ability of the waves to interfere with each other. Laser light usually has far greater coherence than nonlaser light. VRDs (see Section 8.4.7) and 3D holographic head-up displays are examples of offscreen display systems.

8.4.2 Cathode Ray Tube

CRTs are the classic cathodoluminescent display. Light is generated by exciting a luminescent material with energetic electrons. A CRT consists of a glass bulb, a cathode, an electron gun, a deflection yoke, a mask, and a phosphor coating. An electron gun located in the back panel of the device emits negatively charged electrons that are attracted and accelerated by an anode located in front of the screen. The electron beam is diverted by an electromagnetic field built up by the deflection coils and thus directed toward the screen. Electrons are extracted from the cathode by thermal emission from low-surface-potential materials (typically metallic oxides), and the electron beam generated at the cathode is then accelerated, deflected, and focused by a series of electrostatic lenses and deflection coils. A screen mask is attached in front of the ground-glass plate so that the electron beam is focused and then steered onto the phosphorus layer deposited on the front surface. Display screen masks are either dot-mask screens, Trinitrons, or slot mask screens.

CRT technology was used in both color and monochrome systems because it offered high-information content at low costs and wide viewing angles from off-axis. Today flat-panel systems have replaced this display technology in most application areas because color CRT systems are usually very large and heavy, have high-power consumption and operating voltage, low vibration robustness, and a maximum screen size of only 40 in. Domains where CRTs are still popular include the printing and broadcasting industries, which prefer them for displaying photos, videos, and graphics because of their high pixels per unit area, color fidelity, contrast, and correct color balance (Castellano 1992; Ozawa 2007).

8.4.3 Liquid Crystal Displays

LCDs have become increasingly popular in recent years and currently hold the largest share in the market. Early commercial developments of LCDs concentrated on small numeric and alpha-numeric displays that rapidly replaced LEDs and other technologies in applications such as digital watches and calculators (Bosman 1989). Now there are ultrahigh-resolution displays for use in many applications such as laptops, handheld computers, HMDs, and miniature televisions (like those in airplane seats). LCDs have the following advantages:

- Their power consumption is low.
- They operate at low voltages.
- Their lifetime is very long in normal environments.
- Displays may either be viewed directly in transmission or reflection, or may be projected onto large screens.

LCDs consist of two glass plates with microscopic lines or grooves on their inner surfaces and a liquid crystal layer between them. Liquid crystal materials do not emit light, so external or back illumination must be provided. This circumstance theoretically puts LCDs among other nonemitter display technologies (e.g., electrophoretic displays, see Section 8.4.8), but the tight integration with an extra light emitter allows LCD technology to firmly stand on its own. The physical principle is based on the anisotropic material qualities of liquid crystals. When substances are in an odd state that is somewhat like a liquid and somewhat like a solid, their molecules tend to point in the same direction like the molecules in a solid, but they can also move around to different positions like the molecules in a liquid. This means that liquid crystals are neither a solid nor a liquid but are closer to a liquid state. LCDs operate by electrically modulating the anisotropy between optical states in order to produce visible contrast. In an electric field, liquid crystals change their alignment and therefore their translucence. If no voltage is applied, light can pass through and the pixels appear bright. When voltage is applied, the pixels become dark. The light to be modulated may either originate from ambient light or from additional bright light sources placed behind the LCD or at the sides (Lueder 2010).

The two principal flat panel technologies are the passive-matrix LCD and active-matrix (AM) LCD. Passive matrix addressing is used in twisted nematic (TN) LCDs. In TN LCD displays, the microscopic lines of the glass plates are arranged orthogonally to each other, and the glass plates serve as polarizers (Precht, Meier, and Kleinlein 1997). Their directions of translucence lie at right angles on top of one another so no light can pass through (see Figure 8.11). Because of the fine grooves on the inner surface of the two glass panels (arranged vertically on one panel and horizontally on the other), the liquid crystal is held between them and can be encouraged to form neat spiral chains. These chains can alter the polarity of light. In the so-called nematic phase, the major axes of the crystal's molecules tend to be parallel to each other.

Nonpolarized light from background illumination can pass the polarization filter with just one plane of polarization. It is twisted about 90° along the helix and can thus pass through the second polarization layer. When there is no electric current, the display appears to be bright. Applying an electric current to TNs causes them to untwist and straighten, changing the angle of the light passing through them so that it no longer matches the angle of the top polarizing filter. Consequently, no light passes through that portion of the LCD; it becomes darker than the surrounding areas, and the pixel appears black.

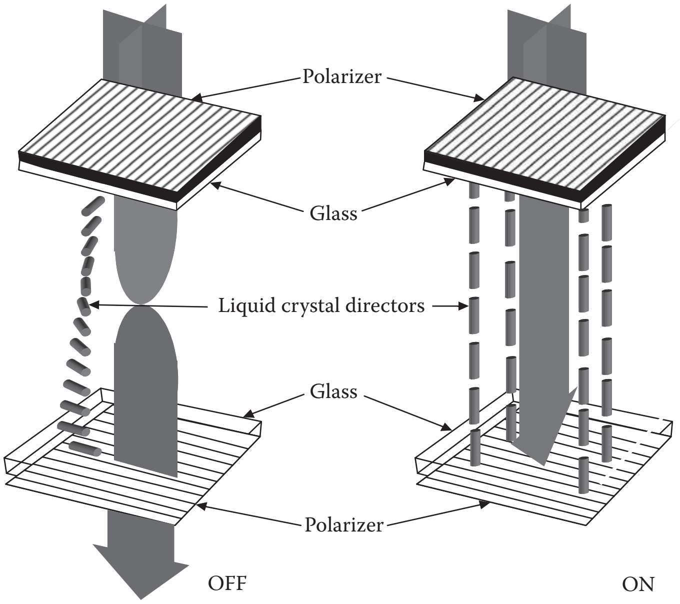

FIGURE 8.11 Principle of operation of a twisted nematic LCD.

Applying different electric currents allows gray scales to be produced with LCD technology. One disadvantage of this is the relatively low contrast, but that can be improved by applying a steep electro-optic characteristic line of the liquid crystals. Low voltage is then sufficient to change the translucence, causing the liquid crystals to twist by more then 90º. Such displays are called super twisted nematic, double super twisted nematic, or triple super twisted nematic (Schadt 1996).

In passive-matrix LCDs, the electric field expands over the pixel to be addressed to the entire horizontal and vertical electrodes. This results in annoying stripes or ghosting. Other disadvantages are slow response times and a prelightening of the pixels.

AM addressing places an electronic switch at each pixel of an LCD thus controlling the charging of the pixel capacitor up to the voltage corresponding to the desired shade and then holding this voltage until the next image information is written in. The available switches are TFTs acting like diodes (Lüder 2003). To display a full range of colors, each element on an LCD is assigned to a primary color by a special filter deposited on the faceplate of the LCD. To guarantee high contrast, brightness, and high quality of color representation, many transistors are needed. For example, a resolution of 1920 × 1080 pixels requires a total of 6.22 million transistors—one per primary color in each subpixel.

The traditional representation errors caused by an incorrect deflection do not occur because of the fixed matrix, but defective transistors can cause errors, leading to permanently bright or dark pixels. These pixels are distracting, particularly when all three transistors of the subpixels are switched to bright, which causes a white pixel to appear on the screen.

CRTs easily represent black; the cathode simply does not emit electrons. LCDs, however, have to completely block out the light from the backlight. Technically, this is impossible, and as a consequence the contrast is reduced. Furthermore, it is often said that CRTs are more suitable for displaying scenes with fast-moving objects. This is true if the response latency of the LCD is slow or the scene is displayed at a low frame rate. Most LCD displays available today have overcome these limitations (see Section 8.3.6).

When an LCD display is viewed from an angle, it appears darker and color representation is distorted (see Section 8.3.2). It is worth mentioning here that the restricted viewing angle has a positive effect on privacy, as in the case of automated teller machines (ATMs). Technologies such as in-plane switching, multidomain vertical alignment, and TFTs have improved the size of the viewing angle. Typically only the color becomes less saturated when viewing at extreme angles. Although many technical improvements to viewing angles have been done on lateral angles, vertical angles still often lead to non-negligible distortion. The nominal screen diagonal of an LCD is equivalent to the effective screen diagonal. In contrast, CRT nominal screen diagonals are smaller than the effective ones.

The well-known liquid crystal on silicon (LCoS) displays are also nonemitter displays. The advantages of LCoS technology are high luminance, high resolution, high contrast, relatively low production costs, and economy of weight. Unlike LCD technology, LCoS displays do not use light transmission through glass layers to create an image on a screen. Instead, an active array of pixels with liquid crystals is directly mounted on silicon that has been coated with aluminum. This additional layer consists of a reflective passivation layer that reflects the incoming RGB light toward a prism. The prism directs the light at a projection target, such as a flat screen or projection field. The crystals' orientation relative to the reflective surface can be controlled using an electric current. The current either brings the crystals into a reflective state or aligns them so that no light is reflected.

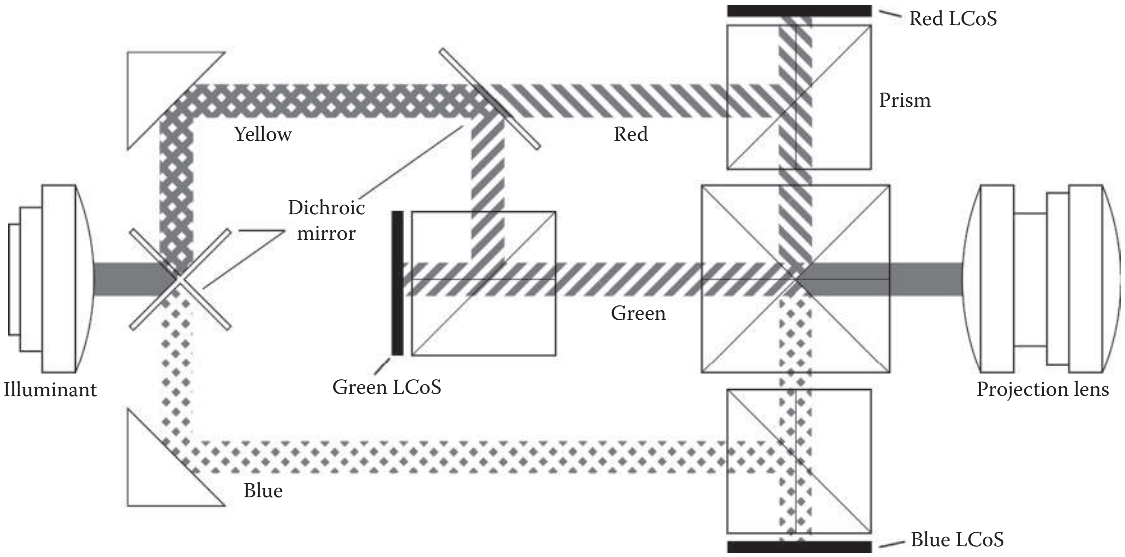

FIGURE 8.12 Conceptual diagram of three-panel liquid crystal on silicon display. The diagram shows the path and the split of the light beam into two beams of different wavelengths with the help of dichroic mirrors.

The light beam from the illuminant is often separated into blue and yellow components by dichroic mirrors (see Figure 8.12). The blue light beam is directed through a prism onto a blue LCoS chip, while the yellow beam passes through another dichroic mirror that splits it into its red and green components. These distinct beams are directed through additional prisms onto additional chips for red and green colors. A prism located directly in front of the LCoS panels directs the light beam toward the combining prism. The combination of the three reflected beams is then passed through a projection lens that transmits a full-color image onto the desired screen.

Two different LCoS display designs are popular—three panel design and one panel design. Three panel design with distinct RGB LCoS chips was explained above. This design distributes the three primary colors among different panels, so all three panels need to be aligned very accurately to precisely create the desired image dots. One panel design uses only one LCoS chip showing the RGB image components by temporal multiplexing. In this case, the observer's eyes put together the color stream. During image generation, a color wheel lightens the display with either red, green or blue light. If the color field frequency drops below about 540 Hz, a so-called color breakup can occur. A color breakup causes viewers to perceive false colors for a short period of time. Color breakup can also occur when using single-chip projectors.

The three-panel design is frequently used in digital light processing projectors for its high luminance and very good contrast. LCoS is not a very common technology for visual displays at present. However, LCoS offers the possibility of building very large high-definition screens for public displays and home entertainment. In digital light processing projectors, an image can also be created using microscopically small mirrors laid out in a matrix on a semiconductor chip. This technology is known as a DMD (see Figure 8.10). Each mirror generates one or more pixels in the projected image. The number of mirrors determines the image resolution. The small mirrors can be positioned rapidly to reflect the incoming ray of light through a lens (Hornbeck 2001).

8.4.4 Plasma Displays

An electrical discharge in gas is the oldest electro-optical phenomenon capable of producing light (Bosman 1989). Millions of years elapsed before this effect was identified, analyzed, and mastered by humans. The first attempts to produce a matrix display panel were made in 1954. Since then, research has continued and a host of approaches have evolved (Bosman 1989). The advantage of this technology is that, unlike front view projection screens, the room lights do not have to be off for people to see the image clearly and easily. This means plasmas are excellent for video conferencing and other presentation needs (Pioneer 2001).

With plasma technology, two glass plates are placed with their parallel thin conducting paths at right angles to one another (Precht, Meier, and Kleinlein 1997). The gap between the plates is evacuated and filled with a gas mixture (see Figure 8.13). If sufficiently high voltage is applied to the cross point of two orthogonal conducting paths, the gas ionizes and begins to shine (like many small gas discharge lamps). The inside of one glass plate is coated with a phosphorus layer, which is, according to the fundamental colors, composed of three different kinds of phosphorus. There is a wired matrix below the phosphorus-layer to trigger the PDP. The space between the glass plates is divided into gas-filled chambers. When voltage is applied to the wired matrix on the bottom of the display, the gas is transformed into a plasmatic state and emits ultraviolet radiation, causing the phosphorus to glow.

The advantage of this technology is that it can produce large, flat screens that perform extraordinarily well under most ambient light conditions. Even very bright light does not wash out the image on these screens. Another characteristic

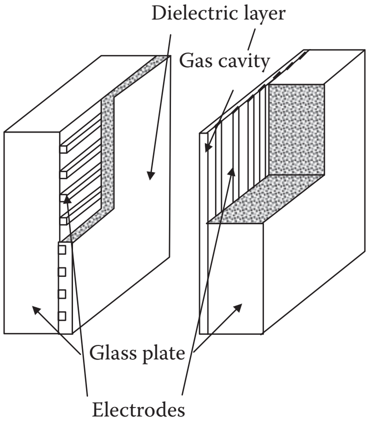

FIGURE 8.13 Major parts and components of a plasma display panel.

of a plasma panel is its extreme viewing angles, both vertically and horizontally. With a 160° viewing angle, people sitting to the side of the screen are still able to see the image without losing any information (Pioneer 2001).

Plasma screens also have disadvantages. They consume a large quantity of power, making the technology unsuitable for battery-operated and portable devices. Further, high voltage is required to ignite the plasma, and the phosphorus layers degrade over time. Finally, the pixels are oversized, so users must be some distance from the display.

8.4.5 Electroluminescent Displays

Electroluminescence (EL) refers to the generation of light by nonthermal means in response to an applied electric field that produces light (Nelson and Wullert 1997). In early ELDs, the phosphors were used in powder form like in CRTs. Current ELDs use a thin film of phosphorescent substance (yellow-emitting ZnS: Mn) sandwiched between two conducting electrodes. The top electrode is transparent. One of the electrodes is coated with vertical wires and the other with horizontal wires, forming a grid. When electrical current passes though a horizontal and a vertical wire, electrons are accelerated and pass through the phosphorous layer. Light is emitted as a pulse by the excited activator atoms. The activators are transition metal or rare-earth atoms. Once excited, these centers can decay to the ground state through a radiating transition, and thus emit light with their specific emission spectrum (Budin 2003). EL can also be obtained from organics. Organic EL devices generally consist of a hole transport layer and an electron transport layer between electrodes. The radiating recombination can be further optimized by introducing fluorescent centers near the interface of the two layers. Such structures are particularly useful in tuning EL colors (Theis 1999).

The main concern for ELDs is high-quality color presentation. A large number of laboratories have experimented with many materials, activators, and full-color solutions (Ono 1993). Color ELDs can be manufactured in different ways. One of these approaches, additive color synthesis, is quite common for emitters and involves using three juxtaposed patterned phosphors. However, this approach suffers from a reduced spatial fill factor for each monochromatic emitter. The second approach to full-color ELDs consists of using a single white-emitting structure with patterned color filters. It requires a much simpler manufacturing process. A hybrid solution, which is being developed into a full-color commercial product at Planar, involves stacking and registering several plates (King 1996). The first plate is a glass plate with the active structure on its far side, and transparent electrodes on both sides of a patterned ZnS:Mn (filtered to red) and ZnS:Tb (green) structure similar to that described before. The second glass plate has a fully transparent blue-emitting Ce:Ca thiogallate structure on top of the plate. On both plates, row electrodes are reinforced by a thin metal bus (Theis 1999; Budin 2003).

There are many different types of EL technology and alternating current thin film electroluminescent displays are probably the most commonly used ELDs. These days displays of 1280 × 1024 pixels with more than 1000 lines per inch (lpi) can be manufactured cheaply and are used for advertising applications such as electroluminescent billboards and signs. ELD offer several advantages: sharp pixel edges, good contrast (10:1 at 400 lux), a wide viewing angle, fast response time, durability, shock resistance, operation at high and low temperatures, and the smallest thickness and lowest weight compared with other flat panel displays (Budin 2003). A significant disadvantage of ELDs is their limited ability to display full color and the relatively high voltage (60–600 V) needed for operation. For battery-operated devices, this voltage must be generated by a converter circuit within the display (Nelson and Wullert 1997). At first, ELDs were primarily used for expensive instruments, but current technical advances allow wide application in industry and service areas.

EL devices also include LEDs. LED technology is used in almost every consumer electronic product on the market. The operational principle of LEDs can be summed up as follows: with no voltage or reversed voltage applied across the pn junctions, an energy barrier prevents the flow of electrons and holes. When a forward bias voltage (1.5–2 V) is applied across the junction, the potential barrier height is reduced by allowing electrons to be injected into the p region and holes into the n region. The injected minority carriers recombine with carriers of the opposite sign, resulting in the emission of photons (Castellano 1992). LEDs as well as some types of ELDs can also be used as a backlight for LCD screens (see Section 8.4.3).

A novel application of the EL principle is OLEDs, whose emissive electroluminescent layer is composed of a thin film of organic semiconductor material. This layer is formed between two electrodes, and at least one of the electrodes is transparent. Unlike inorganic solid-state based LEDs, OLEDs typically emit less light per unit area. However, the absence of brittle materials and the direct emission of colored light enable the production of very thin, flexible displays (<1 mm). Their use in handheld devices is advancing quickly because

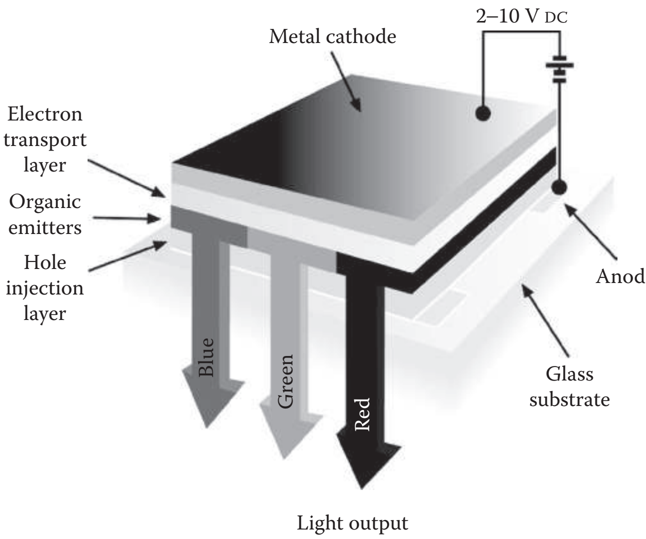

FIGURE 8.14 Layout and operating mode of an active-matrix organic light-emitting diode panel.

of their structural versatility and lower power consumption. OLEDs can be combined with a TFT backplane to actuate the display. Active-matrix OLEDs (AMOLED) are based on an array of thin-film transistor switches that control the state of each of the pixels. RGB subpixels can be either stacked on top of one another or next to another (see Figure 8.14). AMOLEDs provide a higher refresh rate than their passive-matrix OLED counterparts, and they consume significantly less power. AMOLEDs can also have a faster response time than standard TFT LCD screens (up to a 100,000 Hz refresh rate). The amount of power the display uses varies depending on the color and brightness shown (Yagi et al. 2008).

The biggest technical challenge for OLEDs is the limited lifetime of the organic materials. The layers are prone to material degradation and water can damage the organic compounds in the displays. Therefore, improved sealing processes are important for manufacturing. The differential color output has to be adjusted after some usage period, as the OLED material used to produce blue light degrades more rapidly than the materials that produce other colors, and the misaligned color balance becomes noticeable (Fellowes et al. 2009).

8.4.6 Cathodoluminescent Displays

The working principles of these displays are similar to those of a CRT. As a result, they are also referred to as flat CRTs. One of the most successful flat CRT configurations is a vacuum fluorescent display (VFD). It is essentially a triode with arrays of grids and phosphor-coated anodes used for coincident addressing. The grid structure is positioned over the anode and the cathode filaments are stretched and held above the grid. The entire structure is then sealed in an evacuated cell. The electrons, which are emitted by cathode filaments, are controlled by grids. When a grid is supplied with a positive voltage, it attracts the negative electrons; positive electrons are attracted when the grid is supplied with negative voltage. The electrons collide with the phosphor-coated anode, resulting in photon emission (Castellano 1992; Nelson and Wullert 1997).

One of the disadvantages of VFDs is that their manufacture cannot easily be scaled to large sizes because the front and back plates are only supported at the edges. Another problem is equalization of the luminous efficiencies. The blue phosphors tend to be very low in luminous efficiency, making energy efficient use of a full-color matrix VFD difficult. The technology remains promising in narrow application areas because it is possible to create a Lambertian light with 180° viewing cones, and it is not limited by the response of rearranging liquid crystals. It is therefore capable of normal function in subzero temperatures, making it ideal for outdoor devices in cold climates (Ozawa 2007).

8.4.7 Laser Displays

LASER is the acronym for light amplification by stimulated emission of radiation. Laser light is generated in the active medium of the laser. Energy is pumped into the active medium in an appropriate form and is partially transformed into radiation energy. In contrast to thermal emitters, a laser emits a concentrated and monochromatic light with high local and temporal coherence.

In contrast to conventional light sources, laser light has rays that are spatially coherent and narrow low-divergence beams that can be manipulated with lenses. The emitted light is focusable to a specific wavelength and has a high-power density, a monochromatic character (light of one wavelength), and high local and temporal uniformity (the same phase). These characteristics can be used to generate an image in the same way as a conventional CRT system: The laser is directed row by row across the display like conventional rear projection systems. The systems can be classified into two types: single scanning and dual scanning. In a single-scanning mirror system, one mirror directs the laser beam, drawing horizontal lines back and forth to create a frame of the moving image. At the end of each line, the beam shifts vertically. In a dual-scanning mirror system, one mirror directs the laser light back and forth along a horizontal path and then sends it to another mirror that adjusts the vertical position (Lincoln 2010). Called laser video displays, these devices are capable of displaying 90% of the color spectrum that the human eye can potentially perceive. Light output from the diode-pumped solid-state lasers is modulated according to the input signal, and the RGB light is combined. This combined light is then raster-scanned onto the screen to create an image. The laser projects the image either onto a flat area or directly onto the retina. Figure 8.15 shows the principle behind a retinal scanning laser display (RSD).

A collimated low-power laser diode is normally used as a modulated light source. The tiny laser beam is subsequently deflected in the u- and v-direction by two uniaxial scanners. The horizontal scanner (u-direction) operates at several kilohertz. The vertical scanner frequency (v-direction) defines the image refresh rate, which must exceed the critical

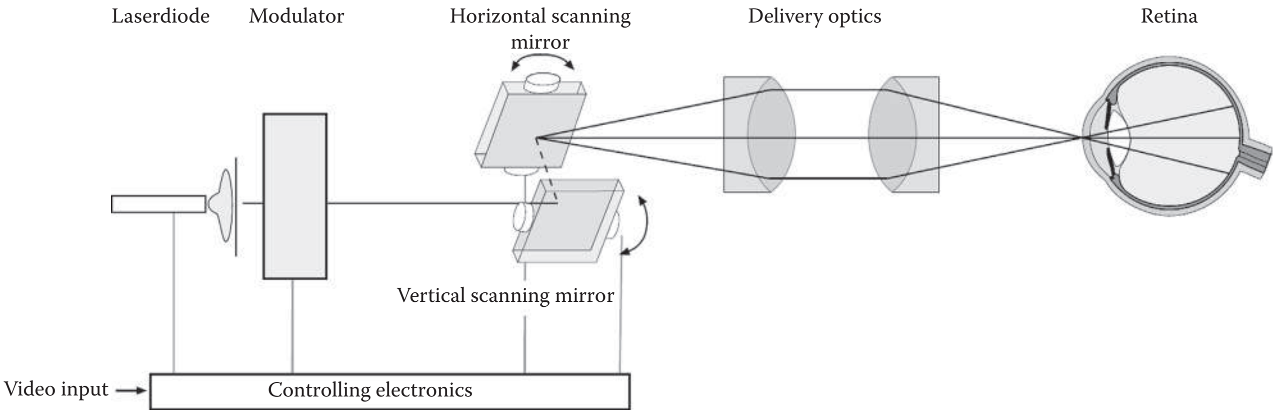

FIGURE 8.15 Illustration of the retinal scanning principle with dual scanning mirrors. (Adapted from Schowengerdt, B. T., and E. J. Seibel. 2006. *J Soc Inf Disp* 14[135]:139.

fusion frequency of about 60 Hz to prevent flickering effects. Finally, a viewing optic projects the laser beam through the center of the eye pupil and onto the retina. The RSD system projects pixels onto the retina as a serial sequence. Because the image refresh rate is more than the temporal resolution limit of the human eye, the user does not perceive any flickering effects (von Waldkirch 2004). Note: While all commercial projection technologies are considered "eye safe" by international standards, these standards distinguish varying levels of eye safety. Right now scanning-mirror technologies are rated Class 2-safe because the normal blink response limits exposure.

8.4.8 Other Nonemissive Displays

For nearly 2000 years, the most popular way to display words and images was to use ink on paper. It still has many advantages over electronic information displays in terms of legibility and price. The biggest limitation of paper displays is that the printed symbols cannot be changed or removed without leaving noticeable marks. The invention of electronic ink has made it possible to overcome this disadvantage. Electronic ink displays are based on the electrophoretic principle. These displays are reflective and promise paper-like properties, that is, wide viewing angle, thin, very flexible, and relatively inexpensive. Unlike paper, they are electrically writeable and erasable. One big advantage over other types of displays is their low-power consumption, which may extend the battery life of devices with such displays to months or even years.

Several nonemitter display technologies such as electronic ink, TFT LCD, and LCoS (see Section 8.4.3) are already on the market, whereas others are still in the fundamental development stage. Among them, the above-mentioned electrophoretic displays as well as electrowetting, cholesteric, and mirasol displays are especially promising for innovative commercial off-the-shelf products. 3QI Multimode, electrofluidic pixels, and photonic ink are generally promising but not as far developed (Heikenfeld 2010).

Electrophoretic displays: The electrophoretic principle was developed by Joseph Jacobson in the early 1990s. Jacobson cofounded the E-Ink Corporation, which later coproduced the first market-ready electrophoretic display (electronic paper) with Phillips Components (Castillo 2010). Electrophoretic displays generate images, viewable in reflective light, by rearranging laden pigment particles using an applied electric field. Titanium dioxide particles are dispersed in a hydrocarbon oil or water. The particles are about 1 μm in diameter. The suspension is allocated between two parallel conductive plates that are 10–100 μm apart (Figure 8.16). Applying voltage over the two plates stimulates the particles to migrate electrophoretically to the plate bearing the opposite charge. The screen appears white when white particles are at the front of the display, the viewing side. Light is scattered back to the observer in the color of the high-index titanium particles. When the particles are electrically stimulated to the rear side, the screen appears dark because the oil film now covers the viewing side. Dividing the rear electrode into a chosen number of small elements (pixels) allows a desired image to be generated in accordance with the resolution of the now-formed screen. An appropriate voltage must be applied to each region in order to create a pattern of dark and light areas.

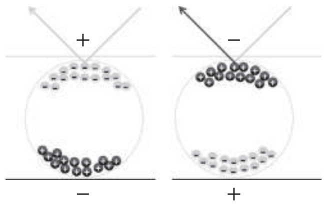

FIGURE 8.16 Illustration of electrophoretic microcapsules with adjacent electric field.

Electrowetting displays: As with electrophoresis, electric voltage stimulates the generation of an image in a suspension of oil and water with microcapsules. The oil (colored) forms a smooth layer between the water and a water repellent when no voltage is applied. This insulates the coating on the electrodes, resulting in a colored pixel. The tension changes between the water and the coating when voltage is applied between the electrode and the water, and the water moves the oil away. The result is a partially transparent pixel. If a white surface is used under the switchable element, the observer sees a white pixel. Due to the small size of the pixel, the user only perceives an average reflection. This means that a switchable element is generated possessing high brightness and high contrast. The element may then form the basis of a reflective display. Electrowetting displays have many advantages: the switch rate allows video, it is a low power and low voltage technology, and screens based on this technology may be very flat and thin. In addition, reflective characteristics are superior or at least equal to those of other reflective technologies, full-color displays with a relatively high brightness are possible, and each subpixel is able to switch independently between two different colors instead of using the three fundamental colors as a filter or alternating between segments of the three. This means two thirds of the display may reflect light in any color. This is achieved by constructing a pixel with a pair of two independently assignable colored oil films and a color filter. The colors used are cyan, magenta, and yellow. This system does not need any polarizers, meaning that e-wetting displays can be twice as bright as ordinary LCDs (Sun and Heikenfeld 2008).

Cholesteric LCDs: A cholesteric liquid crystal is a type of liquid crystal with a helical structure. Cholesteric liquid crystals are also known as chiral nematic liquid crystals. They appear in layers with no positional ordering within the layers, but they do have a director axis that varies with each layer. The variation of the director axis tends to be periodic in nature. The period of this variation (the distance over which a full rotation of 360° is completed) is known as the pitch. The pitch varies with temperature and can also be affected by the boundary conditions when the chiral nematic liquid crystal is sandwiched between two substrate planes (Yeh 2009).

Mirasol displays: Mirasol displays are based on interferometric modulator display (iMoD) technology. The iMoD was invented by Mark W. Miles, a microelectromechanical systems pioneer (Miles 2004). The technology consists of an electrically switched light modulator with a micromachined cavity that is operated using driver ICs similar to those used to address LCDs. An iMoD reflective flat panel display may include hundreds of thousands of individually assignable iMoD elements. iMoD displays incorporate the foremost examples of microelectromechanical systems based devices. An iMoD either reflects light at a given wavelength and the resulting light is seen as pure, bright colors, or it may appear black to the viewer because it can absorb all incident light on its surface (Mphepo et al. 2010).

3QI Multimode: This technology from Pixel Qi is a hybrid system which combines reflective and transmissive characteristics. It enables comparatively low-power consumption and indoor and outdoor viewing. However, compromises had to be made in terms of brightness and color saturation. Several reviews suggest that this technology may appear soon in laptop screens. The system combines a standard LCD with a standard black and white electrophoretic display and a restricted color electrophoretic display (Heikenfeld 2010).

Electrofluidic pixels are small reservoirs that may be filled with an ink-like fluid. An applied voltage either fills or empties the reservoir with an ink, generating the picture. The switch rate is very fast and allows the display of videos but also reaches paper-like conditions, making it very comfortable for the observer to read text (Heikenfeld et al. 2009).

Unlike the first prototypes of electronic paper, which could only display two colors, usually black and white, photonic ink can display any color value in the spectrum. Photonics (from photon) is an area of study based on the utilization of radiant energy, such as light, for various applications (Duncan 2008). Photonic ink, or p-ink, consists of planar arrays of silica microspheres—an opal film embedded in a matrix of cross-linked polyferrocenylsilane. Photonic ink is able to display color by controlled Bragg diffraction of light. Varying the size of the spaces between the particles creates different colors. A polymer gel is filled between the stacked spheres. The gel swells when soaked in a solvent and shrinks when it dries out, changing the distance between the tiny spheres. Because the size of the spaces determines the wavelength that is reflected, the swelling and drying of the gel results in a continuously tunable display of color across the entire visible spectral range. The amount of solvent absorbed by the gel is controlled by applying an electrical voltage. The optical response time of the film to a change in solvent is less than half a second (American Chemical Society 2003).

Electronic paper is often regarded as a substitute for paper products such as books and newspapers, as rewriteable paper in the office, as a material for price tags and retail signs, as wall-sized displays, and as a low-power display for smartphones. The general demand of the consumer for information "on the move" by means of sufficiently large, mobile, robust displays has consistently increased over the past years (Bhowmik, Li, and Bos 2008). New technological concepts to satisfy these demands include foldable and flexible displays that can be wrapped around a device, making the screen size to scale with the actual surface area (Myeon-Cheon, Youngkyoo, and Chang-Sik 2008). These "bendable display devices" can have a thickness of only a few micrometers. Candidate technologies are electrophoretic, cholesteric, electrowetting, and OLED displays. Except for OLEDs, all those technologies are reflective so they have certain limitations and are produced only in small scale (Crawford 2005).

8.4.9 Touch Sensitive Displays

Since their introduction the 1970s, touchscreens have turned from a futuristic input medium into a commodity device. The appearance has become so common that people today often don't take any extraordinary notice of this versatile technology. The use of touchscreens varies from mobile phones to desktop computers, handheld tablets, and large presentation screens. Elderly and disabled users in particular prefer touchscreens because of their intuitive direct manipulation mode (Mertens et al. 2010; Schneider et al. 2007).

The most popular technologies for touchscreens are as follows.

Resistive touch screens react to pressure generated by a finger or stylus. A resistive touch screen principally consists of several layers. Two of these layers are electrically conductive and slightly separated. Pressure "connects" these two layers and they act as voltage dividers generating two output currents. This change is identified as an input signal and is processed further according to the selected device drivers.

Capacitive touch screens consist of an insulator coated with a transparent conductor. Generally glass serves as the insulator. The human body is a natural conductor and is also used as such in this technology. A touch on the screen's surface results in an alteration of the human body's electrostatic field, which may then be measured as a change in capacitance.

Surface acoustic wave touch screens are widely used in publicly accessible interfaces such as ATMs and ticket vending machines. The system uses the ultrasonic wave created by a fingertip on the surface, which in this case may be a plain glass plate. Sensors aligned on every side (left, right, top, bottom) emit a sonic wave and also detect the wave emitted from the other side. When a finger makes contact with the screen surface, the sonic waves emitted are absorbed through the finger and the sensor arrays may locate the fingers position according to the interference patterns.

Optical touch screens use several optical sensors (such as infrared sensors) around the corners of the screen. The sensors are located in the range of a camera across the screen, such as on a wall on the other side of the display. A touch appears as a shadow on the screen and optical sensors may apply a simple triangulation algorithm to identify the location of the movement or touch.

Dispersive signal touch screens detect the mechanical load created by a touch. The general advantage of this technology is its relative resistance toward outside influences. Even scratches on the screen surface allow a further use of the system.

Strain gauge touch screens, also known as force panel technology, are spring mounted at every corner. Strain gauge touch screen indentifies the corresponding deflection when the screen is touched and locates it. It may also detect a person's force and movement along the *z*-axis.

The ability of several touch screen technologies to serve multitouch applications finds particular demand in cooperative product design and project management. Multitouch screens allow the precise measurement of more than one touch point on screen simultaneously. They can therefore identify complex gestures for advanced interaction. From the technologies just mentioned, the following can be used for multitouch purposes: capacitive screens, optical (infrared) screens, and more recently, resistive screens. More details can be found in Brown (2008), Chen, Cranton, and Fihn (2011), Jhuo, Wu, and Hu (2009), Maxwell (2007), Mertens et al. (2011), and Saffer (2008).

8.4.10 3D Displays

In general, two kinds of 3D displays must be distinguished because the mechanisms that carry the depth information by the light field they produce differ significantly. Stereoscopic displays produce only the light fields of two plain images of different views on a scene. The light fields of both views are independent and they carry by themselves no depth information other than perspective and occlusion. In contrast, volumetric displays produce one homogenous light field that simulates the light field of real objects. This homogenous light field carries inherently multiple views on the object and the depth information resulting from different focal lengths of object distances. Figure 8.17 shows how these two kinds of 3D displays can be further categorized according to technical principles.

Stereoscopic displays can be further distinguished according to the manner in which the images are multiplexed for the left and the right eye. Both images may be multiplexed spatially, temporally, or spectrally. For instance, shutter glasses multiplex both images temporarily. The display alternates images between the left and right eye. A synchronized shutter glass alternately blocks each eye's view so each one only perceives the image intended for it. In the case of polarizing glasses, different light polarization modes are used to encode and filter the images for the left eye and the right eye, respectively. Light can be polarized linearly or circularly. The modes of circularly polarized light are clockwise and counter-clockwise. The modes of linearly polarized light differ with the orientation of the plane along which they are polarized. The planes for the modes of linear polarization are perpendicular to each other. Using circular polarized light has the advantage that both images are correctly inverse multiplexed for arbitrary orientations of the user's head to the display screen, which is not the case if linear polarized light is used. Both images can also be multiplexed by using nonoverlapping spectral distributions for both images. One

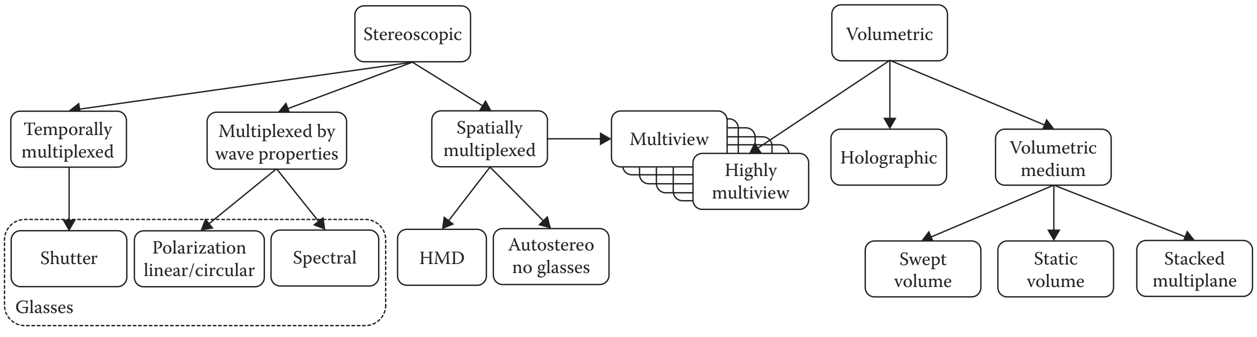

FIGURE 8.17 Taxonomy of three-dimensional displays.

example of this technology is an anaglyph that is viewed with two color glasses, where each lens has a chromatically opposite color, usually red and cyan. The disadvantage is that color perception is distorted. However, there are also more sophisticated filters in use that divide the visible color spectrum into six narrow bands—two in the red region, two in the green region, and two in the blue region (called R1, R2, G1, G2, B1, and B2 for the purposes of this description). The R1, G1, and B1 bands are used for one eye image, and R2, G2, and B2 for the other eye. The human eye is largely insensitive to such fine spectral differences so this technique is able to generate full-color 3D images with only slight color differences between the two eyes (Jorke and Fritz 2006). All these technologies have in common that the user needs glasses to see the 3D image. Autostereoscopic displays enable the user to see both images separately without using glasses. This is achieved by multiplexing both images spatially with an optical system that deflects the light of each image to the spatial position of the addressed eye. This is usually done by lenticular lenses in front of a common display and alternate columns in the image are deflected horizontally into different directions. This creates zones in front of the display in which one eye can only see one of the two images. Using lenticular lenses means halving the horizontal image resolution for each eye. New technologies combine temporal multiplexing with spatial multiplexing to implement autostereoscopic displays with full resolution per eye (Stolle et al. 2008). If the optical system that deflects the optical path of both images is not adapted to the movement of the user's head, the user may only see a clear 3D image within a restricted area in front of the display called the sweet spot.

One limitation of stereoscopic displays is that they do not support depth cues from motion parallax per se. This limitation can be bypassed if the position of the user's head is tracked and the generated images are computed to show intermediate views on the object according to the path of the movement of the user's head (Cruz-Neira, Sandin, and DeFanti 1993; Kruger et al. 1995).

Other autostereoscopic displays not only deflect two different images into different regions, but are able to deflect multiple views of an object in appropriate regions of visual space so that a user who is moving in front of the display has a stereoscopic view as well as depth cues from motion parallax between different views. If the angular density of views is sufficiently high, a single eye receives images of multiple views on the virtual object and it needs to adjust to the displayed depth of the object to see it clearly (Honda 2000; Takaki and Nago 2010). Thus, the light field becomes similiar to the light field of a volumetric display. In this sense, highly multiview displays can also be considered volumetric. Holographic displays are similar. They reconstruct the light field not by synthesizing multiple views through deflection but by scattering a chromatic wave front at fringe patterns. The scattered planar wave front reconstructs the original light field of a 3D object through interference (Leister et al. 2008).

Classic volumetric 3D displays use some medium in which dedicated voxels can be activated to emit light. Each voxel has a unique position (*x*, *y*, *z*) and can be assigned a color or gray scale value. Depending on the technology used to activate the voxels, volumetric displays can be assigned to several categories. Swept volume displays produce volume-filling images by reflecting or transmitting light from a rotating 2D surface within the desired 3D space. To display a point light at a specific location in the volume, it simply needs to be accomplished that any time the rotating 2D surface surpasses this volume element, it emits light of the desired color and brightness. This can be accomplished either by using active light elements like LEDs on the surface (Budinger 1984) or by using a laser that illuminates the point on a reflective surface at the right time (Langhans et al. 1998). Because of the human persistence of vision, an observer will perceive a stable 3D image if the volume is refreshed frequently enough. In a static volume display, there are no moving parts within the display volume. Several static-volume volumetric 3D displays achieve this by using a laser beam to excite visible radiation in a solid, liquid, or gas. Downing et al. (1996) developed a three-color volumentric display using high-power infrared laser beams. RGB voxels were created by sequential two-step absorption induced at the intersection of two laser beams with different wavelengths. The 3D image was drawn by scanning the volume with the laser beams to produce intersections at different locations inside the volume. Another technology to avoid moving parts is to use multi-stacked planes that can switch between a transparent and a light scattering state. Only one plane is in a light-scattering state, whereas the other planes are transparent. A high-speed digital projector reconstructs the scene by illuminating the voxels that lie within the successive opaque planes. A more detailed description of volumetric display technology can be found in Blundel and Schwarz (2000).

8.5 VISUAL PERFORMANCE

Impairment-free usage and user acceptance of interactive media depend substantially on the quality of the visual display as well as on the ease with which the displays allow information to be perceived and processed. A careful ergonomic evaluation is therefore essential to assess visual performance and identify existing shortcomings in displays.

Looking back, there is quite a long history of studies concerned with the ergonomic evaluation of visual displays (Dillon 1992; Schlick et al. 1997; Luczak and Oehme 2002; Pfendler and Schlick 2007). To estimate the costs and benefits of electronic displays in terms of human performance and visual load, the main interest was to learn which factors affect visual performance to what extent. One research approach was to compare display types in terms of visual processing efficiency. Most of these studies performed a basic comparison of the traditional hard copy with different electronic displays (Heppner et al. 1985; Gould et al. 1987). Another approach was to study the effects of specific quality criteria on performance (Pfendler, Widdel, and Schlick 2005; Sheedy, Subbaram, and Hayes 2003; Plainis and Murray 2000; Ziefle 1998, 2009). This procedure helps to distinguish different sources that account for performance shifts. Other studies gave attention to user characteristics (Kothiyal and Tettey 2001; Ziefle 2003a), workplace settings (Sommerich, Joines, and Psihoios 2001; Ziefle 2003b), and body posture (Aarås et al. 1997, 1998; Helander, Little, and Drury 2000) in the context of visual performance. Increasingly, ergonomic issues are under study for handheld devices and laptop computers, given the impact of reflection characteristics in TFT LCD displays, which often have disturbing glare and poor legibility under high levels of enviromental illuminance (e.g., Kubota 1997; Ziefle 2010a; Zingale, Ahlstrom, and Kudrick 2005).

Beyond display characteristics, any visual evaluation should also consider different task demands because they can strongly influence performance outcomes. The influence can be either positive, by compensating other suboptimal visual boundary conditions, or negative, when several negative factors accumulate, possibly leading to visual complaints and vision impairments.

8.5.1 Task Demands

Task demands are of crucial importance for evaluations of visual displays because they represent a complex entity of different factors and their interactions. The combination of (1) the task type (what the user is requested to do), (2) user characteristics (level of expertise, visual abilities, or working motivation), (3) text factors (font size, line pitch), (4) display factors (e.g., contrast, response times, resolution), (5) surrounding factors (e.g., ambient light or time on task), and (6) information access in multitasking settings has a considerable impact on performance outcomes. Because these factors were found to interact, it is necessary to examine the particular conditions and settings that were used in the different studies concerned with visual evaluations.

In order to evaluate visual displays, simple detection tasks, memory and recognition tasks, visual search tasks, and proof reading were used. Overall, two basic task forms can be distinguished: tasks in which a semantic context is present (e.g., proof reading) and tasks with no semantic context (e.g., visual search for multiple targets). This distinction has implications in terms of the ecological validity and generalizability of outcomes and in terms of the sensitivity with which shortcomings in visual displays are revealed. Tasks that have a semantic context have the general advantage of simulating what users usually do when using displays, thus the evaluation process is ecologically valid. However, these tasks were found be not very sensitive to visual degradation effects (Stone, Clarke, and Slater 1980; Ziefle 1998) for two main reasons. One is that the encoding and processing of text material represents behavior gained through intensive training. A top–down process comprehension guides the reader through the text and possibly masks the degradation effects. The second objection is concerned with reading strategies involving different combinations of cognitive and perceptual processes. When proofreading, for example, participants may read for comprehension or scan for unfamiliar letter clusters and word shapes. Thus, it is possible that performance outcomes do not reflect degradation properly even when display quality is suboptimal. Deteriorations might then be overlooked, especially in short test periods. Even though ecological validity is lower, visual search and detection tasks showed a higher sensitivity to degradation effects because the visual encoding process predominately relies on visual properties of the display (bottom-up process) without being masked by compensating cognitive strategies.

But text factors were also found to considerably affect performance. Among them, display size, the amount of information to be processed at one time and font size (Duncan and Humphreys 1989; Oehme et al. 2001; Ziefle, Oehme, and Luczak 2005; Ziefle 2008, 2010a) were revealed to be crucial in this context. The smaller the font size and the larger and denser the amount of (text) material to be processed, the stronger the performance decrements were. Age-related differences in response time can best be compensated by enlarging the font size from 16 to 22 arc minutes. Results from partial correlation analysis show that an age-differentiated adaptation of font size is recommended rather than an adaptation based on measurement of visual acuity (Vetter et al. 2010).

Whenever a detailed visual evaluation procedure is needed to analyze the effects of visual displays on performance, a two-step procedure is recommended. A benchmark procedure is advised as a first step. This procedure includes young and well-sighted participants and a task that is visually rather than cognitively strenuous. The second step includes a broadened scope. Older users (as they represent a major part of the workforce) and tasks with different visual and cognitive demands need to be addressed. In addition, extended periods of on-screen viewing are to be examined in order to realistically assess the long-term effects of computer displays.

8.5.2 Measures Used for Evaluation

The measures used to quantify the effects of visual display quality also differ regarding their sensitivity to visual degradation. In addition to effectiveness and efficiency of task processing, judgments of visual strain symptoms and the presence of visual complaints were also assessed.

Among performance measures, global and local parameters can be distinguished. Global performance measures are the speed and accuracy of task performance; they were widely used across visual evaluation studies. Reading and search times reflect the basic velocity of the encoding and visual processing. However, speed can only be meaningfully interpreted when the accuracy of task completion is also considered. In this context, the speed-accuracy tradeoff has a considerable impact. Whenever visual conditions, in computer monitors for example, are suboptimal (under low resolution or contrast conditions), the speed and accuracy of information processing cannot be simultaneously kept at a constantly high level. Rather, one of the two components deteriorates while the other remains constant. When both components are considered, the overall costs for information processing can be assessed. Nevertheless, reliable, global measures do not provide an understanding of the processes that cause the performance decrement. Oculomotor behavior was thus consulted to gain deeper insights into the nature of the deteriorated encoding process (Owens and Wolf-Kelley 1987; Iwasaki and Kurimoto 1988; Jaschinski, Bonacker, and Alshuth 1996; Best et al. 1996; Piccoli et al. 2001). The spatial and temporal characteristics of saccades were predominantly analyzed. Under visual degradation conditions, more saccades are executed, they are smaller in size, and they are accompanied by increased fixation times (Baccino 1999; Ziefle 1998, 2001a,b). Accommodation states, pupil size, vergence efforts, and visual scan path complexity (Schlick et al. 2006) were also used as measures to quantify the effects of display quality. The higher effort required for the visual system observed when reading electronic texts is assumed to form the physiological basis of visual fatiguing (Wilkins et al. 1984). Beyond oculomotor measures, stressor variables such as heart rate variability and eye blinks were used to determine the effects of display quality (Oehme, Schmidt, and Luczak 2003).

Another approach to quantifying effects of display quality is to collect user judgments with respect to what is called visual fatiguing, visual stress, visual strain, visual load, or discomfort. Visual fatiguing is considered a complex subjective measure based on the awareness of several symptoms: burning, dry, aching, watery eyes, difficulties in reading (text becomes blurred and fades away), as well as increased blinking and eye pressure (Piccoli et al. 2001; Stone, Clarke, and Slater 1980; Hung, Ciuffreda, and Semmlow 1986). User judgments represent an important aspect of display quality because perceived visual comfort is the most direct source of users' satisfaction (e.g., Oetjen and Ziefle 2007a,b, 2009). Even though ratings are easy to obtain, their validity is not without controversy. First, users differ considerably with respect to their responsiveness to visual strain symptoms. Furthermore, sensitivity to visual stress is not constant, but changes with the time spent on the task and age (Wolf and Schaffra 1964). Second, factors like fear of failing and the misinterpretation of one's own performance may contaminate judgments and make it necessary to prove that ratings match performance outcomes. Third, the emergence of visual fatiguing does not necessarily follow the same time course as performance shifts. Visual fatiguing is therefore not necessarily accompanied by performance decrements and vice versa (Chen and Lin 2004; Lin et al. 2009; Yeh and Wickens 1984; Howarth and Istance 1985). It is therefore advisable to include both subjective and objective measurements to obtain a complete evaluation.

8.5.3 Effects of Specific Quality Criteria on Visual Performance

As a first quality criterion, effects of display resolution (see Section 8.3.3) are considered. The psychophysical correlate of display resolution, and this is of visual ergonomic interest, is the sharpness of contours and the clarity with which objects can be identified. High-display resolutions allow more objects to be displayed on a given screen space. Even if this is advantageous when screen space restrictions are considered, it can be counter-productive: The benefit of higher resolutions in terms of contour sharpness may be negated by the smaller object sizes, and this has to be counterbalanced. The central question is whether higher resolutions lead to quantifiable improvements. The relevant literature shows that this is indeed the case (Gould et al. 1987; Huang, Rau, and Liu 2009; Miyao et al. 1989; Ziefle 1998). Due to unequal technical standards over time, resolution levels differ considerably between the studies (40–90 pixels per inch). In summary, it can be said that for up to 90 pixels per inch, higher resolution is better. Young adults' search performance was increased by 20% in the 90 pixels per inch condition compared with the 60 pixels per inch condition. This greater effectiveness was caused by a more efficient oculomotor control: Fixation times decreased by 11%, and in addition, less saccades (5%) were executed to process the visual information. Furthermore, performance in the low-resolution condition was not only found to be interrelated with the emergence and strength of visual fatiguing symptoms, but also the probability of fatiguing symptoms was significantly higher when two suboptimal viewing conditions were coincident: The longer participants worked in the low-resolution condition, the stronger performance decrements were (Huang, Rau, and Liu 2009; Ziefle 1998).

A second criterion to be examined extensively was intermittent light stimulation, which is characteristically present in CRT screens and is referred to as refresh rate (see Section 8.3.5). The perceptual component is a flicker sensation at low-refresh rates. Reading on a screen with low-refresh rates (50 Hz) is extremely hard work for users and leads to considerable eyestrain symptoms even after short reading periods. With increasing refresh rates (>70 Hz), the flicker sensation decreases, but it should be noted that the intermittent stimulation is nevertheless still physically present and may affect performance. It was shown that performance with a 100-Hz screen was 14% better than 50-Hz screen, and ocular efficiency was 16% better (fixation times and the number of fixations per line). However, performance decrements were also found at high-refresh rates (140 Hz), showing that effects of refresh rates on performance do not follow a linear, but a curvlinear relationship (Ziefle 2001a). In summary, we can say that refresh rates of 90–100 Hz in CRTs facilitate reasonably good visual performance.

Third, effects of luminance (see Section 8.3.2) and contrast (see Section 8.3.3) are also reported to play a major role in visual performance when computer displays are used (Plainis and Murray 2000; Van Schaik and Ling 2001; Ziefle, Gröger, and Sommer 2003; Oetjen, Ziefle, and Gröger 2005). However, results are not easy to integrate. Contrast is a complex factor, but it is also accompanied by several other lighting characteristics that are highly interdependent and affect the visual performance outcomes separately as well as in combination. Always a ratio of two luminance levels (background and object), in terms of Weber Contrast was proven to markedly affect the visual performance. Low contrast leads to performance decrements and oculomotor efficiency in a range of 10%–20%. But this ratio does not specify which absolute luminance levels constitute the respective contrast and—depending on which contrast definition is used—they mostly do not differentiate between whether information is displayed in negative or positive polarity (bright letters on a dark background vs. dark letters on a bright background). In addition, ambient lighting considerably interferes with the display contrast (Piccolo et al. 2004, 2007; Shen et al. 2009; Shieh and Lin 2000; Wang et al. 2009). Thus, knowing the contrast level without detailing polarity, absolute luminance levels and the kind of ambient lighting does not allow the interpretation of performance outcomes. Generally, it was found that positive polarity displays result in better visual performance than negative ones (Bauer and Cavonious 1980; Buchner, Mayr, and Brandt 2009; Wang and Chen 2000). The positive effect of positive polarity occurs due to the (simple) fact that light is essential for visual encoding (the absolute light level is higher with positive displays), and because it is less demanding when the computer display has the same polarity as the hardcopy (especially because both media are often used simultaneously in the same work setting) not requiring the user to alternately readapt. Ambient lighting usually reduces the contrast levels on the screen because the two lighting sources interfere. Thus, it is advantageous for performance if illumination in the room is sparse (Kokoschka and Haubner 1986). As for display luminance, it is recommended that luminance levels should not be too bright, preventing interfering glare, especially when ambient lighting is low and the probability of glare rises (Kubota 1997; Schenkmann, Fukunda, and Persson 1999).

Recent studies have shown renewed interest in the importance of contrast and luminance (Hollands et al. 2001, 2002; Gröger, Ziefle, and Sommer 2003; Ziefle, Gröger, and Sommer 2003; Oetjen and Ziefle 2004). Among visual factors, LCD displays (see Section 8.4.3) have the basic advantage of being flicker-free. However, they also have one major disadvantage: The displayed information is “perfectly” visible if users work in front of the screen and whenever this “optimal” position is not present, visibility is distinctly worse. This specific property of LCD screens is called “anisotropy.” A display is called anisotropic if it shows a deviation of more than 10% of its luminance subject to the target location or viewing angle (ISO 13406-2 2001). The nature of anisotropy is such that photometric measures (contrast and luminance) are not constant over the screen surface, but rather decrease with larger viewing angles. To quantify the change in photometric measures at different viewing angles, a measurement setup was developed which made it possible to exactly correlate photometric measures and visual performance (Gröger, Ziefle, and Sommer 2003; Ziefle, Gröger, and Sommer 2003). The screen was virtually cut into 63 fields (9 × 7). The luminance of bright/dark areas was individually measured by a photometer and contrasts were determined. Then different measuring positions were adopted: First, the “standard view” was applied, commonly used by the industry. The photometer was set in front of the screen and displaced gradually from field to field, with the photometer always set at right angles to the screen (Figure 8.18a).

From an ergonomic point of view, this procedure (as shown in Figure 8.18a) is highly artificial, as users do not displace themselves, but rather change their view: Viewing angles change remarkably depending on where users are looking. This fact is entirely disregarded in this measurement procedure. To simulate real viewing conditions, the “user view” (Figure 8.18b) and the “bystander view” (Figure 8.18c) were used. For the “user view,” the photometer was positioned centrally in front of the screen. Because the position of the photometer did not change, viewing angles increased with distance from the center of the screen, emulating a user’s head movements when looking toward the screen edges. For the “bystander view,” the photometer was set to a central point on the display and turned to the different measuring fields (30° and 50°). For extended viewing conditions,

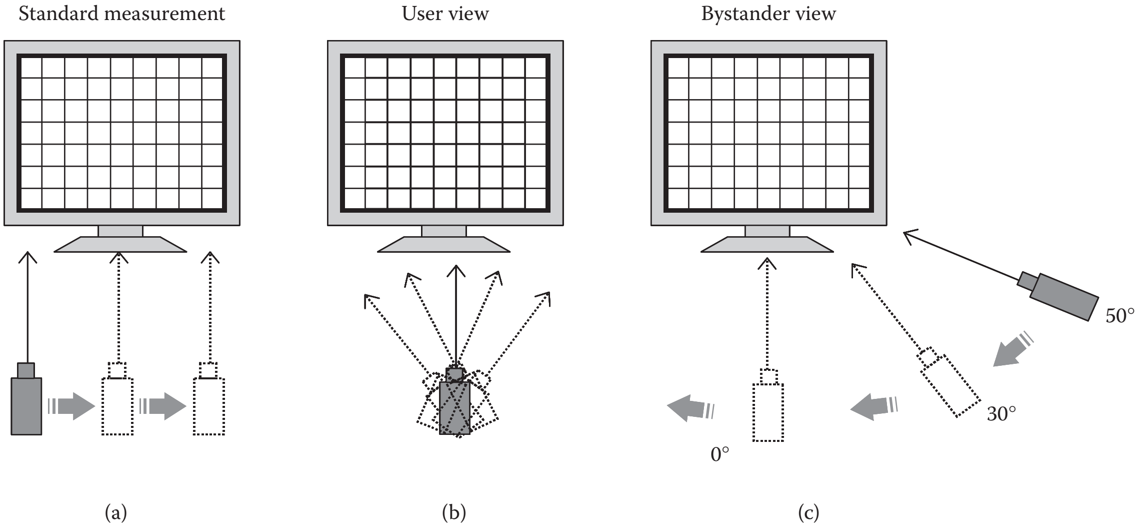

FIGURE 8.18 Quantifying anisotropy in LCD screens. (a) “Standard view” with the photometer displaced at right angles. (b) “User view” with the photometer emulating the user’s head movements. (c) “Bystander view” with the photometer positioned off-axis. (Data from Ziefle, M., T. Groger, and D. Sommer. 2003. *Int J Occup Saf Ergon* 9[4]:507–17; Oetjen, S., and M. Ziefle. 2009. *Appl Ergon* 40:69–81.)

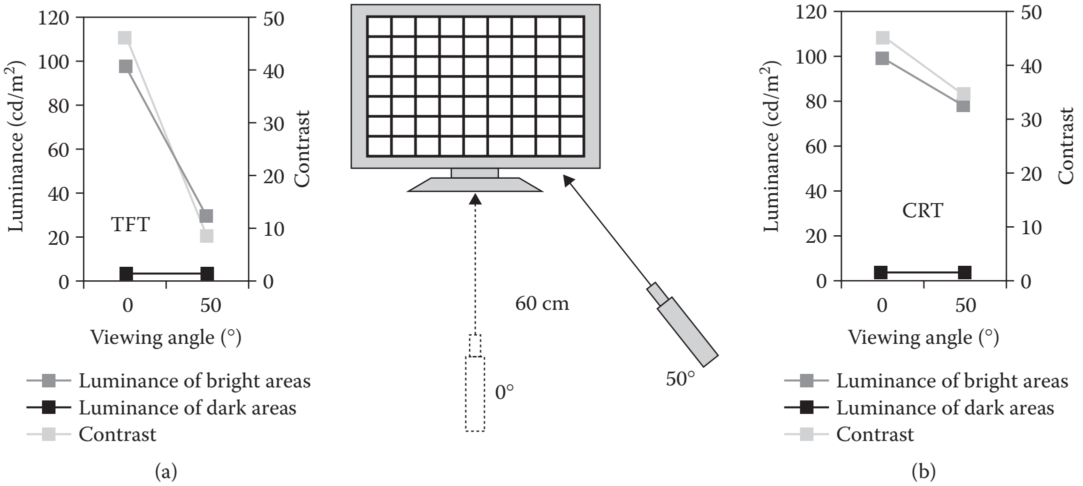

FIGURE 8.19 Photometric measures in the "bystander view" for (a) a liquid-crystal display and (b) a cathode ray tube display. (Data from Oetjen, S., and M. Ziefle. 2004. Effect of anisotropy on visual performance regarding different font sizes. In *Work with Computing Systems*, ed. H. Khalid, M. Helander, and A. Yeo, 442–7. Kuala Lumpur, Malaysia: Damai Sciences.)

the photometer was set off-axis, and its view pointed to the screen from the side (left and right side, respectively).

In Figure 8.19, it becomes evident that photometric measures change significantly as a function of viewing angle in LCDs (Figure 8.19a) and to a much lesser extent in CRTs (Figure 8.19b).

Performance outcomes showed that anisotropic effects have to be taken seriously. Visual performance with TFT LCD screens considerably deteriorates by about 10% for young adults when they had to look at the screen off-axis. Anisotropy plays a role in many real-life work settings: (air, rail) traffic controlling environments or stock exchanges use several displays simultaneously (placed next to and/or on top of each another) that have to be surveyed by one operator. Another example is the schooling and training context where it is quite normal for several users to work together on just one screen. Thus, from an ergonomic point of view, LCD's anisotropy must be regarded as a visual limitation of the display technology, at least when a fast and accurate visual detection performance is important.

8.5.4 Comparison of Display Types

Over the past 40 years, ever since the first evaluation studies of electronic information displays were published, a huge number of studies have dealt with the fundamental question of which display type assures the highest reading comfort and the best visual performance. Typically, and this reflects the chronological development, hardcopy, CRT, and LCD displays were compared for visual performance. As display quality has improved continuously over time, the technical standards on which the evaluations were based differ greatly. This is a factor that should be kept in mind. Recent studies include new developments (augmented reality, see Section 8.7.2) in visual display technology.

However, independently of the time and technical standard of visual displays, the one and only display that outperformed all others with respect to visual performance and comfort is the traditional hardcopy. Its development covers more than 200 years (since the invention of the industrial production of hardcopy in France) and has been continuously amended with respect to readability and visibility, by the expertise of typesetters and typographers. Thus, hardcopy can be regarded as an outstandingly suitable display with regard to visual ergonomic demands. It provides high contrast and resolution with neither disturbance by glare, screen reflections, or flicker. Accordingly, the majority of studies show that performance in CRT screens is significantly lower compared with paper (Heppner et al. 1985; Ziefle 1998). Hardcopy was also found to outperform modern TFT LCD displays (Ziefle 2001a).

Because the private and public need for electronically displayed information is continuously increasing nowadays, the evaluation should focus on the quality of different electronic displays. Here, the classic comparison of CRT and LCD displays is of central interest. The CRT, the most widespread screen type for decades, quickly phased out as a result of its specific lighting characteristics (flicker). The development of LCD technology was therefore highly welcome. LCD screens, lightweight and flat, are flicker-free and display information at much higher levels of luminance and contrast.

At first sight, the outcomes of studies that compare CRTs and LCDs reveal an inconsistent picture. There are studies in which TFT LCD displays led to higher visual performance than CRT screens (Menozzi et al. 2001; Ziefle 2001a,b), but there are also studies in which CRT displays outperform LCD screens (Oetjen and Ziefle 2004; Oetjen, Ziefle, and Gröger 2005; Oetjen and Ziefle 2007a,b, 2009). This inconsistency can be resolved when the experimental purposes and evaluation settings are considered. Whenever the impact of screen flicker was of main interest, the methodological focus was to compare both displays with respect to refresh rates (present in the CRT and absent in the LCD). This procedure ruled out any other differences between both displays that may confound or compensate flicker effects (anisotropy).

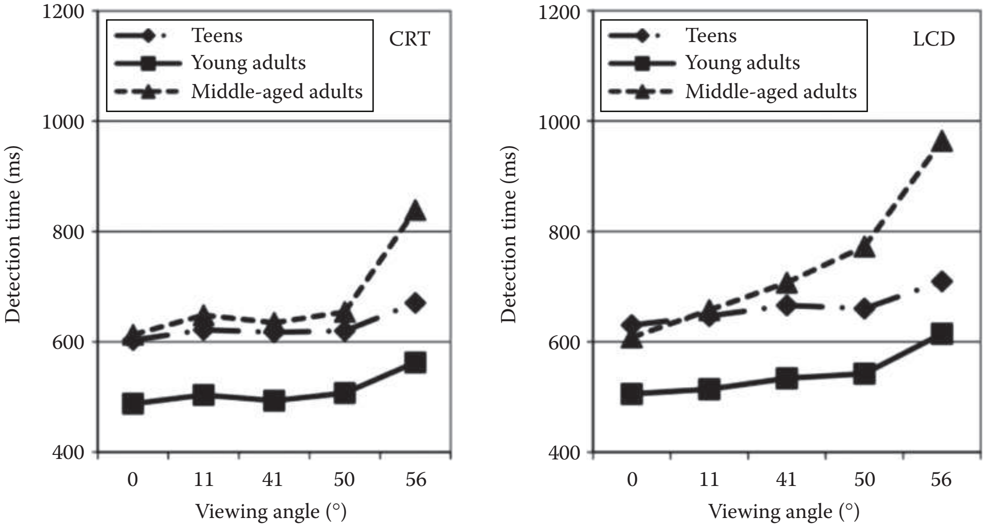

FIGURE 8.20 Effects of display type, viewing angle, and age groups on performance in a target-detection task. (Adapted from Oetjen, S., and M. Ziefle. 2007a. *Hum Factors* 49[4]:619–27.)

Thus, participants were usually seated in front of the screen and had to work on tasks that were displayed centrally (otherwise, anisotropic effects would have been mixed up). In these cases, visual performance clearly favors the TFT LCD and shows that screen flicker in CRTs is disadvantageous. In addition, it was found that the relative benefit from LCD technology is disproportionately higher for older users: While young adults (20–25 years of age) showed performance superiority of 10% for the LCD compared with the CRT (100 Hz), the benefit from the LCD was 16% and 27%, respectively, when older users (40–65 years of age) were examined (Ziefle 2001b). Note, however, that the older adults generally showed nearly 40% lower visual performance.

However, the benefit of the LCD determined in this way has yet to take anisotropic effects into account. As soon as anisotropy is considered, the picture changes. Studies concerned with the anisotropic effects of the two display types showed that the LCD's superiority over the CRT disappears when extended viewing angles were considered (Gröger, Ziefle, and Sommer 2003; Hollands et al. 2001, 2002; Oetjen and Ziefle 2004). When considering all screen positions, visual performance decreased by 8% when an LCD was used instead of a CRT. When a central view was applied, detection times were 14% faster than when viewing 50° off-axis. A further aggravating factor was font size. Deterioration when detecting small targets (1.5 mm vs. 2.4 mm) rose to almost 30% with the LCD, versus "only" 20% with the CRT. Whenever all suboptimal factors (small font, LCD screen, off-axis viewing) occurred simultaneously, performance decrements were found to rise to as much as 38% (Oetjen and Ziefle 2004, 2007a,b).

Visual ergonomic studies examined mostly young adults as participants. However, young adults do not represent the whole work force that uses electronic information displays. Rather, children and teenagers as well as older users do frequently use displays in private and professional settings. Until now, both major user groups have been mostly disregarded by visual ergonomic studies. Because visual functions change significantly with age (e.g., Ellemberg et al. 1999; Kline and Scialfa 1997), we need to know to what extent anisotropy affects visual performance in other age groups so that we can maximize work productivity, safety, and comfort. In one study (Oetjen and Ziefl 2007a,b) teenagers ($M = 13.9$ years), young adults ($M = 23.9$ years), and middle-aged adults ($M = 56.4$ years) were compared for visual performance when working with anisotropic displays (TFT LCD display (CF-L 15, 15-in., 1024 × 768), and a CRT as a control condition (Sony S 200 PS, 17-in., 100 Hz, 1024 × 768). Five different viewing angles were studied (0°, 11°, 41°, 50°, and 56° off-axis). Speed and accuracy of visual performance in a simple detection task was measured. The results show a significant impact of anisotropy on performance. Detection times were 7.6% longer for the LCD compared with the CRT and increased by 21.9% from the central (0°) to the off-axis conditions (56°). The LCD's anisotropy does not equally disadvantage all age groups, but rather appears to be age-related (Ziefle 2009). This is shown in Figure 8.20.

Laptop computers are replacing stationary desktop systems more and more because of increasing demands for work mobility (Kirsch 2004). Extended viewing angles are especially important in mobile contexts. In order to analyze the impact of LCD's anisotropy, visual performance in off-axis viewing conditions was investigated, comparing a mobile TFT LCD to a stationary LCD and a CRT (Oetjen and Ziefle 2009; Ziefle 2009). The study simulated real work situations where several users are viewing one screen or one "operator" has to survey several screens at the same time. Participants worked from two sitting positions (central position where the user was placed directly in front of the screen and an off-axis position where the user was placed off-axis). Again, five different viewing angles were examined (0°, 11°, 41°, 50°, and 56° off-axis). In accordance with findings of earlier studies (e.g., Gröger, Ziefle, and Sommer 2003; Hollands et al. 2002; Oetjen and Ziefle 2004, 2007a,b; Ziefle, Gröger, and Sommer 2003), the present study corroborated anisotropy as a major shortcoming of LCD displays. Although LCD displays have

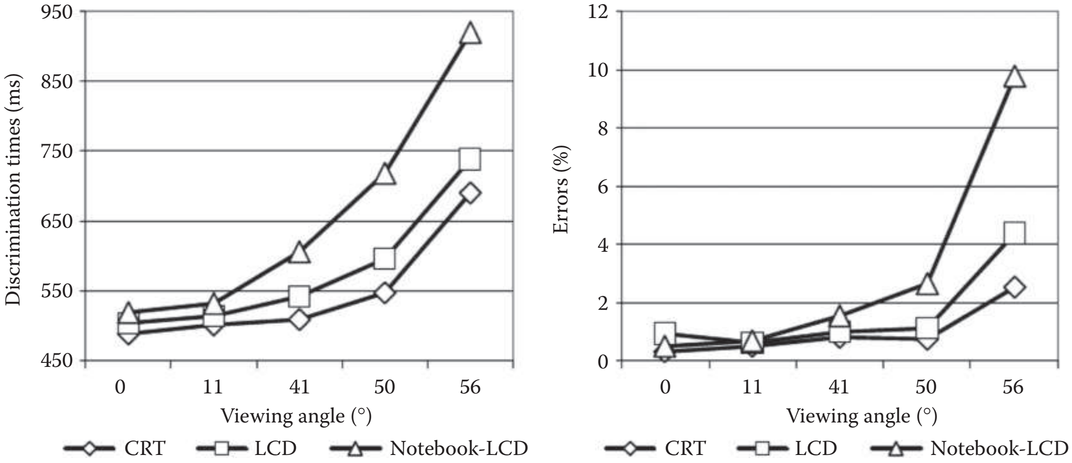

FIGURE 8.21 Visual performance in terms of target discrimination times under different off-axis viewing conditions for three display types. (Adapted from Oetjen, S., and M. Ziefle. 2009. *Appl Ergon* 40:69–81; Ziefle, M. 2009. Visual ergonomic issues in LCD-Displays. An insight into working conditions and user characteristics. In *Methods and Tools of Industrial Engineering and Ergonomics for Engineering Design, Production, and Service-Traditions, Trends and Vision*, ed. C. M. Schlick, 561–72. Berlin: Springer.)

many advantages (see Section 8.4.3), one disadvantage is that luminance is not isotropic, but varies as a function of viewing angle. Physical measurements revealed the strongest fluctuation of luminance for laptop TFT LCDs, followed by desktop LCDs (Oetjen and Ziefle 2009). The CRT technology, however, is not significantly affected by anisotropy. Performance data mirror these differences although the extent of performance deterioration is smaller than the reduction of luminance levels (Figure 8.21). When the discrimination performance of all screen positions is considered, using the CRT led to the best performance and using the laptop LCD led to the worst performance. In all screen positions, the mean difference was about 6% when CRT and external LCD were compared, and it increased to a surprising 18% between CRT and laptop LCD. The strong susceptibility to off-axis viewing becomes even more evident when only the off-axis conditions are considered. At the 56° position, the speed of visual discrimination decreased by 33% when the laptop LCD was compared with the traditional CRT.

In summary, LCD anisotropy is a limiting factor for visual performance, especially in work settings where fast, accurate reactions are necessary. Nevertheless, it should be taken into account that any comparison of laptop LCDs and external LCDs is unbalanced if only one dimension—visual quality—is focused upon. Other aspects of working contexts are also important in real-life applications. One must consider that the major advantage of laptop computers is their ability to be mobile and change work settings. Besides their susceptibility to the negative effects of restricted viewing angles, it should also be mentioned that for privacy reasons the effects are sometimes highly welcome (e.g., in ATMs and mobile phones).

Recommendations for display types should therefore be related to the specific task context in which they are to be used. When considering human performance in off-axis viewing conditions from a visual ergonomic perspective, there is a clear ranking of screen types for this kind of task demand. Considerably lower performance is to be expected when LCDs are used, when time-critical tasks have to be completed, when the whole display surface is used to display the stimuli and when extended viewing angles are present. The decrements are most pronounced in laptop LCDs because their LCD technology is very susceptible to off-axis viewing conditions.

8.6 STANDARDS, REGULATIONS, AND SEALS OF APPROVAL

There are a large number of national and international standards, regulations, and seals of approval that regulate multiple aspects of the design and use of visual displays. They cover areas such as ergonomics, emissions, energy consumption, electrical safety, and documentation. Various federal institutions and private organizations such as the European Agency for Safety and Health at Work, the German Technical Surveillance Association (TÜV), or the American National Standards Institute (ANSI) are responsible for product surveillance and awarding safety seals and recommendations for use. Similarly, the ASEAN Consultative Committee on Standards and Quality (ACCSQ), which represents 10 Southeast Asian nations, aims to form a region of product standards. China and Japan have their own respective federal institutions, SAC and JAS. Display users should generally be aware that many of the awarded quality and ecological seals are often created by the producer and therefore do not guarantee a rigorous quality comparison among different producers and their products. The significant rise in the importance of ecological labeling and consumer demands has prompted producers to join in this widespread global industrial trend. Public awareness of this matter has led the industry to highly praise their own products and advertise them with attention to their ecological thriftiness (e.g., "standby" energy balance of visual displays).

ISO Technical Committee 159 (ISO/TC 159 SC 4/WG 2) is an important international committee for the development of ergonomics standards for visual displays. The most important directives for all display types can be found in Table 8.1.

Technical documentation and user manual	German Equipment Safety Law, GS Mark

Due to rapid technological development, only selected criteria can be covered. Up-to-date information and advanced information can be found on the websites listed in Table 8.2.

8.7 DISPLAYS FOR SELECTED APPLICATIONS

8.7.1 Virtual Reality

Immersive VR is a technology that enables users to "enter into" computer generated 3D environments and interact with them. VR technology involves the additional monitoring of body movements using tracking devices, enabling intuitive participation with and within the virtual world. Additional tracked peripheral devices permit virtual navigation, pick-and-place manipulation of virtual objects (Schlick, Reuth, and Luczak 2000) and interaction with humanoids and avatars by using data gloves, space joysticks, or 3D tracked balls (Holmes 2003).

A 3D view is generated using different concepts and technologies (see Sections 8.2.5, 8.3.7, and 8.4.10). HMDs are a commonly used display device. For VR, a closed-view HMD in non-see-through mode is usually used (see Section 8.7.2). Visual displays, especially HMDs, have decreased substantially in weight since the first invention of an immersive head worn display, but are still hindered by cumbersome designs, obstructive tethers, suboptimal resolution, and an insufficient field of view. Recent advantages in wearable computer displays, which can incorporate miniature TFT LCDs directly into conventional eyeglasses or helmets, should simplify ergonomic design and further reduce weight. Most of the advanced closed-view HMDs have adjustable interpupillary distance in order to avoid mismatches in depth perception. They provide a horizontal field of view of 30°–50° per eye and a resolution of at least 1024 × 768 and therefore outperform predecessor systems (Stanney and Zyda 2002). Large images of animated VR scenes can be generated by LCoS-based or DMD projectors on the front or back of one or multiple screens. Stereoscopic images are projected on the basis of spatial, temporal, or spectral multiplexing (see Section 8.4.10).

The computer animated virtual environment (CAVE) is a further development in projection technology. It consists of a cube with several panels onto which the images are projected from behind. Depending on the construction, there are C3 (two walls and the floor), C4, C5, and C6 designs. A CAVE provides space for small groups but can usually only track and optimize the stereoscopic view for one person. The other people perceive distortions, especially at corners and edges.

8.7.2 Augmented Reality

Augmented reality (AR) characterizes the visual fusion of 3D virtual objects into a 3D real environment in real time.

Unlike virtual environments, AR supplements reality rather than completely replacing it (Azuma 2001). AR can be used in many applications, such as production (Schlick et al. 1997; Park et al. 2008; Odenthal et al. 2009), assembly and service (Kleiber and Alexander 2011), medical (Park, Schmidt, and Luczak 2005), architecture, entertainment and edutainment, military training, design, robotics, and telerobotics.

One approach to overlaying the real world with virtual information is to use an HMD (see Section 8.2.5). Superimposition can be done in two ways: using an HMD in see-through mode (optical-see-through) or an HMD in non-see-through mode, called video-see-through (feed-through). The HMD in the non-see-through mode optically isolates the user completely from the surrounding environment, and the system must use video cameras to obtain a view of the real world. The optical see-through HMD eliminates the video channel, so the user is directly looking at the real scene through optical combiners. The merging of the real work environment and virtual augmentation is performed by screen-based optical combiners in front of the eyes, often based on half-silvered mirrors. Both systems have advantages and disadvantages in usability and technology. In an optical see-through system, there is a time lag between the real-world information and the virtual information that is blended into the field of view. This is caused by the computing time for image generation. In addition, the calibration of such a system is rather complicated. In video see-through systems, the quality of the video depends on both the technology of the cameras and the displays. There are several factors such as limited response time, displacement of the cameras from eye level and time delay of the channels, which have an adverse effect on human perception and hand–eye coordination (Biocca and Rolland 1998; Oehme et al. 2001; Luczak et al. 2003; Park, Schmidt, and Luczak 2005; Ziefle, Oehme, and Luczak 2005). Another disadvantage is a certain loss of information caused by the fact that the perception of the real work environment is limited to the maximum resolution and field of view of the displays and cameras. An interesting approach to overlaying visual information is to use a VRD (see Section 8.4.7). Unlike the screen-based HMDs, a VRD reaches the retina directly with a single stream of pixels, thus guaranteeing a clear projection of different kinds of information. Because of the higher laser light intensity, the half-silvered mirrors commonly used for see-through HMDs can be optimized for maximum translucence, improving the see-through quality. Furthermore, the display's maximum resolution is no longer determined by the tolerances used in manufacturing the display pixels, but by the control logic and quality of the deflection mirror.

Ergonomic experiments based on geographic orientation tasks have shown that human performance in terms of task completion time and experienced task difficulty is significantly better when optical see-through HMDs are used instead of paper-based maps (Pfendler and Schlick 2007). Moreover, the evaluation of three different electronic information displays for geographic orientation tasks (optical see-through HMD with full-color AMOLED, full-colored TFT LCD hand-held display, and optical see-through HMD with two-colored VRD) showed no significant differences in human performance (Pfendler et al. 2011).

A recent study by Odenthal et al. (2009) investigated the ergonomic presentation of assembly information by an augmented vision system set up to support human operators in the task of detecting assembly errors in small work pieces. A high-resolution binocular/stereoscopic optical see-through HMD and a common monoscopic TFT LCD display, which was mounted on a table behind the work piece were used for visual augmentation. The statistical analysis showed that error detection rate with the HMD instead of the table-mounted display significantly increased. However, this was accompanied by a trend toward longer detection times.

A clip-on display tries to combine the optical and video see-through modes. A tiny TFT LCD screen can be clipped onto eyeglasses or safety glasses. The user of such a display can easily change between the generated image on the screen and the real world beyond it. However, the screen area covers a certain fraction of the field of view, so that objects can be fully or partially occluded.

8.7.3 Mobile Phones and Handheld Devices

Mobile information and communication technologies are one of the fastest growing technological fields ever and have interpenetrated many professional and private fields in the last decade. According to recent estimates, there are 4 billion users of Global System for Mobile Communications connections per year worldwide. Data are usually transmitted by mobile phones or smartphones. The main reason for their popularity is on-the-go lookup and entry of information, quick communication, and instant messaging (Weiss 2002). As mobile devices provide wireless Internet access, web services can be used everywhere and at any time (Rao and Minakaki 2003). Mobile computing has already expanded into very different areas such as field services, healthcare, and journalism. Experts predict that by 2013 more than 445 million people will be regularly using their mobile phones to purchase goods remotely (Informa Telecoms and Media Global 2008).

Mobile devices are all battery operated, and this imposes severe limitations on power use for the display. In contrast to early LCD displays, which were reflective and had a very limited resolution, today's emitter and nonemitter displays require a certain power budget to be dedicated solely to information visualization. Even with high-resolution passive-matrix displays, which are very power-efficient, an increase of nearly one order of magnitude in power consumption should be expected. The commercial release of Li^+ batteries provided a jump in power density and peak power, opening up the area to emitter and AM nonemitter displays. When using TFT LCD displays, power consumption can account for 80% of the overall system (Li, Bhowmik, and Bos 2008).

Handheld devices may differ with respect to physical dimensions, display resolution, contrast, luminance, and touch/stylus sensitivity, but they all are characterized by small screen size, something that has a considerable impact on human information processing. For instance, the number of menu items that can be displayed at a time on the screen is severely limited. Hence, many items must be memorized by the user. Some devices display as many menu items as possible to support information in a user's working memory, whereas others prefer to show only a few menu items per screen to improve legibility of characters. Current mobile phones (e.g., models from Nokia, Motorola, Samsung, Sony Ericsson) have screen sizes of about 3.5–6 cm (length) and 2.5–5 cm (width) and display between two and eight lines of characters. Character sizes vary between 2 and 5 mm. Display sizes for smartphones are typically bigger and have about a length of 6–9 cm and a width of 4–6.5 cm. Handheld devices are also often used in medical care so they must be small to meet intimacy and/or acceptance demands, for example, signal warning devices for blood pressure or diabetes (Calero Valdez et al. 2009, 2010; Mertens et al. 2009).

Limited screen space is very problematic for providing optimized information access, and the question of how to "best" present the information on the small display is challenging. At first glance, the challenge seems to be mainly related to visibility concerns. If that is the case, visually ergonomic principles should be given primary consideration. To provide fast, accurate information access, objects and letters should be big enough, text lines should not be too close together and information density should be low. This is especially important for older adults, who usually have problems with their sight (Brodie et al. 2003; Omori et al. 2002). However, visibility concerns are not the only point of concern. There is also the cognitive aspect of information visualization, that is, the requirement that the presentation of information should help users orient themselves properly. Disorientation in the menus of handheld devices is a rather frequent problem (Ziefle and Bay 2005, 2006; Ziefle 2008, 2010b). Users have to navigate through a complex menu of functions, which is mostly hidden from sight because the small window only allows a few functions or small text fragments to be displayed at a time.

Several techniques have been proposed to accommodate the problem of displaying a lot of information on a small screen. One is rapid serial visual presentation (RSVP), which is based on the idea of presenting information temporally instead of spatially (Rahman and Muter 1999; Goldstein et al. 2001). With RSVP, one or more words are presented at a time at a fixed location on the screen and users have to integrate text fragments bit by bit by scrolling the text forward and, if necessary, backward. A similar technique is the times square method (TSM), also known as leading. With TSM, the information is not static but moves across the screen (word by word or sentence by sentence), with the text scrolling autonomously from left to right. Even if trained readers reach a reasonable level of efficiency with both presentation modes (RSVP and TSM), users report a dislike for both presentation forms. The low acceptance may be because of high cognitive and visual demands imposed by the presentation mode. Either memory load is high because it is difficult for users not to lose the plot while integrating the words and sentences that are displayed one after another (RSVP), or visual and attentional demands are high because it is essential to catch the text content in moving sentences. Accordingly, when users fail to read content on the first attempt, they have to wait until the scrolling information appears again (TSM).

Considering visual and cognitive demands concurrently, two alternatives can be contrasted. The first alternative is to display only a little information on screen at a time. This helps avoid visibility problems resulting from high-information density. The other alternative is to display as much information on screen as possible. This allows users to have maximum foresight (cognitive preview) of other functions on the menu, which should benefit information access from a cognitive point of view and minimize disorientation. It appears that a sensitive cutoff needs to be defined between visual and cognitive impacts. Additionally, it needs to be determined whether the impact of cognitive preview and the impact of visual density are crucial for efficient information access. An initial study experimentally investigated the role of menu foresight (Bay and Ziefle 2004). Young adults processed tasks on a simulated mobile phone where one, three, or seven menu items were presented at a time. The results corroborated the significance of information presentation on small screens with regard to efficiency of usage: Intermediate foresight (three functions) was found to lead to the best performance. When only one menu item was shown at a time—as is the case for a number of devices on the market—users needed 40% more steps to process tasks than when three items were shown, conforming the cognitive facet to be crucial. But also when information density was high (seven functions), performance declined by more than 30% compared with the presentation of three menu functions per screen, confirming that the visual facet also plays an important role.

Another study (Ziefle 2010a) scrutinized the tradeoff between legibility and menu foresight (number of functions seen at one time). Ergonomically, this tradeoff is critical because displayed information needs to have a sufficiently large font size to provide good legibility. However, menu orientation is facilitated when the amount of information per screen is maximized and a large preview is allowed. Thus, it is of interest which of the two processes is critical for the usability of small screen devices—the influence of cognitive preview or the effects of legibility. Independent variables font size (8 pt, 12 pt), information density, and cognitive preview (one or five functions per screen at a time) were experimentally varied, and the effects on navigation performance in mobile phones were observed. Because older adults are an increasingly key target group for mobile technologies (Ziefle 2008, 2010b; Ziefle and Bay 2008), and because they sometimes have special problems with information representation on small screens, older participants were chosen to solve very common phone navigation tasks on a simulated mobile phone. Navigation performance was assessed according to task success (effectiveness) and time needed to solve phone tasks as well as disorientation measures, that is, the number of (unnecessary) returns in the menu hierarchy and the number of returns to the top menu level to start over. Both measures had previously been shown to be very sensitive to reflect problematic interface design and low usability (Ziefle and Bay 2006, 2008).

The outcomes clearly revealed that both visibility issues and orientation concerns have a major impact on older users' navigation performance. This can be taken from the fact that the best navigation performance—in terms of effectiveness and efficiency—was obtained for the display design with a large font size and a large preview. However, when weighing the relative impact of both factors, proper orientation in the menu is more decisive than visibility effects for the older group. The lowest performance resulted from the display with a large font size. Visibility there was good, but because the preview was small, it could only display one function per screen at a time (Figure 8.22).

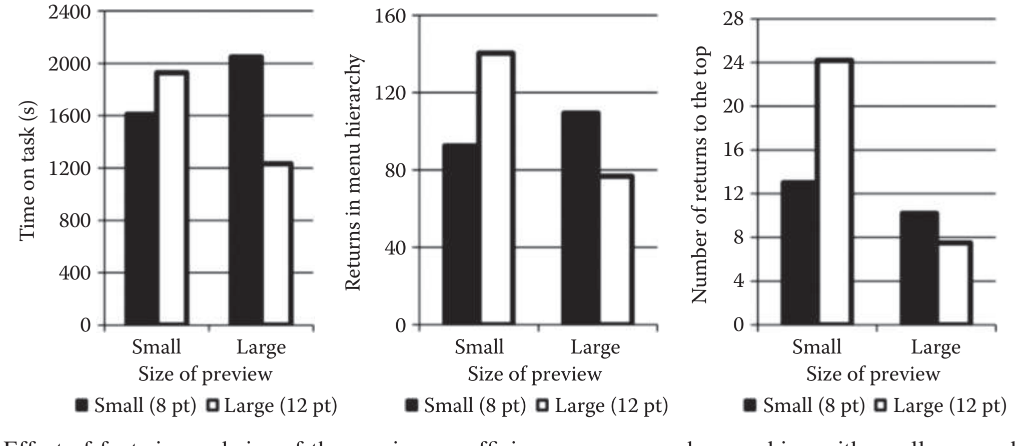

FIGURE 8.22 Effect of font size and size of the preview on efficiency measures when working with small screen devices. From left to right: time on task (s), number of returns in menu hierarchy, number of returns to the top. (Adapted from Ziefle, M. 2010a. *Applied Ergonomics* 41(6):719–30.)

9 Haptic Interface

Hiroo Iwata

CONTENTS

9.1 INTRODUCTION

It is well known that sense of touch is inevitable for understanding the real world. The use of force feedback to enhance computer–human interaction (HCI) has often been discussed. A haptic interface is a feedback device that generates sensation to the skin and muscles, including a sense of touch, weight, and rigidity. Compared with ordinary visual and auditory sensations, haptics is difficult to synthesize. Visual and auditory sensations are gathered by specialized organs, the eyes and ears. On the other hand, a sensation of force can occur at any part of the human body and is therefore inseparable from actual physical contact. These characteristics lead to many difficulties when developing a haptic interface. Visual and auditory media are widely used in everyday life, although little application of haptic interfaces is used for information media.

In the field of virtual reality, haptic interface is one of the major research areas. The last decade has seen significant advances in the development of haptic interfaces. High-performance haptic devices have been developed and some of them are commercially available. This chapter presents current methods and issues in developing haptic interfaces.

Section 9.2 describes the mechanism of haptic sensation and overall view of feedback technologies. This section is followed by three sections (9.3, 9.5, 9.6, and 9.9) that introduce examples of haptic interface technologies developed by the author. Section 9.7 presents application areas and future prospects of haptic interfaces.

9.2 MECHANISM OF HAPTICS AND METHODS FOR HAPTIC FEEDBACK

9.2.1 Somatic Sensation

Haptic interface presents synthetic stimulation to somatic sensation. Somatic sensation comprises proprioception and skin sensation. Proprioception is complemented by mechanoreceptors of skeletal articulations and muscles. There are three types of joint position receptors: (1) free nerve endings, (2) Ruffini corpuscles, and (3) Pacinian corpuscles. The Ruffini corpuscle detects static force. On the other hand, Pacinian corpuscle has a function to measure acceleration of the joint angle. Position and motion of the human body is perceived by these receptors. Force sensation is derived from mechanoreceptors of muscles, muscle spindles, and golgi tendons. These receptors detect contact forces applied by an obstacle in the environment.

Skin sensation is derived from mechanoreceptors and thermoreceptors of the skin. The sense of touch is evoked by these receptors. Mechanoreceptors of the skin are classified into four types: (1) Merkel disks, (2) Ruffini capsules, (3) Meissner corpuscles, and (4) Pacinian corpuscles. These receptors detect edge of object, skin stretch, velocity, and vibration, respectively.

9.2.2 Proprioception and Force Display

Force display is a mechanical device that generates a reaction force from virtual objects. Haptic interfaces have recently become a rapidly growing research area, although the technology is still in a state of trial and error. There are several approaches to implementing haptic interfaces, which are described in Sections 9.2.2.1 through 9.2.2.4.

9.2.2.1 Exoskeleton-Type Force Display

An exoskeleton is a set of actuators attached to a hand or a body. In the field of robotics research, exoskeletons have often been used as master manipulators for teleoperations. However, most master manipulators entail a large amount of hardware and therefore have a high cost associated with them, which restricts their application areas. Compact hardware is needed in order to use them in human–computer interactions. The first example of a compact exoskeleton suitable for desktop use was published in 1990 (Iwata 1990a,b). The device applies force to the fingertips as well as the palm. Figure 9.1 shows the overall view of the system.

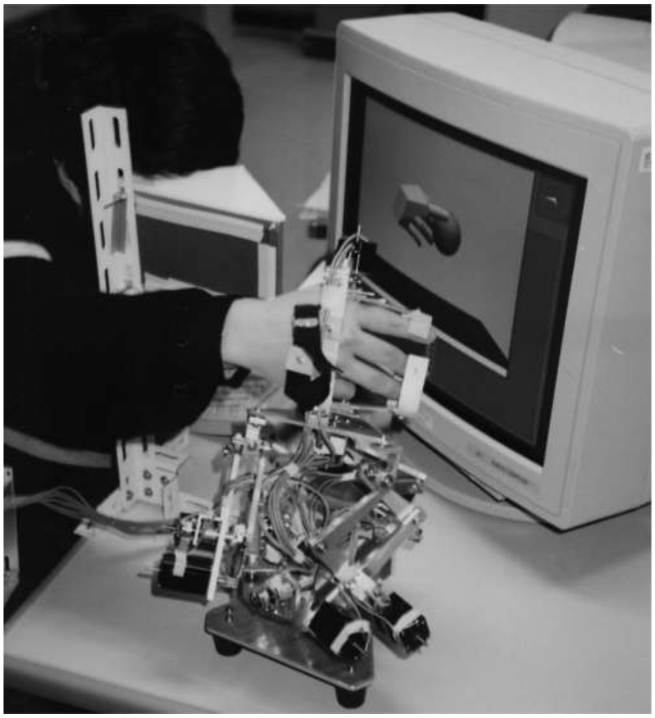

FIGURE 9.1 Overall view of a desktop force display system.

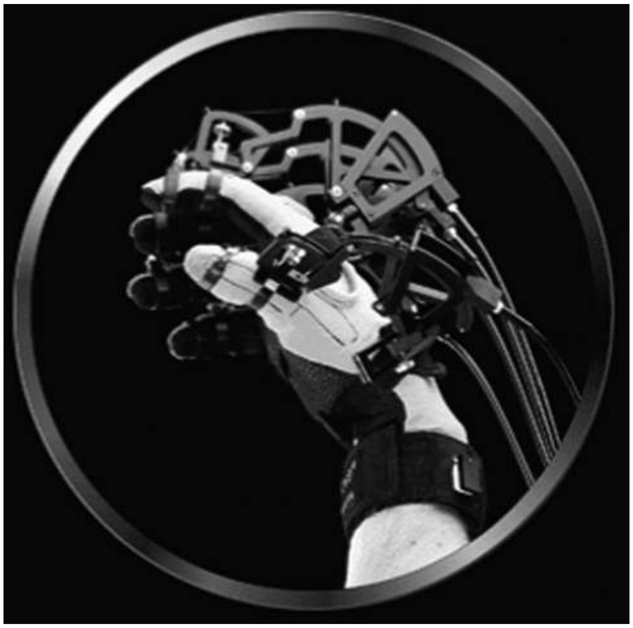

FIGURE 9.2 CyberGrasp, a commercially available exoskeleton in which cables are used to transmit force.

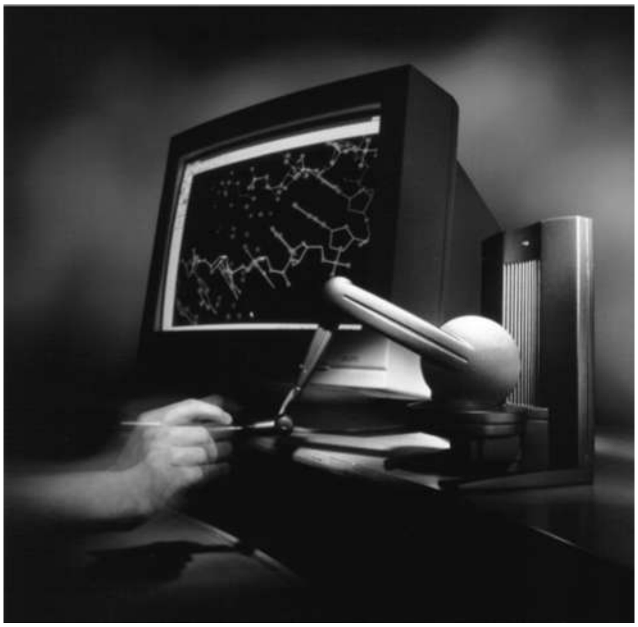

FIGURE 9.3 PHANToM, one of the most popular commercially available haptic interfaces.

Lightweight and portable exoskeletons have also been developed. Burdea et al. (1992) used small pneumatic cylinders to apply force to the fingertips. CyberGrasp (Figure 9.2) is a commercially available exoskeleton in which cables are used to transmit force (http://www.vti.com).

9.2.2.2 Tool-Handling-Type Force Display

A tool-handling-type force display is the easiest way to realize force feedback. The configuration of this type of display is similar to that of a joystick. Unlike an exoskeleton, the tool-handling-type force display is free from the need to be fitted to a user's hand. It cannot generate a force between the fingers, but it has practical advantages.

A typical example of this category is the pen-based force display (Iwata 1993). A pen-shaped grip is supported by two pantographs of three degrees of freedom (DOFs) that enables a six-DOF force/torque feedback. Another example of this type of display is the HapticMaster, which was demonstrated at the Edge venue of SIGGRAPH '94. The device has a ball-shaped grip to which six-DOF force/torque is fed back (Iwata 1994). This device employs a parallel mechanism in which a top triangular platform and a base triangular platform are connected by three sets of pantographs. This compact hardware has the ability to carry a large payload.

Massie and Salisbury (1994) developed the PHANToM, which has a three-DOF pantograph. A thimble with a gimbal is connected to the end of the pantograph, which can then apply a three-DOF force to the fingertips. The PHANToM has become one of the most popular commercially available haptic interfaces (Figure 9.3).

9.2.2.3 Object-Oriented-Type Force Display

The object-oriented-type force display is a radical idea for the design of a haptic interface. The device moves or deforms to simulate the shapes of virtual objects. A user of the device can come into physical contact with the virtual object through its surface.

An example of this type of display can be found in the work by Tachi et al. (1994). Their device consists of a shape approximation prop mounted on a manipulator. The position of the fingertip is measured and the prop moves to provide a contact point for the virtual object. McNeely (1993) proposed an idea "robotic graphics," which is similar to Tachi's method. Hirose (Hirota and Hirose 1996) developed a surface display that creates a contact surface using a 4 × 4 linear actuator array. The device simulates an edge or a vertex of a virtual object.

9.2.2.4 Passive Prop

A passive input device equipped with force sensors is a different approach to developing a haptic interface. Murakami and Nakajima (1994) used a flexible prop to manipulate a three-dimensional (3D) virtual object. The force applied by a user is measured and the deformation of the virtual object is determined based on the applied force. Sinclair (1997) developed a force sensor array to measure pressure distribution. These passive devices allow users to interact using their bare fingers. However, these devices have no actuators, so they cannot represent the shape of virtual objects.

9.2.3 Proprioception and Full-Body Haptics

One of the new frontiers of haptic interface development is full-body haptics that includes foot haptics. Forces applied to a whole body play very important roles in locomotion. The most intuitive way to move about the real world is to walk on foot. Locomotion interface is a device that provides the sense of walking while the walker's body is maintained localized in the real world. There are several approaches to realize locomotion interfaces, which are discussed in Sections 9.2.3.1 through 9.2.3.5.

9.2.3.1 Sliding Device

A project named Virtual Perambulator was aimed at developing locomotion interfaces using a specialized sliding device (Iwata and Fujii 1996). The primary object of the first stage was to allow for the changing direction of a walker's feet. Controlling steering bars or joysticks is not as intuitive in this case as in locomotion. The first prototype of the Virtual Perambulator was developed in 1989 (Iwata and Matsuda 1992). Figure 9.4 shows the overall view of the apparatus. A user of the system wears a parachute-like harness and omnidirectional roller skates. The trunk of the walker is fixed to the framework of the system by a harness. An omnidirectional sliding device is used for changing the direction using the feet. A specialized roller skate equipped with four casters was developed, which enabled two-dimensional (2D) motion. The walker could freely move his or her feet in any direction. Motion of the feet was measured by an ultrasonic range detector. From the result of this measurement, an image of the virtual space was displayed in the head-mounted display corresponding with the motion of the walker. The direction of locomotion in virtual space was determined according to the direction of the walker's step.

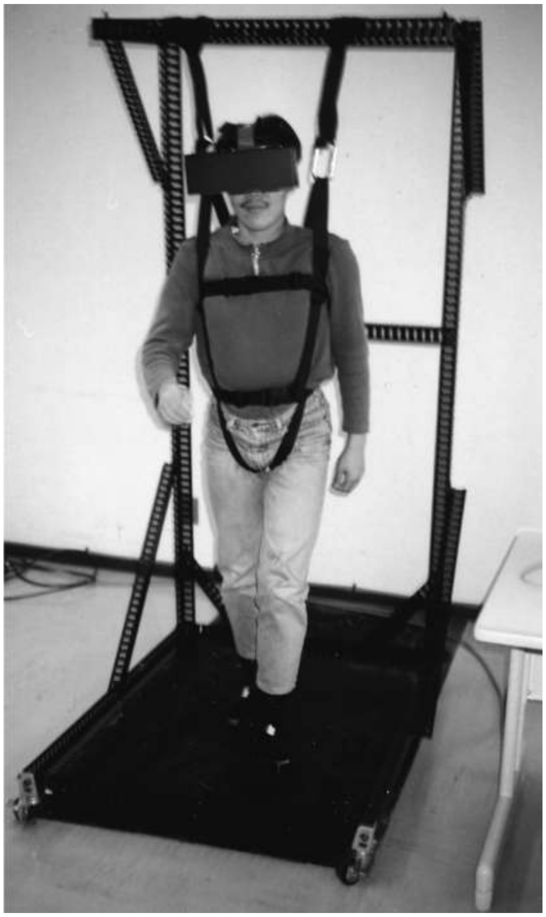

FIGURE 9.4 The first prototype of Virtual Perambulator.

9.2.3.2 Treadmill

A simple device for virtual walking is a treadmill, ordinarily used for maintaining physical fitness. An application of this device to virtual building simulation was developed at the University of North Carolina (UNC) (Brooks 1986). The treadmill has a steering bar similar to that of a bicycle. A treadmill equipped with a series of linear actuators underneath the belt was developed at Advanced Telecommunication Research (ATR) (Noma, Sugihara, and Miyasato 2000). The device is named GSS, which simulates the slope of virtual terrain. The TreadPort developed at the University of Utah is a treadmill that is combined with a large manipulator connected to a walker (Christensen et al. 1998). The manipulator provides gravitational force while the walker is passing a slope. Figure 9.5 shows the overall view of a TreadPort.

The omnidirectional treadmill employs two perpendicular treadmills, one inside the other. Each belt is made from approximately 3400 separate rollers, woven together into a mechanical fabric. Motion of the lower belt is transmitted by the rollers to a walker. This mechanism enables omnidirectional walking (Darken, Cockayne, and Carmein 1997).

9.2.3.3 Footpad

Footpad applied to each foot is an alternative implementation of a locomotion interface. Two large manipulators driven by hydraulic actuators were developed at the University of Utah and applied to a locomotion interface. These manipulators are attached to the feet of a walker. The device is named BiPort (http://www.sarcos.com). These manipulators can present the viscosity of virtual ground. A similar device has been developed at the Cybernet Systems Corporation, Michigan, which uses two three-DOF motion platforms for the feet (Poston et al. 1997). These devices, however, have not been evaluated or applied to virtual environments.

9.2.3.4 Pedaling Device

In the battlefield simulator of the NPSNET project, a unicycle-like pedaling device was used for locomotion in a

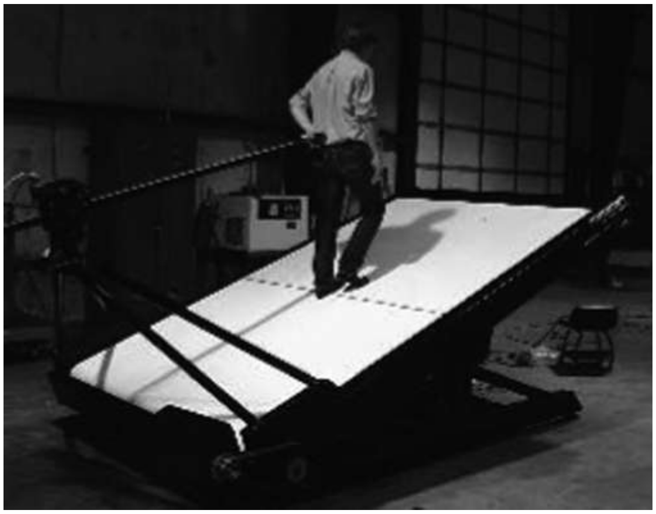

FIGURE 9.5 Overall view of a TreadPort.

virtual battlefield (Prat et al. 1994). A player of the system changes direction by twisting his or her waist.

The OSIRIS, a simulator of night-vision battle, utilizes a stair stepper device (Lorenzo et al. 1995). A player of the system changes direction by controlling the joystick or twisting his or her waist.

9.2.3.5 Gesture Recognition of Walking

Slater et al. (1994) proposed locomotion in virtual environments by "walking in place." They recognized the gesture of walking using a position sensor and a neural network.

9.2.4 Skin Sensation and Tactile Display

The tactile display that stimulates skin sensation is a well-known technology. It has been applied to communication aids for blind individuals as well as manipulator. A sense of vibration is relatively easy to produce, and a good deal of work has been done using vibration displays (Kontarinis and Howe 1995; Minsky and Lederman 1997). The micropin array is also used for tactile displays. Such a device enables the provision of a teletaction and communication aid for blind individuals (Moy, Wagner, and Fearing 2000; Kawai and Tomita 2000). It has the ability to convey texture or 2D geometry (Burdea 1996).

A micropin array looks similar to an object-oriented-type force display, but it can only create the sensation of skin. The stroke distance of each pin is short, so the user cannot feel the 3D shape of a virtual object directly. The major role of a tactile display is to convey a sense of fine texture of an object's surface. Latest research on tactile displays focuses on selective stimulation of mechanoreceptors of the skin. As mentioned in Section 9.2.1, there are four types of mechanoreceptors in the skin: (1) Merkel disks, (2) Ruffini capsules, (3) Meissner corpuscles, and (4) Pacinian corpuscles. By stimulating these receptors selectively, various tactile sensations such as roughness or slip can be presented. Micro–air jets (Asamura, Yokoyama, and Shinoda 1999) and microelectrode arrays (Kajimoto et al. 1999) are used for selective stimulation. Notes 9.3–9.5 describe four types of finger/hand haptics.

9.3 TECHNOLOGIES IN FINGER/HAND HAPTICS: MANIPULATOR

9.3.1 Exoskeleton

Exoskeleton is one of the typical forms of haptic interfaces. Figure 9.6 shows the detailed view of an exoskeleton that is introduced in Section 9.2.2.1 (Iwata 1990).

A force sensation contains six-dimensional information, comprising 3D force and 3D torque. The core element of a force display is a six-DOF parallel manipulator. The typical design feature of parallel manipulators is an octahedron called "Stewart platform." In this mechanism, a top triangular platform and a base triangular platform are connected by six length-controllable cylinders. This compact hardware has the ability to carry a large payload. The structure, however, has some practical disadvantages with respect to its small working volume and its lack of backdrivability (reduction of friction) of the mechanism. In our system, three sets of parallelogram linkages (pantograph) are employed instead of linear actuators. Each pantograph is driven by two direct current (DC) motors. Each motor is powered by a pulse-width-modulation (PWM) amplifier. The top end of the pantograph is connected with a vertex of the top platform by a spherical joint. This mechanical configuration has the same advantages as an octahedron mechanism. The pantograph mechanism improves the working volume and backdrivability of the parallel manipulator. The inertia of moving parts of the manipulator is so small that compensation is not needed.

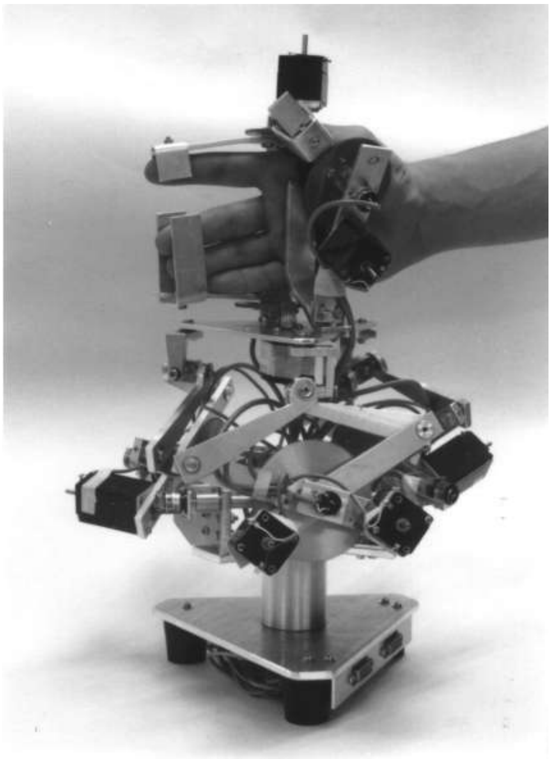

FIGURE 9.6 Mechanism of a desktop force display.

The working space of the center of the top platform is a spherical volume whose diameter is approximately 30 cm. Each joint angle of the manipulator is measured by potentiometers. Linearity of the potentiometers used is 1%. The maximum payload of the manipulator is 2.3 kg, which is more than that of a typical human hand.

The top platform of the parallel manipulator is fixed on the palm of the operator by a U-shaped attachment, which enables the operator to move his or her hand and fingers independently. Three actuators are set coaxially with the first joint of the thumb, forefinger, and middle finger of the operator. The last three fingers work together. It is noted that DC servomotors are employed for each actuator.

9.3.2 Tool-Handling-Type Haptic Interface

Users of exoskeletons feel troublesome when they put on or off these devices. This disadvantage obstructs the practical

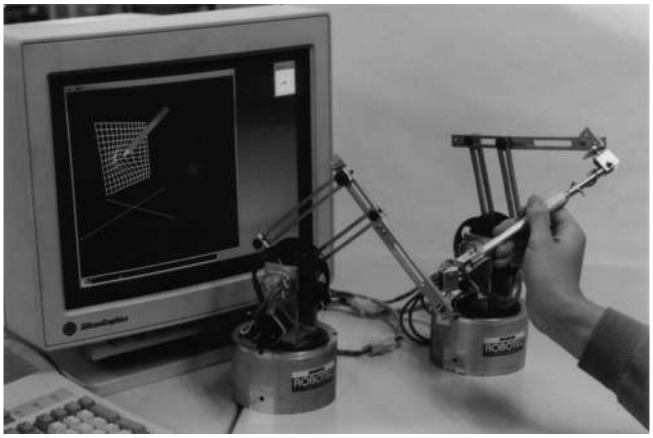

FIGURE 9.7 Pen-based force display.

use of force displays. Tool-handling-type is a method of implementation of force display without using a glovelike device. A pen-based force display is proposed as an alternative device (Iwata 1993). A six-DOF force reflective master manipulator, which has pen-shaped grip, was developed. Users are familiar with a pen in their everyday life. Most of the human intellectual work is done with a pen. People use spatulas or rakes for modeling solid objects. These devices have stick-shaped grips similar to that of a pen. In this aspect, a pen-based force display is easily applied to the design of 3D shapes.

Human hand has the ability of six-DOF motion in 3D space. In case a six-DOF master manipulator is built using serial joints, each joint must support the weight of its upper joints. These characteristics result in large hardware for the manipulator. We use parallel mechanism in order to reduce the size and weight of a manipulator. The pen-based force display employs two three-DOF manipulators. Both ends of the pen are connected to these manipulators. The force display has a total of six DOFs. A three-DOF force and a three-DOF torque are applied at the pen. An overall view of the force display is shown in Figure 9.7. Each three-DOF manipulator is composed of pantograph links. By this mechanism, the pen is kept free from the weight of the actuators.

Figure 9.8 shows the mechanical configuration of the force display. Joints MA1, MA2, MA3, MB1, MB2, and MB3 are equipped with DC motors and potentiometers. Other joints move passively. The positions of joints A and B are measured by potentiometers. A 3D force vector is applied at the joints A and B. Joint A determines position of the pen point, and joint B determines orientation of the pen. The working space of the pen point is a part of a spherical volume whose diameter is 44 cm. The rotational angle around the axis of the pen is determined by the distance between the joints A and B. A screw-motion mechanism converts rotational motion of the pen into translation along the distance between joints A and B.

Applied force and torque on the pen is generated by a combination of forces at the points A and B. In case these forces have the same direction, translational force is applied to the user's hand. If the directions of the forces are reverse to each other, a torque around the yaw axis or the pitch axis is generated. If two forces are opposite to each other, a torque around the roll axis is generated by the screw-motion mechanism.

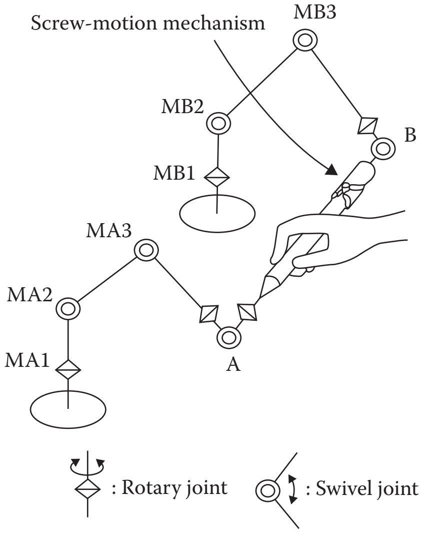

FIGURE 9.8 Mechanical configuration of a pen-based force display.

9.4 TECHNOLOGIES IN FINGER/HAND HAPTICS: OBJECT-ORIENTED-TYPE HAPTIC INTERFACE

9.4.1 Basic Idea of FEELEX

The author demonstrated haptic interfaces to a number of people and found that some of them were unable to fully experience virtual objects through the medium of synthesized haptic sensation. There seem to be two reasons for this phenomenon: First, these haptic interfaces only allow users to touch the virtual object at a single point or at a group of points. These contact points are not spatially continuous due to the hardware configuration of the haptic interfaces. The user feels a reaction force through a grip or a thimble. Exoskeletons provide more contact points, but these are achieved by using Velcro bands attached to a specific part of the user's fingers, which are not continuous. Therefore, these devices cannot recreate a natural interaction sensation when compared with manual manipulation in the real world.

The second reason why some people fail to perceive the sensation is related to a combination of visual and haptic displays. A visual image is usually combined with a haptic interface by using a conventional cathode-ray tube or projection screen. Thus, the user receives visual and haptic sensations through different displays and has to integrate the visual and haptic images in his or her brain. Some users, especially elderly people, face difficulty in this integration process.

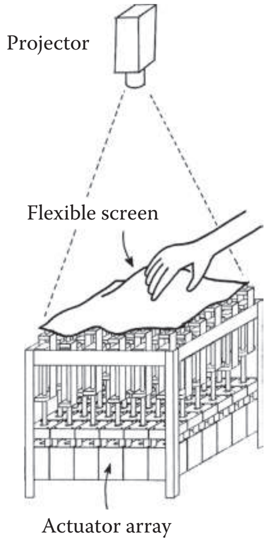

FIGURE 9.9 Basic design of FEELEX.

Considering these problems, new interface devices have been developed. The project is named FEELEX. The word FEELEX is derived from a conjunction of "feel" and "flex." The major goals of this project are as follows:

- To provide a spatially continuous surface that enables users to feel virtual objects using any part of the fingers or even the whole palm
- To provide visual and haptic sensations simultaneously using a single device that does not oblige a user to wear any extra apparatus

A new configuration of visual/haptic display was designed to achieve these goals. Figure 9.9 illustrates the basic concept of the FEELEX. The device comprises a flexible screen, an array of actuators, and a projector. The flexible screen is deformed by the actuators in order to simulate the shape of virtual objects. An image of the virtual objects is projected onto the surface of the flexible screen. Deformation of the screen converts the 2D image from the projector into a solid image. This configuration enables users to touch the image directly using any part of their hand. The actuators are equipped with force sensors to measure the force applied by a user. The hardness of a virtual object is determined by the relationship between the measured force and its position on the screen. If the virtual object is soft, a large deformation is caused by a small applied force.

9.4.2 Design Specification and Implementation of Prototypes

9.4.2.1 The FEELEX 1

The FEELEX 1, developed in 1997, was designed to enable double-handed interaction using the whole of the palm. Therefore, the optimum size of the screen was determined to be 24 cm × 24 cm. The screen is connected to a linear actuator array that deforms its shape. Each linear actuator comprises a screw mechanism driven by a DC motor. The screw mechanism converts the rotation of an axis of the motor to the linear motion of a rod. The motor must generate both motion and a reaction force on the screen. The diameter of the smallest motor that can drive the screen is 4 cm. Therefore, a 6 × 6 linear actuator array can be set under the screen. The deformable screen is made of a rubber plate and a white nylon cloth. The thickness of the rubber plate is 3 mm. Figure 9.10 shows an overall view of the device.

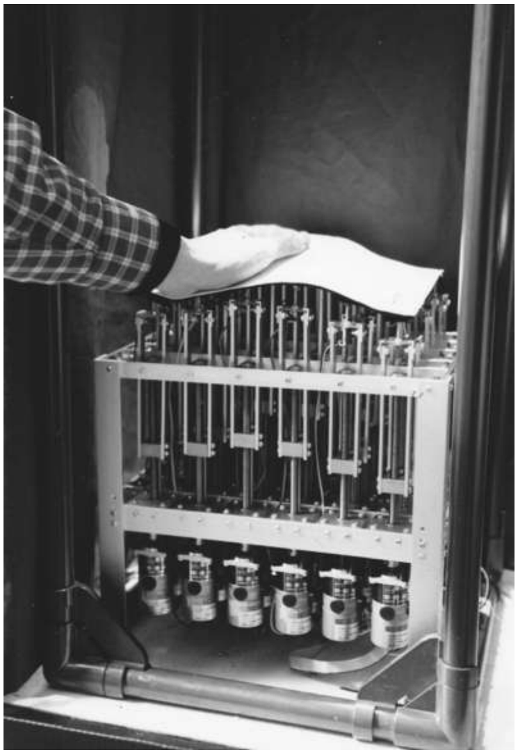

FIGURE 9.10 Overall view of FEELEX 1.

The screw mechanism of the linear actuator has a self-lock function that maintains its position when the motor power is off. A hard virtual wall is difficult to simulate using tool-handling-type force displays. Considerable motor power is required to generate the reaction force from the virtual wall, which often leads to uncomfortable vibrations. The screw mechanism is free from this problem. A soft wall can be represented by the computer-controlled motion of linear actuators based on the data from the force sensors. A force sensor is set at the top of each linear actuator. Two strain gauges are used as a force sensor. The strain gauge detects small displacements of the top end of the linear actuator caused by the force applied by the user. The position of the top end of the linear actuator is measured by an optical encoder connected to the axis of the DC motor. The maximum stroke of the linear actuator is 80 mm, and the maximum speed is 100 mm/s.

The system is controlled via a personal computer. The DC motors are interfaced by a parallel input/output unit, and the force sensors are interfaced by an alternating current (AC) to DC (A/D) converter unit. The force sensors provide interaction with the graphics. Position and strength of the force applied by the user are detected by a 6 × 6 sensor array. The graphics projected onto the flexible screen are changed according to the measured force.

9.4.2.2 The FEELEX 2

The FEELEX 2 is designed to improve the resolution of the haptic surface. In order to determine the resolution of the linear actuators, we considered the situation in which a medical doctor palpates a patient. The results of interviewing several medical doctors proved that they usually recognized a tumor using their index finger, middle finger, and third finger. The size of a tumor is perceived by comparing it to the width of their fingers, that is, two-finger large or three-finger large tumors. Thus, the distance between the axis of the linear actuators should be smaller than the width of a finger. Considering the aforementioned condition, the distance is set to 8 mm. This 8-mm resolution enables the user to hit at least one actuator when he or she touches any arbitrary position on the screen. The size of the screen is 50 mm × 50 mm, which allows the user to touch the surface using three fingers.

In order to realize 8-mm resolution, a piston–crank mechanism is employed for the linear actuator. The size of the motor is much larger than 8 mm, so the motor should be placed at a position offset from the rod. The piston–crank mechanism can easily achieve this offset position. Figure 9.11 illustrates the mechanical configuration of a linear actuator. A servomotor from a radio-controlled car is selected as the actuator. The rotation of the axis of the servomotor is converted to the linear motion of the rod by a crankshaft and a linkage. The stroke of the rod is 18 mm, and the maximum speed is 250 mm/s. The maximum torque of the servomotor is 3.2 kg · cm, which applies a 1.1 kg force at the top of each rod. This force is sufficient for palpation using fingers.

The flexible screen is supported by 23 rods, and the servomotors are set remotely from the rods. Figure 9.12 shows an overall view of FEELEX 2. The 23 separate sets of piston–crank mechanisms can be seen in the figure.

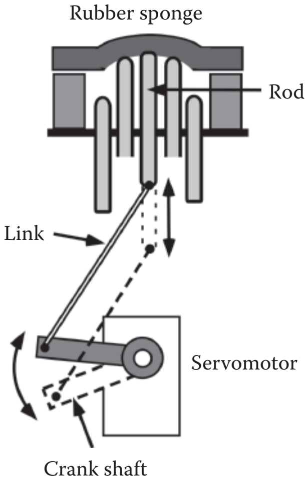

FIGURE 9.11 The piston–crank mechanism.

Figure 9.13 shows the top end of the rods. The photograph was taken when the flexible screen was off. The diameter of each rod is 6 mm. A strain gauge cannot be put on top of the rod because of its small size. Thus, the electric current going to each servomotor is measured to sense the force. The servomotor generates a force to maintain the position of the crankshaft. When a user applies a force to the rod, the electric current on the motor increases to balance the force applied. The relationship between the applied force and the electric current is measured. The force applied at the top of the rods is calculated using data from the electric current sensor. The resolution of the force-sensing capability is 40 gf.

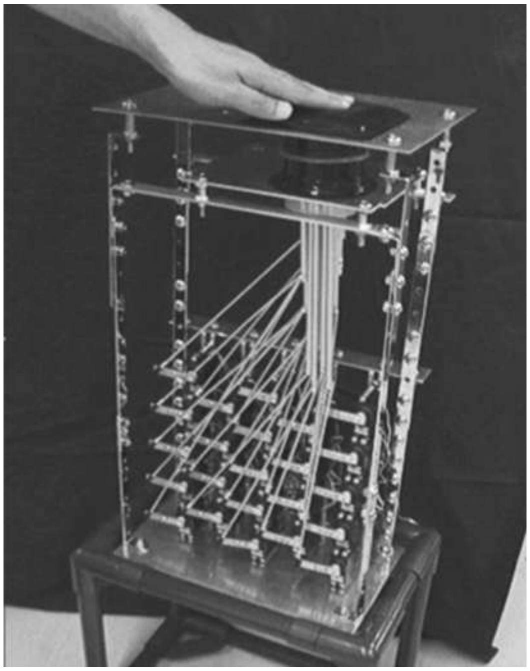

FIGURE 9.12 Overall view of FEELEX 2.

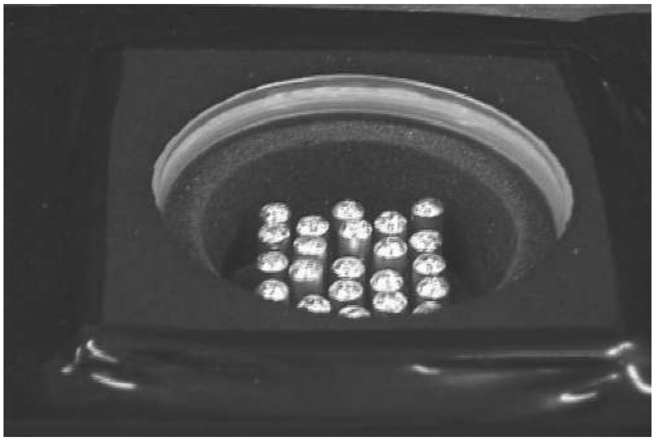

FIGURE 9.13 Top end of the rods conforming haptic surface.

9.4.3 Characteristics of FEELEX

The performance of existing haptic interfaces is usually represented by the dynamic range of force, impedance, inertia, friction, and so on. However, these parameters are crucial only while the device is attached to a finger or the hand. In the case of a tool-handling-type haptic interface or the exoskeleton, the devices move with the hand even though the user does not touch the virtual objects. Therefore, inertia or friction degrades the usability and dynamic range of force determines the quality of the virtual surface. On the other hand, FEELEX is entirely separate from the user's hand; so its performance is determined by the resolution and speed of the actuators. The resolution of the actuator corresponds to the smoothness of the surface, and its speed determines the motion of the virtual object. Compared with FEELEX 1, FEELEX 2 has improved resolution and motion speed. Each actuator of FEELEX 2 has a stroke rate of up to 7 Hz, which can simulate the motion of a very fast virtual object. The rod pushes the rubber sponge so that the user feels as if the object is pulsating. It is of interest that 7 Hz is much faster than the human pulse rate.

The major advantage of FEELEX is that it allows natural interaction using only the bare hand. In SIGGRAPH '98, 1992 subjects spontaneously enjoyed the haptic experience. One of the subject contents of the FEELEX 1 system, known as Anomalocaris, was selected as a long-term exhibition at the Ars Electronica Center (Linz, Austria). The exhibition has been popular among visitors, especially children.

Another advantage of FEELEX is safety. The user of FEELEX does not wear any special equipment while the interaction is taking place. The exoskeleton and tool-handling-type force displays have control problems in their contact surface for the virtual objects. Vibration or unwanted forces can be generated back to the user, which is sometimes dangerous. The contact surface of the FEELEX system is physically generated, so it is free from such control problems.

The major disadvantage of FEELEX is the degree of difficulty present in its implementation. It requires a large number of actuators that must be controlled simultaneously. The drive mechanism of the actuator must be robust enough for rough manipulation. Since FEELEX provides a feeling of natural interaction, some of the users apply large forces. Our exhibit at the Ars Electronica Center suffered from an overload of actuators.

Another disadvantage of FEELEX is its limitation in presenting the shape of objects that can be displayed. Current prototypes cannot present a sharp edge on a virtual object. Furthermore, the linear actuator array can simulate only the front face of objects. Some of the participants of the Anomalocaris demonstration wanted to touch the rear of the creature, but an entirely new mechanism would be required in order to also simulate the reverse side of an object.

9.4.4 Volumetric Object-Oriented-Type Haptic Interface

9.4.4.1 Basic Design of Volflex

In order to present the side or backside of a virtual object, we designed a volumetric object-oriented haptic interface. Volflex is a new haptic interface that provides the user a physical 3D surface for interaction. The device comprises a group of air balloons. The balloons fill the interaction surface (Figure 9.14). They are arranged in a body-centered cubic lattice. A tube is connected to each balloon. Volume of each balloon is controlled by an air cylinder. The tubes are connected to each other by springs. This mechanical flexibility enables arbitrary shape of the interaction surface. Each air cylinder is equipped with a pressure sensor that detects the force applied by a user. According to the pressure data, the device is programmed to perform like clay (Figure 9.15). Unlike real clay, Volflex allows a user to "undo" an operation.

A projector is set above the balloons. The image is projected on the surface of the device, not on the user's hand. We developed a mechanical rotary shutter that separates the projector and the camera. The camera captures the user's hand, which is eliminated from the projected image.

9.4.4.2 Virtual Clay Volflex

Virtual clay is one of the ultimate goals of the interactive technique of 3D graphics. Digital tools for 2D paint comprise mature technology. On the other hand, tools for 3D shape manipulation are currently in a preliminary stage of development. Shape design of 3D objects is one of the major application areas of haptic interfaces. Shape design of 3D objects requires good sensation of haptics.

Volflex provides an effective interface device for the manipulation of virtual clay by using a lattice of air balloons.

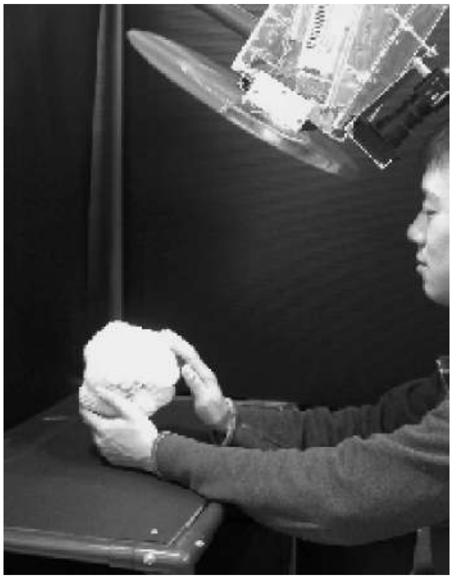

FIGURE 9.14 Overall view of Volflex.

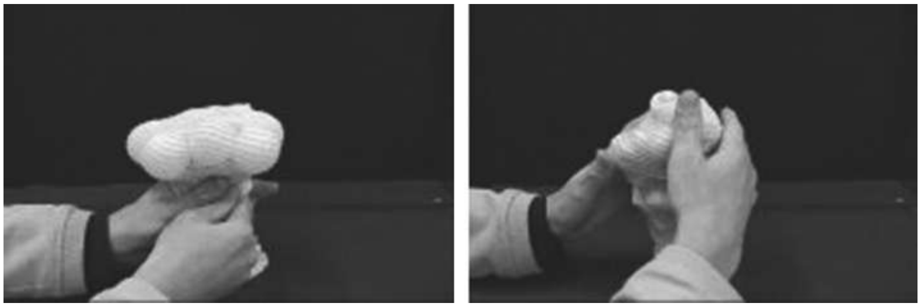

FIGURE 9.15 Examples of deformation.

Two-dimensional paint tools are popular and digital pictures are easy to draw. Volflex is a new digital tool for making 3D shapes. It has the potential to bring about a revolution in methods of industrial design. Designers use their palms or the joints of their fingers to deform a clay model when carrying out rough design tasks. Volflex has the ability to support such natural manipulations.

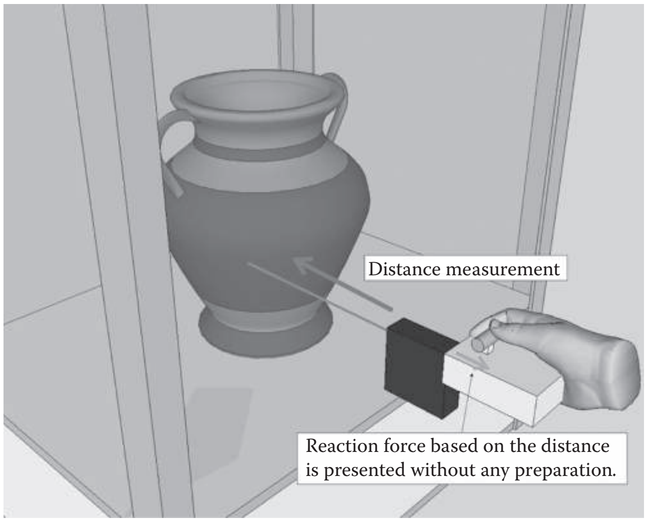
Volflex is not only a tool for 3D shape designing but also an interactive artwork in itself. A physical property of a virtual object can be designed by programming the controllers of the balloons. It is also possible to design a projected image. The combination of haptic and visual displays provides a new platform for interactive sculpture.

9.5 TECHNOLOGIES IN FINGER/HAND HAPTICS: REMOTE HAPTICS

In the real world, we usually touch real objects that are placed on a reachable area and we can notice their properties by touching them. However, we cannot touch real objects that are placed on an untouchable area. In daily life, there are many untouchable objects such as objects in the showcase of a museum. However, if we can touch them we can learn many things from such valuable objects. Therefore, the objective of this study is to realize a feeling of touching untouchable objects by using a haptic interface that has no need to premeasure their shapes, although we do not touch them directly.

Figure 9.16 illustrates the basic method of remote haptics. As a real-time shape measurement device, a laser range finder (LRF) is used. It can measure the distance to a front object in less than 1 millisecond. Since laser light can pass through glass, the LRF can measure the distance to an object even when the object is placed beyond a glass. Therefore, we can measure the distance to an untouchable object without there being any prerecorded data.

For using a haptic interface at a museum, the interface should be a mobile one. Two types of haptic interfaces can be considered for this purpose: (1) One is a wearable type of haptic interface and (2) the other is a handheld type. It is difficult to attach and remove a wearable type of haptic interface, and if it is attached for a long time the user will get fatigued. On the other hand, handheld types of haptic interfaces are easier to use, since they are easy to attach and remove when the user gets fatigued. Hence, handheld-type haptic interfaces can be applied for this purpose. In addition, force feedback for the whole hand or multifinger is not practical since the apparatus is complex and heavy. As a first step, a one-DOF haptic interface was used in our study. For a haptic rendering, the position of a virtual object is determined based on the distance data from an LRF. When a user's finger penetrates the virtual object, reaction force, which is proportional to penetration depth from the surface of the virtual object, is applied to the user's finger. In this case, when the user presses the interface to a glass case and moves it freely on the surface of the glass, the user can feel the reaction force, which is proportional to the "depth information" from the LRF. Then the user can reconstruct the shape information of a given object by integrating the depth information from the interface and the "position sense of user's hand." Figure 9.17 shows the overall view of the system. This system can be applied for educational purposes in understanding many characteristics of valuable exhibits in museums and for quality inspection of engineering products.



Distance measurement
Reaction force based on the distance is presented without any preparation.

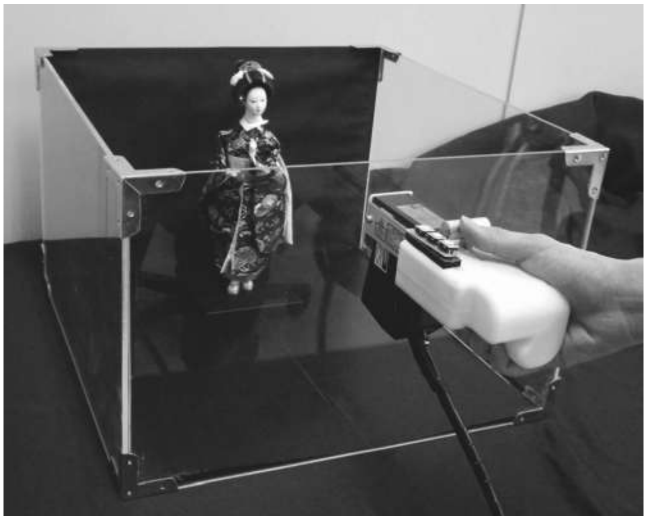

FIGURE 9.17 Overall view of the remote haptics system.

9.6 TECHNOLOGIES IN FULL-BODY HAPTICS

9.6.1 Treadmill-Based Locomotion Interface

9.6.1.1 Basic Design of the Torus Treadmill

A key principle of treadmill-based locomotion interfaces is to make the floor move in a direction opposite to that of the walker. The motion of the floor cancels the displacement of a walker in the real world. The major challenge of a treadmill-based locomotion interface is to allow the walker to change his or her direction. An omnidirectional active floor enables a virtually infinite area. In order to realize an infinite walking area, geometric configuration of an active floor must be chosen. A closed surface driven by actuators has the ability to create an unlimited floor. The following requirements for implementing a closed surface must be considered:

- The walker and the actuators must be placed outside the surface.
- The walking area must be a plane surface.
- The surface must be made of a material that stretches very little.

A closed surface in general is a surface with holes. If the number of holes is zero, the surface is a sphere. The sphere is the simplest infinite surface. However, the walking area of a sphere is not a plane surface. A very large diameter is required to make the surface plane on a sphere, which restricts the implementation of a locomotion interface.

A closed surface with one hole like a doughnut is called a "torus." A torus can be implemented by a group of belts. These belts make a plane surface for the user to walk on. A closed surface with more than one hole cannot make a plane walking surface. Thus, torus is the only form suitable for a locomotion interface.

9.6.1.2 Mechanism and Performance

The Torus Treadmill is implemented by a group of belts connected to each other. The Torus Treadmill is realized by these belts (Iwata 1999). Figures 9.18 and 9.19 illustrate the basic structure of a Torus Treadmill. The Torus Treadmill employs 12 treadmills. These treadmills move a walker along an *x* direction. The 12 treadmills are connected side by side and driven in a perpendicular direction. This motion moves the walker along a *y* direction.

Figure 9.20 shows the overall view of the apparatus. A total of 12 treadmills are connected to four chains and mounted on four rails. The chain drives the walker along

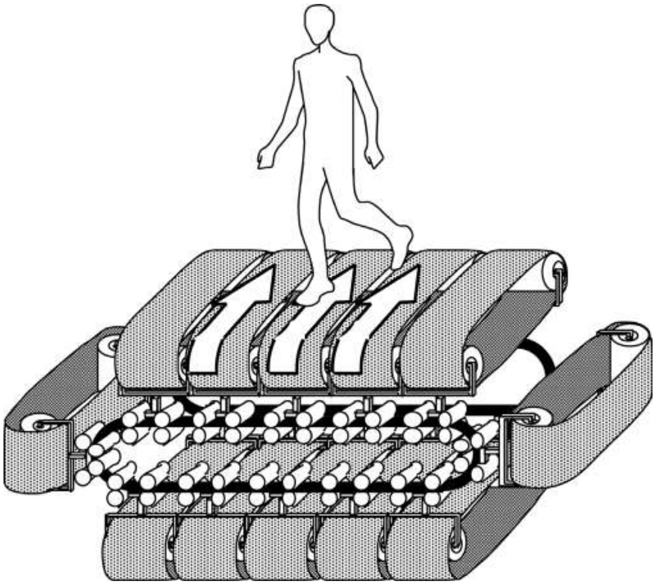

FIGURE 9.18 Structure of a Torus Treadmill (*x* motion).

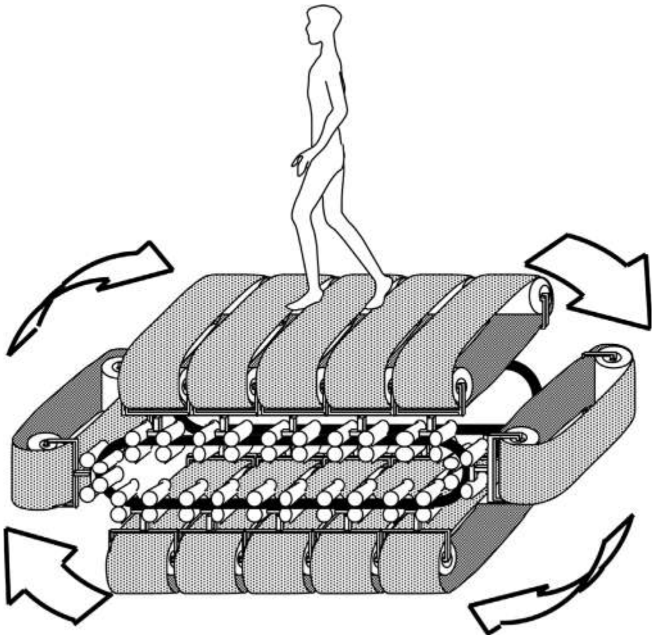

FIGURE 9.19 Structure of a Torus Treadmill (*y* motion).

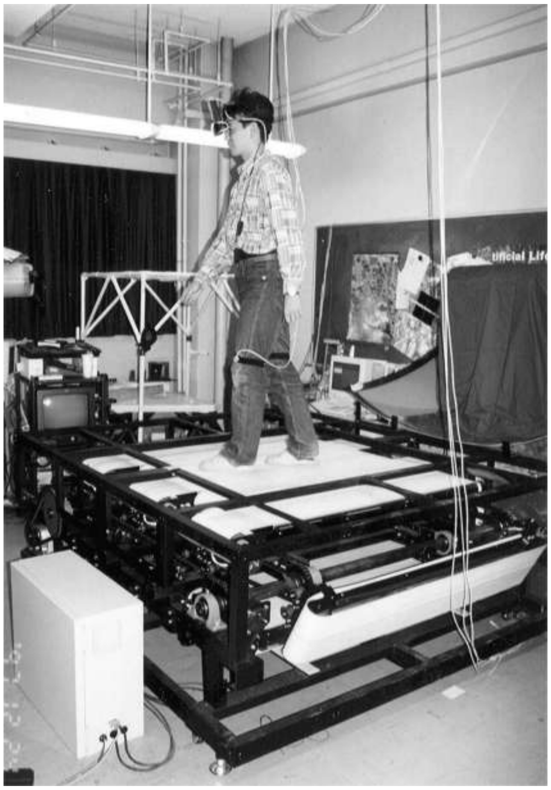

FIGURE 9.20 Overall view of the Torus Treadmill.

the *y* direction. The rail supports the weight of the treadmills and the walker. An AC motor is employed to drive the chains. The power of the motor is 200 W and it is controlled by an inverter. The maximum speed of rotation is 1.2 m/s. The maximum acceleration is 1.0 m/s^2. The deceleration caused by friction is 1.5 m/s^2. Frequency characteristics are limited by a circuit protector of the motor driver. The maximum switching frequency is 0.8 Hz.

Each treadmill is equipped with an AC motor. In order to shorten the length of the treadmill, the motor is put underneath the belt. The power of each motor is 80 W and it is controlled by an inverter. The maximum speed of each treadmill is 1.2 m/s. The maximum acceleration is 0.8 m/s^2. The deceleration caused by friction is 1.0 m/s^2. The width of each belt is 250 mm and the overall walkable area is 1 m × 1 m.

A problem with this mechanical configuration is the gap between the belts in the walking area. In order to minimize the gap, we put a driver unit of each treadmill alternatively. The gap is only 2-mm wide in this design.

9.6.1.3 Control Algorithm of the Torus Treadmill

A scene of the virtual space is generated corresponding to the results of motion tracking of the feet and head of the walker. The motion of the feet and head is measured by a Polhemus FASTRACK. The device measures six-DOF motion. The sampling rate of each point is 20 Hz. A receiver is attached to each knee. We cannot put sensors near the motion floor because a steel frame distorts magnetic field. The length and direction of a step is calculated by the data from those sensors. The user's viewpoint in virtual space moves in accordance with the length and direction of his or her steps.

To keep the walker in the center of the walking area, the Torus Treadmill must be driven in correspondence with the walker. A control algorithm is required to achieve safe and natural walking. From our experience from the Virtual Perambulator project, the walker should not be connected to a harness or mechanical linkages since such devices restrict the motion and inhibit natural walking. The control algorithm of the Torus Treadmill must be safe enough to allow removal of the harness from the walker. At the final stage of the Virtual Perambulator project, we succeeded in removing the harness using a hoop frame. The walker can freely walk and turn around in the hoop, which supports the walker's body while he or she slides the feet. We simulated the function of the hoop in the control algorithm of the Torus Treadmill by putting a circular deadzone in the center of the walking area. If the walker steps out of this area, the floor moves in the opposite direction so that the walker is carried back into the deadzone.

9.6.2 Footpad-Based Locomotion Interface

9.6.2.1 Methods of Presentation of Uneven Surfaces

One of the major research issues in the field of locomotion interfaces is the presentation of uneven surfaces. Locomotion interfaces are often applied for the simulation of buildings or urban spaces. Those spaces usually include stairs. A walker should be provided a sense of climbing up or going down these stairs. Some applications of locomotion interfaces, such as training simulators or entertainment facility, rough terrain should be presented.

The presentation of a virtual staircase was tested in the early stage of the Virtual Perambulator project (Iwata and Fujii 1996). A staircase is a typical example of a rough terrain. A string is connected to the roller skate of each foot. The string is pulled by a motor. When the walker climbs up a stair, the forward foot is pulled up. When the walker goes down a stair, the backward foot is pulled up. However, this method was not successful because of instability.

Later, a six-DOF motion platform was applied to the final version of the Virtual Perambulator, where a user walked in a hoop frame. The walker stood on the top plate of the motion platform. Pitch and heave motions of the platform were used. When the walker stepped forward to climb up a stair, the pitch angle and vertical position of the floor increased. After finishing the climbing motion, the floor went back to the neutral position. When the walker stepped forward to go down a stair, the pitch angle and vertical position of the floor decreased. This inclination of the floor was intended to present height difference between the feet. The heave motion was intended to simulate vertical acceleration. However, this method failed in simulating the stairs. The major reason was that the floor was flat.

A possible method for creating height difference between the feet is application of two large manipulators. The BiPort is a typical example. A four-DOF manipulator driven by hydraulic actuators is connected to each foot. A major problem of this method involves how the manipulators trace the turning motion of a walker. When the walker turns around, two manipulators interfere with each other.

The Torus Treadmill provides natural turning motion. The walker on the Torus Treadmill can physically turn about on the active floor. Turning motion using the feet makes a major contribution to human spatial recognition performance. Vestibular and proprioceptive feedback is essential to the sense of orientation (Iwata and Yoshida 1999). The Torus Treadmill can be modified for the simulation of uneven surfaces. If we install an array of linear actuators on each treadmill, an uneven floor can be realized by controlling the length of each linear actuator. However, this method is almost impossible to implement, because a very large number of linear actuators are required to cover the surface of the torus-shaped treadmills and the control signal for each actuator must be transmitted wirelessly.

9.6.2.2 Basic Design of the GaitMaster

A new locomotion interface that simulates omnidirectional uneven surfaces has been designed. The device is named GaitMaster. The core elements of the device are two six-DOF motion bases mounted on a turntable. Figure 9.21 illustrates the basic configuration of the GaitMaster.

A walker stands on the top plate of a motion base. Each motion base is controlled to trace the position of the foot. The turntable is controlled to trace the orientation of the walker. The motion of the turntable removes interference between the two motion bases.

The *x* and *y* motions of the motion base traces the horizontal position of the feet and cancel its motion by moving in the opposite direction of the feet. The rotation around the yaw axis traces the horizontal orientation of the feet. The *z* motion traces vertical position of the feet and cancels their motion. The rotation around the roll and pitch axes simulates the inclination of a virtual surface.

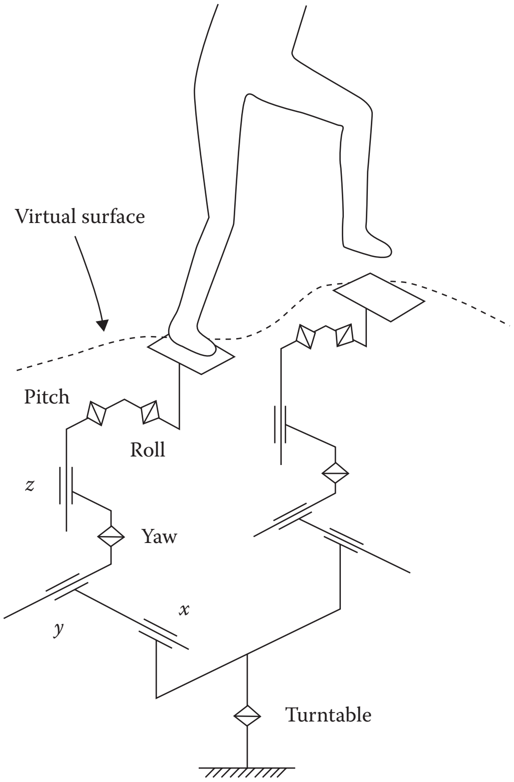

FIGURE 9.21 Basic design of the GaitMaster.

9.6.2.3 Control Algorithm of the GaitMaster

The control algorithm must keep the position of the walker at the neutral position of the GaitMaster. In order to maintain the position, the motion of motion platforms must cancel the motion of the feet. The principle of cancellation is explained in the following four steps:

1. Suppose the right foot of the walker is at the forward position and left foot is at the backward position while walking.
2. When the walker puts his or her left foot forward, the weight of the walker falls on the right foot.
3. The motion platform of the right foot goes backward in accordance with the displacement of the left foot so that the central position of the walker is maintained.
4. The motion platform of the left foot follows the position of the left foot. When the walker finishes stepping forward, the motion platform supports the left foot.

If the walker climbs up or goes down a flight of stairs, a similar procedure can be applied. The vertical motion of the feet is canceled using the same aforementioned principle. The vertical displacement of the forward foot is canceled in accordance with the motion of the backward foot, so that the central position of the walker is maintained at the neutral height. Figure 9.22 illustrates the method of canceling the climbing-up motion.

The turntable rotates so that the two motion platforms can trace the rotational motion of the walker. If the walker changes the direction of walking, the turntable rotates to trace the orientation of the walker. The turntable orientation

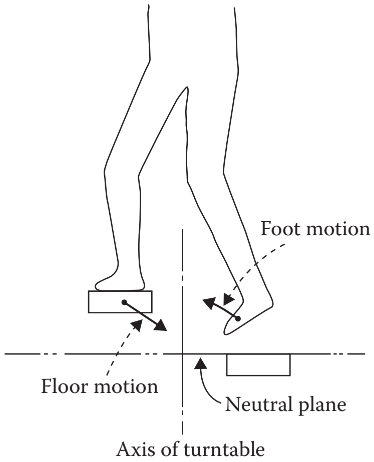

FIGURE 9.22 Method of canceling the climbing-up motion of a walker.

is determined according to the direction of the feet. The turntable rotates so that its orientation is at the middle of the feet. The walker can physically turn around on the GaitMaster using this control algorithm of the turntable.

9.6.2.4 Prototype GaitMaster

Figure 9.23 shows the overall view of the prototype GaitMaster. In order to simplify the mechanism of the motion platform, the surface of the virtual space was defined as sets of plane surfaces. Most of the buildings or urban spaces can be simulated without inclination of the floor. Thus, we can neglect the roll and pitch axes of motion platforms. Each platform of the prototype GaitMaster comprises three linear actuators atop of which a yaw joint is mounted. We disassembled a six-DOF Stewart platform and made two *xyz* stages. Three linear guides are applied to support the orientation of the top plate of the motion platform. The payload of each motion platform is approximately 150 kg. A rotational joint around the yaw axis is mounted on each motion platform. The joint is equipped with a spring that moves the feet to the neutral direction.

A turntable is developed using a large direct drive (DD) motor. The maximum angular velocity is 500°/s. A three-DOF goniometer is connected to each foot. The goniometer measures back-and-forth and up-and-down motion as well as the yaw angle. The control algorithm mentioned in Section 9.6.2.3 was implemented and it succeeded in the presentation of virtual staircases.

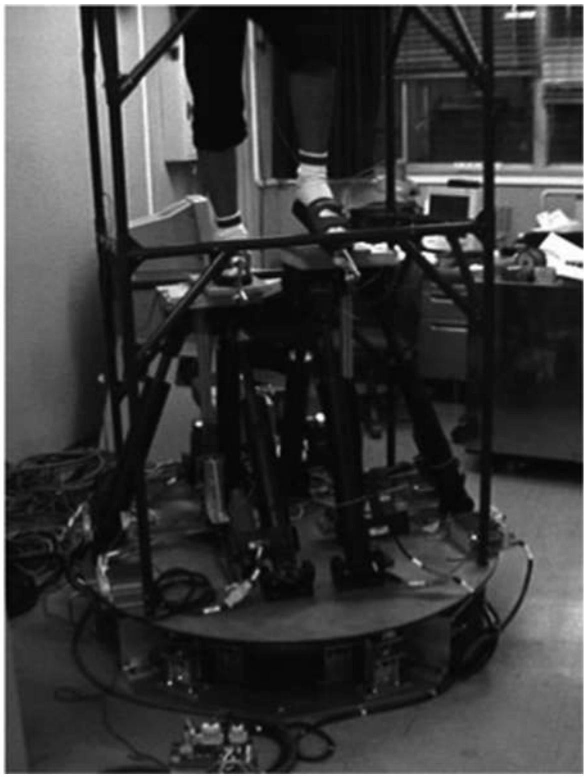

FIGURE 9.23 Overall view of the prototype GaitMaster.

9.6.3 Robot-Tile-Based Locomotion Interface

9.6.3.1 CirculaFloor Project

Locomotion interfaces often require bulky hardware, since they have to carry a user's whole body. Also, the hardware is not easy to reconfigure to improve its performance or to add new functions. Considering these issues, the goals of the CirculaFloor project are as follows:

To develop a compact hardware for the creation of an infinite surface for walking: The major disadvantage of existing locomotion interfaces is the difficulty in installation. We need to solve this problem for a demonstration at SIGGRAPH.

To develop scalable hardware architecture for future improvement of the system: Another disadvantage of existing locomotion interfaces is the difficulty faced when improving the system. We have to design a new hardware architecture that allows us to easily upgrade the actuation mechanism or to add new mechanisms for the creation of uneven surfaces.

In order to achieve these goals, we designed a new configuration for a locomotion interface by using a set of omnidirectional movable tiles. Each tile is equipped with a holonomic mechanism that achieves omnidirectional motion. An infinite surface is simulated by the circulation of movable tiles. The motion of the feet is measured by position sensors. The tile moves opposite to the measured direction of the walker so that the motion of the step is canceled. The position of the walker is fixed in the real world by this computer-controlled motion of the tiles. The circulation of the tiles has the ability to cancel the displacement of the walker in an arbitrary direction. Thus, the walker can freely change his or her direction while walking. Figure 9.24 shows an overall view of CirculaFloor.

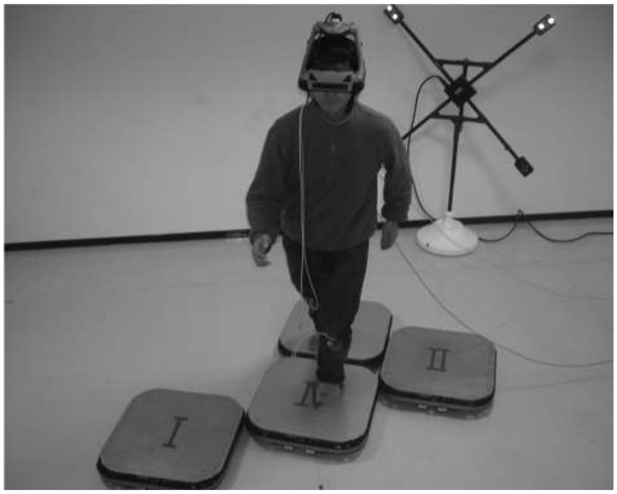

FIGURE 9.24 Overall view of the CirculaFloor project.

The CirculaFloor is a new method that takes advantage of both the treadmill and the footpad. It creates an infinite omnidirectional surface by using a set of movable tiles. The combination of tiles provides a sufficient area for walking and, thus, precision tracing of foot position is not required. It has the potential to create an uneven surface by mounting an up-and-down mechanism on each tile.

9.6.3.2 Method of Creating an Infinite Surface

The current method of circulating movable tiles is designed to satisfy the following conditions:

- Two of the movable tiles are used for pulling back the user to the center of the deadzone.
- The rest of the movable tiles are used to create a new front surface.
- These tiles are moved the shortest distances to the next destination, while they avoid colliding with other tiles.
- The control program allocates all destinations to the tiles, when the tiles reach their destinations.
- The tiles do not rotate corresponding to the walking direction to simplify the algorithm.

According to the aforementioned conditions, the circulation method is varied corresponding to the walking direction. Three modes, "alternating circulation," "unidirectional circulation," and "crossed circulation," are designed corresponding to the direction (Figure 9.25); representative motions of each mode are illustrated in Figures 9.26 through 9.28:

Alternating circulation (Figure 9.26): This mode is adopted for the directions between ±15° and ±75°–105°. The tiles used for creating a new front surface (white-colored tiles in Figure 9.26) move around to the front of the tiles for alternatively pulling back (in Figure 9.24, gray-colored tiles) from the left (path 1)/right (path 2) sides.

Unidirectional circulation (Figure 9.27): This mode is adopted for the directions between ±15°–30° and ±60°–75°. The tiles used for creating a new front surface move around to the right/left front of the tiles for pulling back with a unidirectional circulation.

Crossed circulation (Figure 9.28): This mode is adopted for directions of ±30°–60°. The tiles used for creating a new front surface move around to the left/right front (path 1) or the left/right sides (path 2) of the tiles for pulling back.

When a user of the CirculaFloor switches his or her walking direction, the control program calculates the nearest phase of each tile by using a template-matching technique corresponding to the new direction. Then the tiles take the shortest way to their destinations.

9.7 APPLICATION AREAS FOR HAPTIC INTERFACE

9.7.1 Application Areas for Finger/Hand Haptics

9.7.1.1 Medicine

Medical applications for haptic interfaces are currently growing rapidly. Various surgical simulators have been developed using tool-handling-type force displays. We developed a simulator for laparoscopic surgery using the HapticMaster. Simulator software using PHANToM are commercially available.

Palpation is typically used in medical examinations. The FEELEX 2 is designed to be used as a palpation simulator. If we display a virtual tumor based on a computed tomography or magnetic resonance imaging image, a medical doctor can palpate the internal organs before surgery; this technique can be also applied to telemedicine. Connecting two FEELEXs together via a communication line would allow a doctor to palpate a patient remotely.

9.7.1.2 Three-Dimensional Shape Modeling

The design of 3D shapes definitely requires haptic feedback. A typical application of the tool-handling-type force display is in 3D-shape modeling. One of the most popular applications of the PHANToM system is as a modeling tool. Such a tool-handling-type force display allows a user to contact at a point, and point contact manipulation is most suited for precision modeling tasks. However, it is not effective when the modeling task requires access to the whole shape. Designers use their palm or the joints of their fingers to deform a clay model when carrying out rough design tasks. The FEELEX has the ability to support such natural manipulation.

9.7.1.3 Haptic User Interface

Today, touch screens are widely used in automatic teller machines, ticketing machines, information kiosks, and so on. A touch screen enables an intuitive user interface, although it lacks haptic feedback. Users can see virtual buttons, although they cannot feel them. This is a serious problem for a blind person. The FEELEX provides a barrier-free solution to the touch-screen-based user interface. Figure 9.13 shows an example of a haptic touch screen using FEELEX 1.

9.7.1.4 Art

Interactive art may be one of the best applications of the FEELEX system. As we discussed in Section 9.4.5, the Anomalocaris has been exhibited at a museum in Austria. It succeeded in evoking haptic interaction with many visitors. The FEELEX can be used for interactive sculptures. Although visitors are usually prohibited from touching physical sculptures, they cannot only touch sculptures based around FEELEX but also deform them.

9.7.2 Application Areas for Locomotion Interfaces

As a serious application of our locomotion interface, we are currently working with the Ship Research Laboratory to develop an "evacuation simulator" (Yamao et al. 1996). The Ship Research Laboratory is a national research institute that belongs to the ministry of transportation of Japan. Analysis of evacuation of passengers during maritime accidents is very important for ship safety. However, it is impossible to carry out experiments with human subjects during an actual disaster. Therefore, researchers introduced virtual reality tools for simulating a disaster in order to analyze the evacuation of passengers. They built a virtual ship that models the generation of smoke and the inclination of the vessel. Experiments of evacuation are carried out for constructing a mathematical model of passengers' behavior during disaster. The Torus Treadmill will be effective in such experiments.

Locomotion by walking motion is intuitive and is inevitable in studies on human behavior in virtual environments. We are applying the system to conduct research on human model of evacuation in maritime accidents. The GaitMaster can be applied to areas other than the ones for Torus Treadmill. Its application may include rehabilitation of walking or simulators for mountain climbing.

9.8 CONCLUSION AND FUTURE PROSPECTS

This chapter describes major topics under the field of haptic interfaces. A number of methods have been proposed to implement haptic interfaces. Future work in this research field will include the two issues discussed in Sections 9.8.1 and 9.8.2.

9.8.1 Safety Issues

Safety of users is an important consideration in haptic interface development. Inadequate control of actuators may injure the user. The exoskeleton and tool-handling-type force displays have control problems in their contact surface for virtual objects. Vibrations or unwanted forces can be generated and transmitted back to the user, which are sometimes dangerous. One of the major advantages of FEELEX is its safety. The user of FEELEX does not wear any special equipment while the interaction is taking place. The contact surface of FEELEX is physically generated, so it is free from control problems.

Locomotion interfaces pose much more important safety issues. The system supports the whole body of the user so that inadequate control causes major damage to the user. Specialized hardware for maintaining the safety of the walker must be developed.

9.8.2 Psychology in Haptics

There have been many findings regarding haptic sensation. Most of these are related to skin sensation, and research activities on muscle sensation are very few in number. Among these, Lederman and Klatzky's work (1987) is closely related to the design of force displays. Their latest work involves spatially distributed forces (Lederman and Klatzky 1999). They also performed an experiment involving palpation. The subjects were asked to find a steel ball placed underneath a foam rubber cover. The results showed that steel balls smaller than 8 mm in diameter decreased the score. This finding supports our specification for FEELEX 2 in which distance between the rods is 8 mm. This kind of psychological studies will support future development of haptic interfaces.

Haptics is indispensable for human interaction in the real world. However, haptics is not commonly used in the field of HCI. Although there are several commercially available haptic interfaces, they are expensive and limited in their function. Image display has a history spanning over 100 years. Today, image displays, such as television displays or movies, are used in everyday life. On the other hand, haptic interfaces have only a 10-year-old history. There are hazards to overcome before the popular use of haptic interfaces can become a reality. However, haptic interface forms a new frontier of media technology and it will definitly contribute to the betterment of human life.

10 Nonspeech Auditory and Crossmodal Output

Eve Hoggan and Stephen Brewster

CONTENTS

10.1 INTRODUCTION AND A BRIEF HISTORY OF NONSPEECH SOUND AND TACTILE FEEDBACK IN HUMAN–COMPUTER INTERACTION

Our senses of hearing and touch are very powerful and can convey a wealth of information. Sound gives us a continuous, holistic contact with our environment and what is going on around us. Nonspeech sounds (such as music, environmental sounds, or sound effects) give us different types of information to those provided by speech; they can be more general and ambient where speech is precise and requires more focus. Nonspeech sounds complement speech in the same way as visual icons complement text. For example, icons can present information in a small amount of space compared with text, whereas nonspeech sounds can present information in a small amount of time compared with speech.

Similarly, our sense of touch can also provide us with a vast amount of information. Geldard (1960) wrote: "for some kinds of messages the skin offers a valuable supplement to ears and eyes" (p. 1583). The skin offers a large display space, which can be used to display information (Geldard 1960). As the skin is often less engaged in other tasks than the eyes or ears, it is always ready to receive information (van Veen and van Erp 2000). Using the sense of touch enables subtle and private communication unlike sound.

The combination of visual, tactile, and auditory feedback at the user interface is a powerful tool for interaction. In our everyday life, these primary senses combine to give complementary information about the world. Blattner and Dannenberg (1992) discuss some of the advantages of using this approach in multimedia or multimodal computer systems: "In our interaction with the world around us, we use many senses. Through each sense, we interpret the external world using representations and organizations to accommodate that use. The senses enhance each other in various ways, adding synergies or further informational dimensions" (p. 5). These advantages can be brought to the multimodal (or crossmodal) human–computer interface by the addition of nonspeech auditory output with tactile feedback to standard graphical displays (see Chapter 18 for more on multimodal interaction). While directing our visual attention to one task, for example, while editing a document, we can still monitor the state of other tasks on our machine using sound and touch. Currently, almost all information presented by computers uses the visual sense. This means information can be missed because of visual overload or because the user is not looking in the right place at the right time. A multimodal interface that integrates information output to both senses could capitalize on the interdependence between them and present information in the most efficient way possible. An alternative approach is to use a crossmodal interface where the different senses are used to receive the same data. This provides a common representation of the data from both senses (in this case, audio and tactile) making them congruent informationally (Hoggan 2010a). Crossmodal use of the different senses allows the characteristics of one sensory modality to be transformed into stimuli for another sensory modality.

The classical uses of nonspeech sound can be found in human factors literature (see McCormick and Sanders 1982). Here, it is used mainly for alarms and warnings or monitoring and status information. Buxton (1989) extends these ideas and suggests that encoded messages could be used to present more complex information in sound, and it is this type of auditory feedback that will be considered here.

The use of sound to convey information in computers is not new. In the early days, programmers used to attach speakers to their computer's bus or program counter (Thimbleby 1990). The speaker would click each time the program counter was changed. Programmers would become accustomed to the patterns and rhythms of sound and could recognize what the machine was doing. Another everyday example is the sound of a hard disk. Users often can tell when a save or copy operation has completed by the noise the disk makes. This allows them to do other tasks while waiting for the copy to finish. Nonspeech sound is therefore an important information provider, giving users knowledge about factors they may not see.

Two important events kick-started the research area of nonspeech auditory output: the first was the special issue of the *Human-Computer Interaction* (HCI) journal in 1989 on nonspeech sound, edited by Bill Buxton (1989). This laid the foundations for some of the key works in the area; it included papers by Blattner on *earcons* (Blattner, Sumikawa, and Greenberg 1989), Gaver on *auditory icons* (Gaver 1989), and Edwards on *soundtrack* (Edwards 1989). The second event was the First International Conference on Auditory Display (ICAD'92) held in Santa Fe in 1992 (Kramer 1994b). For the first time, this meeting brought together the main researchers interested in the area (see www.icad.org for the proceedings of the ICAD conferences). Resulting from these two events was a large growth in research in the area during the 1990s that continues today.

Fifty years on from Geldard's original papers on the use of touch for information display (Geldard 1957), tactile feedback is now common in many everyday devices, with mobile phones, handheld computers, and game controllers all featuring vibration feedback. For example, vibrotactile actuators are often used in computer game controllers to provide feedback for weapon fire and environmental effects to provide a more immersive experience for the player.

Originally, work on vibrotactile displays was driven by tactile-audio substitution for persons with profound hearing impairment and was developed in the late 1970s and early 1980s. One of the earliest devices was Tacticon, a commercial device that adjusted the perceived intensity of 16 electrodes, each of which corresponded to a range of frequencies in the auditory spectrum, to improve speech comprehension, auditory discrimination, and the clarity of the users' speech (Kaczmarek and Bach-Y-Rita 1995).

There is commercial interest in this area too, as most mobile telephones include tactile feedback to accompany ring tones. For example, Immersion's VibeTonz (http://www.immersion.com) attempt to extend this simple feedback to enhance games and ring tones. Vibrotactile displays have been incorporated into canes used by visually impaired people. The UltraCane (http://www.soundforesight.co.uk) uses ultrasound to detect objects in a user's environment and presents the location and distance to targets by vibrating pads on the handle of the cane.

The combination of nonspeech audio and tactile feedback in computer interfaces can exploit the complementary relationship between the modalities and has the potential to increase the bandwidth through which information may be presented.

The rest of this chapter goes into detail on all aspects of auditory and crossmodal interface design. Section 10.2 presents some of the advantages and disadvantages of using sound at the interface. Then, Section 10.3 gives a brief introduction to psychoacoustics and psychophysics, or the study of the perception of sound and touch. Section 10.4 gives information about the basic sampling and synthesis techniques needed for auditory interfaces and Section 10.5 describes tactile actuator technology followed by tactile feedback generation techniques. Section 10.6 outlines the main techniques used for auditory and crossmodal information presentation, and Section 10.7 then goes through some of the main applications of sound and touch in HCI. The chapter finishes with some conclusions about the state of research in this area.

10.2 WHY USE NONSPEECH FEEDBACK IN HUMAN–COMPUTER INTERFACES?

10.2.1 Advantages of Nonspeech Feedback

There are many reasons why it is advantageous to use sound and touch at the user interface:

Vision and hearing are interdependent: Our visual and auditory systems work well together. Our eyes provide high-resolution information around a small area of focus (with peripheral vision extending further). On the other hand, sounds can be heard from all around the user: above, below, in front, or behind, but with a much lower resolution. Therefore, "our ears tell our eyes where to look": If there is an interesting sound from outside our view, we will turn to look at it to get more detailed information.

Hearing and touch have amodal properties: Our senses of hearing and touch share several important similarities, in particular their temporal characteristics and their ability to perceive vibrations. Moreover, sounds are often described in tactile terms. Mursell (1937) observed that tones can contain tactile values as can be seen when we describe a tone as hard or soft, rough or smooth, and wooden or metallic. An attribute that can communicate comparable information across modalities is considered to be amodal. Mendelson (1979) provided a scheme or list of such amodal properties. These properties relate to space and time and involve points along a continuum (e.g., location), intervals within continuum (e.g., duration), patterns of intervals (e.g., rhythm), rates of patterns (e.g., tempo), or changes of rate (e.g., texture gradients).

Sound has superior temporal resolution: As Kramer (1994a) says: "Acute temporal resolution is one of the greatest strengths of the auditory system." In certain cases, reactions to auditory stimuli have been shown to be faster than reactions to visual stimuli (Bly 1982).

Sound and touch reduce the overload from large displays: Modern, large, or multiple monitor graphical interfaces use the human visual sense very intensively. This means that we may miss important information because our visual system is overloaded—we have just too much to look at. To stop this overload, information could be displayed in sound or touch so that the load could be shared between senses.

Sound and touch reduce the amount of information needed on screen: Related to the above point is the problem with information presentation on devices with small visual displays, such as mobile telephones or personal digital assistants (PDAs). These have very small screens that can easily become cluttered. To solve this, some information could be presented in sound or touch to release screen space.

Sound reduces demands on visual attention: Another issue with mobile devices is that users who are using them on the move cannot devote all of their visual attention to the device—they must look where they are going to avoid uneven surfaces, traffic, pedestrians, and so on. In this case, visual information may be missed because the user is not looking at the device. If this were played in sound, then the information would be delivered while the user was looking at something else.

Sound is attention grabbing: Users can choose not to look at something, but it is harder to avoid hearing it. This makes sound very useful for delivering important information.

Touch is subtle and private: Using tactile feedback can enable personal and concealed communication, as it can only be felt by the user. Tactile feedback can, therefore, be used in situations where auditory display would be inappropriate (Chang et al. 2002), for example in meetings, or while in a quiet environment such as a library.

Spatial resolution of tactile stimuli is high: Different body locations have different levels of sensitivity and spatial acuity. The most sensitive part of the human body is the fingertip. When applying tactile stimuli to multiple points on the body, the distance between points is extremely important. Two-point discrimination is a measure that represents how far apart two pressure points must be before they are perceived as two distinct points on the skin (Geldard 1960). The point of contact discrimination threshold for two points is 0.9 mm when the stimuli are placed against the subject's finger in the absence of any movement lateral to the skin's surface. It is not possible for two points of contact closer than this threshold to be distinguished as separate stimuli. Experimental evidence suggests "active exploration marginally increases sensitivity, decreasing the threshold to 0.7 mm" (Phillips and Johnson 1985).

Auditory or tactile form makes computers more usable by visually disabled people: With the development of graphical displays, user interfaces became much harder for visually impaired people to operate. A screen reader (see Section 10.2.2) cannot easily read this kind of graphical information. Providing information in an auditory or tactile form can allow visually disabled persons to use the facilities available on modern computers.

10.2.2 Disadvantages of Nonspeech Feedback

Kramer (1994a) suggests some general difficulties with using sound to present information as follows:

Sound has low resolution: Many auditory and tactile parameters are not suitable for high-resolution display of quantitative information. Using sound volume or tactile amplitude, for example, only a very few different values can be unambiguously presented (Buxton, Gaver, and Bly 1991; Geldard 1960). The same also applies to spatial precision in sound, unlike touch. Under optimal conditions, differences of about 1° can be detected in front of a listener (see Section 10.4 and Blauert 1997). In vision, differences of an angle of 2 seconds can be detected in the area of greatest acuity in the central visual field.

Presenting absolute data is difficult: Many interfaces that use nonspeech feedback to present data do it in a relative way. Users hear or feel the difference between two sounds or vibrations to tell if a value is going up or down but absolute values are difficult.

There is lack of orthogonality: Changing one attribute of a sound or tactile cue may affect the others. For example, changing the frequency of stimuli may affect its perceived amplitude and vice versa (see Section 10.3).

There is annoyance due to auditory feedback: There are two aspects to annoyance: A sound may be annoying to the user whose machine is making the noise (the primary user) and/or annoying to others in the same environment who overhear it (secondary users). Buxton (1989) has discussed some of the problems of sound and suggests that some sounds help us (information) and some impede us (noise). We therefore need to design sounds so that there are more informative ones and less noise.

There are many studies of annoyance from speech (e.g., Berglund, Harder, and Preis 1994), from the sounds of aircraft, traffic, or other environmental noise and most of these suggest that the primary reason for the annoyance of sound is excessive volume. In a different context, Patterson (1989) investigated some of the problems with auditory warnings in aircraft cockpits. Many of the warnings were added in a “better safe than sorry” manner that lead to them being so loud that the pilot’s first response was to try and turn them off rather than deal with the problem being indicated.

A loud sound grabs the attention of the primary user, even when the sound is communicating an unimportant event. As the sound is loud, it travels from one machine to the ears of other people working nearby, increasing the noise in their environment.

So, how can annoyance be avoided? One key way is to avoid using intensity as a cue in sound design for auditory interfaces. Quiet sounds are less annoying. Listeners are also not good at making absolute intensity judgments (see Section 10.3). Therefore, intensity is not a good cue for differentiating sounds anyway.

Manipulating sound parameters other than intensity can make sounds attention grabbing (but not annoying). Rhythm or pitch can be used to make sounds demanding because the human auditory system is very good at detecting changing stimuli (for more see Edworthy, Loxley, and Dennis [1991]). Therefore, if care is taken with the design of sounds in an interface, specifically avoiding the use of volume changes to cue the user, then many of the problems of annoyance can be avoided.

The other key way to avoid annoyance is to use the tactile modality instead. At some times, audio feedback may be appropriate and other times the tactile modality may be more appropriate, for example, when surrounded by others. A system could switch to tactile cues in these circumstances (see Section 10.6.5).

10.3 BRIEF INTRODUCTION TO AUDITORY AND TACTUAL PERCEPTION

10.3.1 Auditory Perception

This section provides some basic information about the perception of sound that is applicable to nonspeech auditory output. Auditory interface designers must be conscious of the effects of psychoacoustics, or the perception of sound, when designing sounds for an interface. As Frysinger (1990) says: “The characterization of human hearing is essential to auditory data representation because it defines the limits within which auditory display designs must operate if they are to be effective. There is not enough space here to give great detail on this complex area, for more see the study by Moore (2003).

What is sound? Sounds are pressure variations that propagate in an elastic medium (in this case, the air). The pressure variations originate from the motion or vibration of objects. These pressure variations hit the listener’s ear and start the process of sound perception. A sine wave could be considered the simplest form of sound (as might be produced by a tuning fork). A sound is made up of three basic components:

Frequency is the number of times per second the wave repeats itself (Figure 10.1 shows three cycles). It is normally measured in hertz (Hz). *Amplitude* is the deviation away from the mean pressure level, or force per unit area of a sound. It is normally measured in decibels (dB). *Phase* is the position of the start of the wave on the time axis (measured in milliseconds).

Sounds from the real world are normally much more complex than that shown in Figure 10.1. and tend to comprise many sine waves with different frequencies, amplitudes, and phases. Figure 10.1 shows a more complex sound made of three sine wave components (or *partials*) and the resulting waveform. *Fourier analysis* allows a sound to be broken down into its component sine waves (Gelfand 1981).

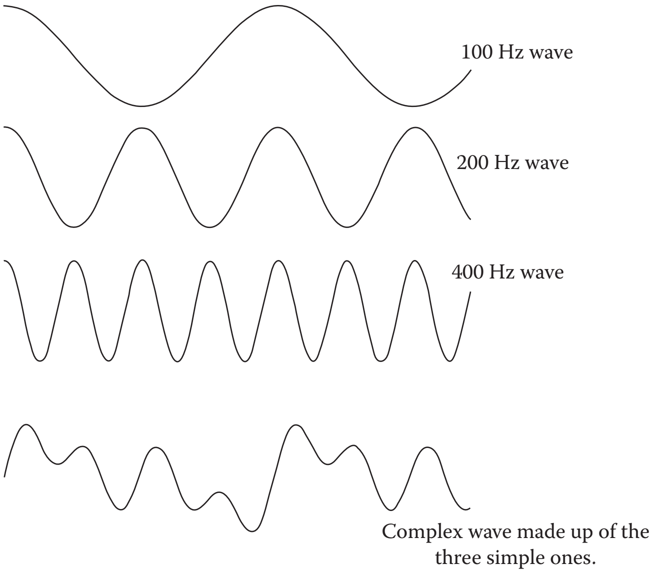

FIGURE 10.1 A complex wave made up of three components with its fundamental at 100 Hz.

The sounds in Figures 10.1 are *periodic*—they repeat regularly over time. This is very common for many types of musical instruments that might be used in an auditory interface. Many natural, everyday sounds (such as impact sounds) are not periodic and do not repeat. The sounds in Figure 10.1 are also *harmonic*—their partials are integer multiples of the lowest (or *fundamental*) frequency. This is again common for musical instruments but not for everyday sounds. Periodic harmonic sounds have a recognizable pitch, whereas nonperiodic, inharmonic sounds tend to have no clear pitch.

The attributes of sound described above are the physical aspects. There is a corresponding set of perceptual attributes. *Pitch* is the perceived frequency of a sound. Pitch is roughly a logarithmic function of frequency. It can be defined as the attribute of auditory sensation in terms of which sounds may be ordered on a musical scale (Moore 2003). In Western musical systems, there are 96 different pitches arranged into eight octaves of 12 notes. Tones separated by an octave have the frequency ratio 2:1. For example, middle C is 261.63 Hz, the octave above this is at 523.25 Hz, and the octave below at 130.81 Hz. It is one of the most useful and easily controlled aspects of sound and is very useful for auditory interface designers. However, as Buxton, Gaver, and Bly (1991) say: “It is important to be aware of the myriad interactions between pitch and other attributes of sound ….” For example, pitch is affected by sound intensity: at less than 2 kHz an increase in intensity increases the perceived pitch, and at 3 kHz and above an increase in intensity decreases the perceived pitch (Gelfand 1981).

Humans can perceive a wide range of frequencies. The maximum range we can hear is from 20 Hz to 20 kHz. This decreases with age so that at the age of 70 a listener might only hear a maximum of 10 kHz. It is therefore important to ensure that the sounds in an auditory interface are perceivable by its users (also poor-quality loudspeakers may not be able to cope with the highest or lowest frequencies). Listeners are not good at making absolute judgments of pitch (Moore 2003). Only 1% of the population has *perfect pitch*. Another important factor is *tone deafness*. Moore suggests that this is a misnomer and almost everyone is able to tell that two sounds are different; they are not always able to say which is higher or lower. Mansur, Blattner, and Joy (1985) give evidence of one other important effect: “There appears to be a natural tendency, even in infants, to perceive a pitch that is higher in frequency to be coming from a source that is vertically higher in space when compared to some lower tone.” This is important when creating an auditory interface as it could be used to give objects a spatial position. If only stereo position is available to provide spatial cues in the horizontal plane, then pitch could provide them in the vertical plane. Guidelines for the use of pitch (and the other parameters below) are described in Section 10.6.

Loudness is the perceived intensity of a sound. Loudness (*L*) is related to intensity (*I*) according to the *Power Law*: $L = k\,I^{0.3}$ (Gelfand 1981). Therefore, a 10-dB increase in intensity doubles the perceived loudness of a sound. Loudness is again affected by the other parameters of sound. For example, sounds of between 1 and 5 kHz sound louder at the same intensity level than those outside that frequency range. Humans can perceive a very wide range of intensities: the most intense sound that a listener can hear is 120 dB louder than the quietest. This equates to a ratio of 1,000,000,000,000:1 (Moore 2003). Buxton, Gaver, and Bly (1991) also report that listeners are “very bad at making absolute judgments about loudness” and “our ability to make relative judgments of loudness are limited to a scale of about three different levels.” It is also a primary cause of annoyance (see Section 10.2) so should be used sparingly by auditory interface designers.

Timbre is the “quality” of the sound. It is the attribute of auditory sensation in terms of which a listener can judge two sounds with the same loudness and pitch to be dissimilar. It is what makes a violin sound different to a piano even if both are playing the same pitch at the same loudness. Its structure and dimensions are not yet fully understood. It is known to be based partly on the spectrum and dynamics of a sound. As Blattner, Sumikawa, and Greenberg (1989) say: “Even though timbre is difficult to describe and notate precisely, it is one of the most immediate and easily recognizable characteristics of sound” (both *auditory icons* and *earcons* use timbre as one of their fundamental attributes—see Section 10.6).

Duration is another important attribute of sound. Sounds of different durations are used to form rhythmic structures that are a fundamental part of music. Duration can also affect the other parameters of sound. For example, for sounds of less than 1 second, loudness increases with duration. This is important in auditory interfaces because short sounds are often needed so that the auditory feedback can keep pace with the interactions taking place, accordingly, they must be made loud enough for listeners to hear.

Direction is the position of the sound source. If a sound source is located to one side of the head, then the sound reaching the further ear will be reduced in intensity (*interaural intensity difference*—IID) and delayed in time (*interaural *time difference*—ITD) (Blauert 1997). These are two key factors allowing a listener to *localize* a sound in space. Humans can detect small changes in the position of a sound source. The minimum auditory angle is the smallest separation between two sources that can be reliably detected. Strybel, Manligas, and Perrott (1992) report that in the median plane sound sources only 1° apart can be detected. At 90° azimuth (directly opposite one ear), accuracy falls to ± 10° (see Section 10.4.3 for more on sound positioning).

10.3.2 Tactual Perception

The term *haptics* means "sensory and/or motor activity based in the skin, muscles, joints and tendons" (*ISO: Ergonomics of human-computer interaction—Part 910: Framework for tactile and haptic interaction* 2009). Under this umbrella term, however, there are several subcategories, as shown in Figure 10.2.

The skin has an area of 1.8 m^2, a density of 1250 kg/m^3, and a weight of 5 kg (Sherrick and Cholewiak 1986). It is classified as either glabrous (i.e., nonhairy) skin, which is found only on the plantar and palmar surfaces, or hairy skin, which is found on the rest of the body. These divisions are relevant to tactile displays because they vary in sensory receptor systems and measures of tactile sensitivity (Cholewiak and Craig 1984). Four types of mechanoreceptive fibers have been identified in glabrous skin: Meissner corpuscle (RA), Merkel cell (SAI), Pacinian corpuscle (PC), and Ruffini ending.

Each mechanoreceptive fiber has a specific role in the perception of vibration that ranges from 0.4 to more than 500 Hz (Sherrick and Cholewiak 1986). The RA are high-density fibers that are abundant in the fingertips. The majority of the tactile feedback used in this thesis research is presented to the fingertips. In contrast, the PCs are less dense than the RA, and are numerous in the distal joints. Since the four fibers overlap in their absolute sensitivities, a vibration stimulus will seldom stimulate a single fiber in the skin but several fibers because the energy applied to the skin will move throughout nearby skin tissues (Sherrick and Cholewiak 1986). Within most of the vibrotactile literature, the fibers are grouped into two systems: the Pacinian and the non-Pacinian systems. "The Pacinian system has a large receptive field excited by higher frequencies and the non-Pacinian system consists of a small receptive field thought to be excited by lower frequencies" (Sherrick, Cholewiak, and Collins 1990). Bolanowski et al. (1988) found threshold sensitivities in the range of 0.4–500 Hz between these two systems. The Pacinian system exhibited a U-shaped function at higher frequencies (40–500 Hz) where maximum sensitivity occurred between 250 and 300 Hz (Bolanowski et al. 1988). Therefore, the majority of the stimuli used in this research have a frequency of 250 Hz. Verrillo (1966) also reported a similar function for hairy skin, where maximum sensitivity occurred at 220 Hz.

Understanding the features of specific skin fibers and their response characteristics when stimulated can help to inform the design of any tactile feedback to ensure that the stimuli are compatible with the characteristics of the particular area of skin on which the feedback will be presented. According to Kandel and Jessell (1991), Meissner's corpuscles and Merkel's cells respond to touch, PCs respond to vibration, and Ruffini's corpuscles respond to rapid indentation of the skin. Vibration is detected best on hairy, bony skin and is more difficult to detect on soft, fleshy areas of the body (Geldard 1960).

The dimensions or attributes of our sense of touch are detailed below:

Frequency range of the skin ranges from 10 to 400 Hz, with maximum sensitivity (Summers, Dixon, and Cooper 1994) and finer spatial discrimination at around 250 Hz (Craig and Sherrick 1982). Investigations by Goff involving the stimulation of the subject's finger with a single probe showed that for lower frequencies (<25 Hz), the discrimination threshold was less than 5 Hz. For frequencies greater than 320 Hz, discrimination capacities were also degraded (Goff 1967). Measures for discrimination thresholds of frequency are problematic, as perception of vibratory pitch is

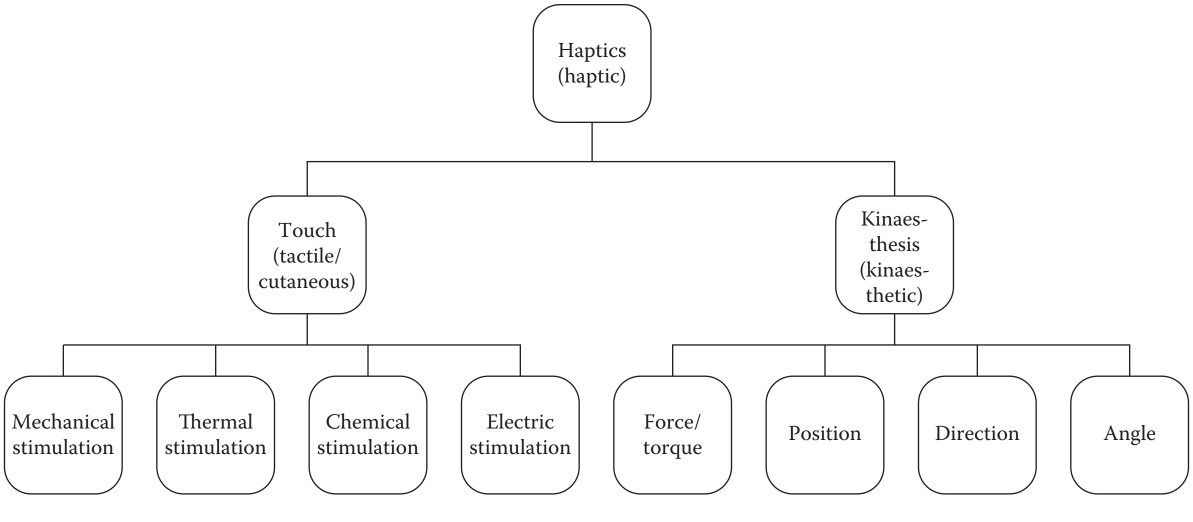

FIGURE 10.2 Definitions of terminology. (Adapted from ISO: Ergonomics of human-computer interaction—Part 910: Framework for tactile and haptic interaction 2009.)

dependent not just on frequency, but also on the amplitude of stimulation. Geldard (1957) found that subjects reported a change in pitch when frequency was fixed, but amplitude of stimulation was changed. Sherrick (Sherrick and Cholewiak 1986) found that combining frequency and amplitude redundantly allowed a greater number of identifiable levels to be created. He found that people could distinguish three to five different levels of frequency, but that adding amplitude as a redundant parameter could increase this range. Therefore, this interaction between frequency and amplitude should to be taken into account or perhaps avoided when designing tactile stimuli.

Duration is another important dimension found in both the audio and tactile modalities. Geldard (1960) reports that the temporal duration just noticeable difference rose from 50 to 150 milliseconds. When duration was increased from 0.1 to 2.0 seconds Gescheider (as reported in [Terhardt 1974]) measured the time difference between two tactile "clicks" on the fingertip, necessary for them to be perceived as two separate sensations and found that the minimum threshold reported was 10 milliseconds. Interactions between duration and perceived amplitude should be considered when using duration, as it has been shown that short intense signals can be confused with longer, lower intensity signals. Gunther (Gunther, Davenport, and O'Modhrain 2002) suggests that stimuli lasting less than 0.1 seconds may be perceived as taps or jabs, whereas longer stimuli may be perceived as smoothly flowing tactile phrases. Craig and Sherrick (1982) warn that very short durations may result in sensations such as pokes or jabs, which might be undesirable.

Rhythms are created by grouping together pulses to create temporal patterns in a similar fashion to rhythms in music. Rhythm is very important and useful in the design of tactile systems. For example, Summers (1992) encoded speech information by modulating vibration frequency and amplitude, and by presenting the temporal pattern of the speech using rhythm. The results of an evaluation showed that users obtained the most information from the rhythmic pattern compared with the frequency/amplitude modulation.

Body locations that have been identified as most sensitive to pressure and stimulus discrimination include the finger, hand, arm, thigh, and torso (Cholewiak and Collins 1995).

Cholewiak, Brill, and Schwab (2004) investigated the vibrotactile localization accuracy for the abdomen using 12, 8, and 6 equidistant actuators, 72, 107, and 140 mm, respectively. Their results showed that the ability to correctly identify which actuator was presenting a stimulus increased as the number of actuators decreased. Study participants were correct in their identification for an average of 74%, 92%, and 97% of the trials for 12, 8, and 6 actuators, respectively. The results also showed that when participants labeled areas on their abdomen, for example, the navel at 12 o'clock and the spine at 6 o'clock, they were better able to localize stimuli. Accuracy rates were much lower when labels were not available. This suggests that accuracy can be increased if a label is provided which is mapped to the locations to be identified.

Intensity detection in our sense of touch is limited, with an intensity range of approximately 55 dB above the detection threshold. Any vibrations above this threshold feel unpleasant or even painful (Verrillo and Gescheider 1992).

10.4 TECHNOLOGY AND PRODUCTION OF NONSPEECH AUDIO FEEDBACK

Most desktop PCs, handheld computers, and mobile telephones have sophisticated sound hardware available for auditory interface designers. This is normally for playing games but is sufficient to do most of the things required by an auditory interface. The aim of this section is to describe briefly some of the main technologies that are important for the designers to understand when creating interfaces.

There are two main aspects of sound production: (1) sound synthesis and (2) sound sampling and playback. A basic overview focusing on aspects related to audio interfaces will be given. For much more detail on sound synthesis and musical instrument digital interface (MIDI), see the study by Roads (1996) and Miranda (1998). For more on sampling, see the study by Pohlmann (2005).

There are many tools available for synthesis and sample playback, and devices from desktop PC's to mobile telephones have the processing power necessary. The Java programming language (www.java.sun.com), for example, has built-in support for a range of synthesis and sampling techniques for many different platforms. Libraries such as Fmod (www.fmod.org) allow standard crossplatform sound and work on many different devices and programming languages. All current desktop operating systems provide support for synthesis and sampling. The basic technologies necessary to make the sounds needed for auditory interfaces are thus readily available, but it is important to know something of how they work to use them most effectively.

10.4.1 Brief Introduction to Sound Synthesis and MIDI

The aim of sound synthesis is to generate a sound from a stored model, often a model of a musical instrument. For auditory interfaces, we need a wide and good quality range of sounds that we can generate in real time as the user interacts with the interface. Synthesizers come in three main forms: (1) soundcards on PCs, (2) external hardware devices, and (3) software synthesizers. The main forms of synthesis will now be briefly reviewed.

Wavetable synthesis is one of the most common and low-cost synthesis techniques. Many of the most popular PC soundcards use this technique (such as the SoundBlaster series from Creative Technology—www.creative.com). The idea behind wavetable synthesis is to use existing sound recordings (which are often very difficult to synthesize exactly) as the starting point and create very convincing simulations of acoustical instruments based on them (Miranda 1998; Roads 1996). A sample (recording) of a particular sound will be stored in the soundcard. It can then be played back to produce a sound. The sample memory in these systems contains a large number of sampled sound segments and can be thought of as a "table" of sound waveforms that may be looked up and used when needed. Wavetable synthesizers use a variety of different techniques, such as sample looping, pitch shifting, mathematical interpolation, and polyphonic digital filtering, to reduce the amount of memory required to store the sound samples and to get more types of sounds. More sophisticated synthesizers contain more wavetables (perhaps one or more for the initial *attack* part of a sound and then more for the *sustain* part of the sound and then more for the final *decay* and *release* parts). It is also possible to combine multiple separately controlled wavetables to create a new instrument.

Wavetable synthesis is not so good if you want to create new timbres as it lacks some of the flexibility that other techniques have. Most wavetable synthesizers contain many sounds (often many hundreds) so there may not be a great need to create new ones. For most auditory interfaces, the sounds from a good quality wavetable synthesizer will be perfectly acceptable. For desktop computers, the storage of large wavetables is no problem, but for mobile telephones with less storage, there may be a much smaller, lower quality set, so care may be needed to design appropriate sounds.

Frequency modulation (FM) synthesis techniques generally use one periodic signal (the modulator) to modulate the frequency of another signal (the carrier) (Chowning 1975). If the modulating signal is in the audible range, then the result will be a significant change in the timbre of the carrier signal. Each FM voice requires a minimum of two signal generators. Sophisticated FM systems may use four or six operators per voice, and the operators may have adjustable envelopes that allow adjustment of the attack and decay rates of the signal. FM synthesis is cheap and easy to implement and can be useful for creating expressive new synthesized sounds. However, if the goal is to re-create the sound of an existing instrument, then FM synthesis is not the best choice as it can generally be done more easily and accurately with wavetable-based techniques.

Additive (and subtractive) synthesis is the oldest form of synthesis (Roads 1996). Multiple sine waves are added together to produce a more complex output sound (subtractive synthesis is the opposite: a complex sound has frequencies filtered out to create the sound required). Using this method, it is theoretically possible to create any sound (as all complex sounds can be decomposed into sets of sine waves by Fourier analysis). However, it can be very difficult to create any particular sound.

Physical modeling synthesis uses mathematical models of the physical acoustic properties of instruments and objects. Equations describe the mechanical and acoustic behavior of an instrument. The better the simulation of the instrument the more realistic the sound produced. Nonexistent instruments can also be modeled and made to produce sounds. Physical modeling is an extremely good choice for synthesis of many classical instruments, especially those of the woodwind and brass families. The downside is that it can require large amounts of processing power, which limits the polyphony.

10.4.1.1 Musical Instrument Digital Interface

The *MIDI* allows the real-time control of electronic instruments (such as synthesizers, samplers, drum machines) and is now very widely used (www.midi.org). It specifies a hardware interconnection scheme, a method for data communications and a grammar for encoding musical performance information (Roads 1996). For auditory interface designers, the most important part of MIDI is the performance data, which is a very efficient method of representing sounds.

MIDI performance information is like a piano roll: notes are set to turn on or off and play different instruments over time. A MIDI message is an instruction that controls some aspect of the performance of an instrument. The MIDI message is made up of a *status byte*, which indicates the type of the message, followed by up to two *data bytes*, which give the parameters. For example, the *Note On* command takes two parameters: one value giving the pitch of the note required and the other the volume. This makes it a very compact form of presentation.

Performance data can be created dynamically from program code or by a sequencer. In an auditory interface, the designer might assign a particular note to a particular interface event—for example, a click on a button. When the user clicks on the button, a MIDI Note On event will be fired, and when the user releases the button, the corresponding Note Off event will be sent. This is a very simple and straightforward way of adding sounds. With a sequencer, data can be entered using classical music notation by dragging and dropping notes onto a stave or using an external piano-style keyboard. This could then be saved to a MIDI file for later playback (or could be recorded and played back as a sample—see Section 10.4.2).

10.4.2 Brief Introduction to Sampling

In many ways, sampling is simpler than synthesis. The aim is to make a digital recording of an analog sound and then to be able to play it back later, with the played back sound matching the original as closely as possible. There are two important aspects: *sample rate* and *sample size*.

10.4.2.1 Sample Rate

This is the number of discrete "snapshots" of the sound that are taken, often measured per second. The higher the sampling rate, the higher the quality of the sound when it is played back. With a low sampling rate, few snapshots of the sound are taken and the recording will not match well the sound being recorded. The *sampling theorem* (Roads 1996) states that "In order to be able to reconstruct a signal, the sampling frequency must be at least twice the frequency of the signal being sampled" (p. 30). The limit of human hearing is about 20 kHz; therefore, a maximum rate of 40 kHz is required to be able to record any sound that a human can hear. The standard audio CD format uses a sample rate of 44.1 kHz, meaning that it covers all of the frequencies that a human can hear. If a lower sampling rate is used, then higher frequencies are lost. For example, the .au audio file format uses a sampling rate of 8 kHz, meaning that only frequencies of less than 4 kHz can be recorded. For more details on the huge range of sample formats, see the study by Bagwell (1998).

Higher sampling rates generate much more data than do lower ones so may not always be suitable if storage is limited (e.g., on a mobile computing device). Auditory interface designers should consider the frequency range of the sounds needed in an interface, and this might reduce the sample rate.

10.4.2.2 Sample Size

The larger the sample size the better the quality of the recording, as more information is stored at each snapshot of the sound. Sample size defines the volume (or dynamic) range of the sound. With an 8-bit sample, only 256 discrete amplitude (or quantization) levels can be represented. Fitting an analog sound into one of these levels might cause it to be rounded up or down, and this can add noise to the recording. CD-quality sounds use 16-bit samples giving 65,536 different levels, so the effects of quantization are reduced. Many high-quality samplers use 24-bit samples to reduce the problems of quantization still further.

The main two bit sizes used in most soundcards are 8 and 16 bits. As with sample rates, the main issue is size: 16-bit samples require a lot of storage, especially at high sample rates. Audio CD-quality sound generates about 10 megabytes of data per minute. Compression techniques such as MP3 can help reduce the amount of storage but keep quality high.

10.4.3 Three-Dimensional Sound

Much of the recorded sound we hear is in *stereo.* A stereo recording uses intensity differences between the ears of a listener. From these differences, the listener can gain a sense of movement and position of a sound source in the stereo field. The perceived position is along a line between two loudspeakers or inside the head between listeners' ears if they are wearing headphones. This simple, inexpensive technique can give useful spatial cues at the auditory interface. This is being taken further to make sounds appear as coming from around a user (in virtual 3D) when only a small number of loudspeakers (or even just a pair of headphones) are used. Spatial sound can be used for a range of things, including giving directional information, spreading sound sources around the head to help users differentiate simultaneous sounds, and to create "audio windows" in which to present information (see Section 10.7.3).

In the real world we use our pinnae (the outer ear) to filter the sounds coming from different directions so that we know where they are coming from. To simulate sounds as coming from around listeners and outside the head when wearing headphones, sounds entering the ear are recorded by placing microphones into the ear canals of listeners. The differences between the sound at the sound source and at the ear canal are then calculated, and the differences, or "head-related transfer functions" (HRTFs), derived are used to create filters with which stimuli can be synthesized (Blauert 1997). This research is important as 3D auditory interfaces can be created that are more natural, with sounds presented around the user as they would be in real life. Almost all current PC soundcards can generate such 3D sounds as they are often used in games.

The main problem with providing simulated 3D sound through headphones comes from the general HRTFs used. If listeners' ears are not like the ears of the head (often a dummy head) from which the HRTFs were generated, then the listeners are likely to feel that the sounds are coming from inside their head, and not outside. It is also very easy for listeners to become confused when they cannot tell whether a sound is in front or behind them. Vertical positioning is also difficult to do reliably. This means that many designers who use spatial sound in their interfaces often limit themselves to a plane cutting through the head horizontally at the level of the ears, creating a 2.5D space. This reduces the space in which sounds can be presented but avoids many of the problems of users not being able to localize the sounds properly.

To improve quality, head-tracking is often used. Once the orientation of the user's head is known, sounds can be respatialized to remain in position when the head turns. "Active listening" is used to disambiguate the location of a sound—listeners naturally make small head movements, and these change the IID and ITD, cueing the listeners to the location of the sound. Using such tracking can significantly improve the performance of 3D auditory user interfaces (Marentakis and Brewster 2004). Marentakis and Brewster also showed that targets should be around ±10° in size when head-tracking is used to enable accurate localization and selection.

10.5 TECHNOLOGY AND PRODUCTION OF TACTILE FEEDBACK

10.5.1 Tactile Actuators

Tactile devices generally stimulate the cutaneous senses through skin indentation, vibration, skin stretch, and electrical stimulation (Brewster et al. 2008). A variety of tactile stimulation devices are available, each of which stimulates a specific tactile response. These include pressure, thermal, slip, electrocutaneous, and vibration displays. In general, vibrotactile actuators are the easiest to work with and in particular, to control. Furthermore, most mobile devices already include a vibrotactile actuator.

Vibrotactile actuators can provide a sustained feedback allowing many different textures and intensities to be presented. By using the built-in actuator in commercial devices, the tactile feedback is not restricted by expensive or rare technology and does not require any hardware to be added to the device, which could increase its size, weight, or battery consumption, which may be inappropriate in mobile devices for example.

Most vibrotactile actuators stimulate the skin using electromagnetic actuation to drive a mass in either a linear or rotational manner. The Engineering Acoustics Inc (EAI) C2 Tactor is shown in Figure 10.3. This device is resonant

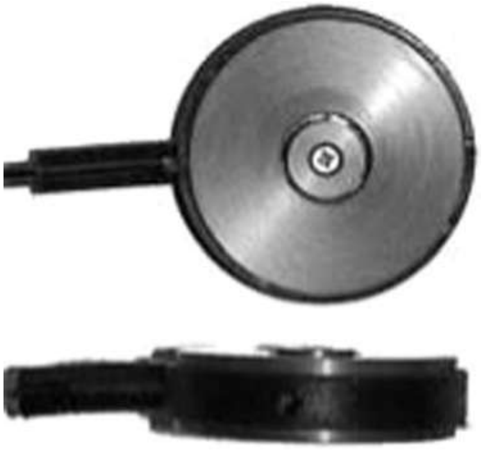

FIGURE 10.3 Engineering Acoustics Inc C2 vibrotactile actuator.

at 250 Hz with much reduced response at other frequencies (which is another reason for the reduced usefulness of frequency as a parameter for vibrotactile interfaces). The advantage of vibrotactile cues is that they can apply high levels of force (so can be felt through clothing) and they can also be distributed over the body or device to give spatial cues (often attached to a user's belt around the waist). For a more detailed review of vibrotactile devices, see the study by Summers (1992).

Piezoelectric actuators can create short, more display-localized tactile bursts by moving touch-screen display modules within the device (Laitinen and Mäenpää 2006). Piezoelectric actuators are also able to generate quick pulses, and the tactile feedback is concentrated to move the display mass, which is commonly 20% of the whole device mass, providing large displacement with rapid responses, but with less kinetic energy compared with traditional vibration motor systems.

Koskinen, Kaaresoja, and Laitinen (2008) conducted three laboratory-based studies to determine which tactile click (from a set of various different designs) is most pleasant to use in fingertip interaction with a mobile touch-screen device. Using two different types of actuator—piezo or vibration motor—the experiments allowed the authors to find the most pleasant tactile feedback as perceived by participants. The results showed that feedback from piezoelectric actuators was perceived as more pleasant than that from vibrotactile motors.

10.5.2 Tactile Feedback Generation

It is difficult to summarize tactile feedback generation as it depends heavily on the type of actuator used. Given that this chapter focuses mainly on vibrotactile feedback, this section outlines generation methods for the most commonly used vibrotactile actuators: voice coil motors (e.g., the C2 Tactor) and eccentric rotating mass (ERM) motors (e.g., standard built-in mobile phone motors).

As mentioned in Section 10.3, the dimensions or parameters of touch include amplitude, frequency, and rhythm. All these can be controlled in tactile feedback generation.

10.5.2.1 Using Audio Synthesis or Sampling Software for External Voice Coil Motors

Much like audio, tactile feedback can be generated using synthesis or sampling methods. Audio is played back normally from an application but instead of using speakers, audio output is forwarded to the actuators. Sampling behaves in the same way as audio sampling. In synthesis applications, both frequency and amplitude can be controlled somewhat independently, but it must be noted that actuators always have an optimum frequency. The human fingertip is most sensitive to a frequency of 250 Hz, and actuators such as the C2 are best used at this frequency. Most actuators have an optimum frequency in the range of 100–300 Hz. Virtually, any waveform can be used but most actuators are optimized for sine waves. Duration can also be easily controlled, meaning that rhythms can be created (as discussed in Section 10.3, rhythm is one of the most important and effective design parameters). Most standard commercial audio synthesis programs can be used such as Pure Data (http://puredata.info).

10.5.2.2 Using APIs and Eccentric Rotating Mass

When using ERMs (found in mobile phones), there are two issues to consider. First, it takes time to start and stop the rotating mass, which means there may be a slight delay in feedback. Second, when the rotating mass is mounted inside a device, the vibration disperses and can be felt across the whole device. Using standard application programming interfaces (APIs) provided by mobile phone manufacturers, for example, QT or in JavaME, it is possible to manipulate several parameters. It is possible to change the frequency by adjusting the supply voltage provided to the rotating mass. The direction of rotation can also be changed; alternating between two opposite driving directions can provide very distinctive feedback. Rhythms can be created by creating structured units of pulses and pauses.

10.6 NONSPEECH FEEDBACK TECHNIQUES

The two main types of nonspeech audio presentation techniques commonly used are *auditory icons* and *earcons*. There are also two main types of tactile presentation techniques called haptic icons and tactons. Following on from the audio and tactile presentation techniques, crossmodal icons can be used to make effective use of both modalities. Substantial research has gone into developing all of these, and the main work is reviewed in Section 10.6.1.

10.6.1 Auditory Icons

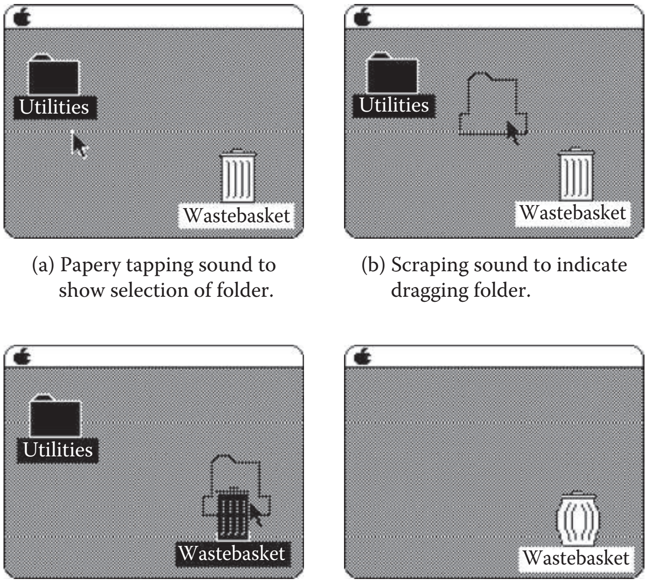
Gaver (1989, 1997) developed the idea of *auditory icons*. These are natural, everyday sounds that can be used to represent actions and objects within an interface. He defined them as "everyday sounds mapped to computer events by analogy with everyday sound-producing events. Auditory icons are like sound effects for computers." Auditory icons rely on an analogy between the everyday world and the model world of the computer (Gaver 1997) (for more examples of the use of earcons, see the work on Mercator and Audio Aura described in Sections 10.7.2 and 10.7.3).

Gaver used sounds of events that are recorded from the natural environment, for example, tapping or smashing sounds. He used an "ecological listening" approach (Neuhoff 2004), suggesting that people do not listen to the pitch and timbre of sounds but to the sources that created them. When pouring liquid, a listener hears the fullness of the receptacle, not the increases in pitch. Another important property of everyday sounds is that they can convey multidimensional data. When a door slams, a listener may hear the following: the size and material of the door; the force that was used; and the size of room where the door was slammed. This could be used within an interface so that selection of an object makes a tapping sound, the type of material could represent the type of object, and the size of the tapped object could represent the size of the object within the interface.

Gaver used these ideas to create auditory icons and from these built the *SonicFinder* (Gaver 1989). This ran on the Apple Macintosh and provided auditory representations of some objects and actions within the interface. Files were given a wooden sound, applications a metal sound, and folders a paper sound. The larger the object the deeper the sound it made. Thus, selecting an application meant tapping it—it made a metal sound, which confirmed that it was an application and the deepness of the sound indicated its size. Copying used the idea of pouring liquid into a receptacle. The rising of the pitch indicated that the receptacle was getting fuller and the copy progressing.

To demonstrate how the SonicFinder worked, a simple interaction is provided in Figure 10.4, showing the deletion of a folder. In Figure 10.4a, a folder is selected by tapping on it; this causes a "papery" sound indicating that the target is a folder. In Figure 10.4b, the folder is dragged toward the wastebasket causing a scraping sound. In Figure 10.4c, the wastebasket becomes highlighted, and a "clinking" sound occurs when the pointer reaches it. Finally, in Figure 10.4d, the folder is dropped into the wastebasket and a smashing sound occurs to indicate it has been deleted (the wastebasket becomes "fat" to indicate there is something in it).

Problems can occur with representational systems such as auditory icons because some abstract interface actions and objects have no obvious representation in everyday sounds. Gaver used a pouring sound to indicate copying because there was no natural equivalent; this is more like a "sound effect." He suggested the use of movie-like sound effects to create sounds for things with no easy representation. This may cause problems if the sounds are not chosen correctly as they will become more abstract than representational, and the advantages of auditory icons will be lost.



(a) Papery tapping sound to show selection of folder.

(b) Scraping sound to indicate dragging folder.

(c) Clinking sound to show wastebasket selected.

(d) Smashing sound to indicate folder deleted.

FIGURE 10.4 An interaction showing the deletion of a folder in the SonicFinder. (From Gaver, W. 1989. *Hum Comput Interact* 4(1):67–94. With permission.)

Gaver developed the ideas from the SonicFinder further in the *ARKola* system (Gaver, Smith, and O'Shea 1991), which modeled a soft drinks factory. The simulation consisted of a set of nine machines split into two groups: those for input and those for output. The input machines supplied the raw materials; the output machines capped the bottles and sent them for shipping. Each machine had an on/off switch and a rate control. The aim of the simulation was to run the plant as efficiently as possible, avoid waste of raw materials, and make a profit by shipping the bottles. Two users controlled the factory, with each user able to see approximately one-third of the whole plant. This form of plant was chosen because it allowed Gaver et al. to investigate how the sounds would affect the way users handled the given task and how people collaborated. It was also an opportunity to investigate how different sounds would combine to form an auditory *ecology* (integrated set of sounds) or soundscape. Gaver et al. related the way the different sounds in the factory combined to the way a car engine is perceived. Although the sounds are generated by multiple distinct components, they combine to form what is perceived as a unified sound. If something goes wrong, the sound of the engine will change, alerting the listener to the problem, but in addition, to a trained ear the change in the sound would alert the listener to the nature of the problem. The sounds used to indicate the performance of the individual components of the factory were designed to reflect the semantics of the machine.

Each machine had a sound to indicate its status over time, for example, the bottle dispenser made the sound of clinking bottles. The rhythm of the sounds reflected the rate at which the machine was running. If a machine ran out of supplies or broke down, its sound stopped. Sounds were also added to indicate that materials were being wasted. A splashing sound indicated that liquid was being spilled; the sound of smashing bottles indicated that bottles were being lost. The system was designed so that up to 14 different sounds could be played at once. To reduce the chance that all sounds would be playing simultaneously, sounds were pulsed once a second rather than playing continuously.

An informal evaluation was undertaken where pairs of users were observed controlling the plant, either with or without sound. These observations indicated that the sounds were effective in informing the users about the state of the plant and that the users were able to differentiate the different sounds and identify the problem when something went wrong. When the sounds were used, there was much more collaboration between the two users. This was because each could hear the whole plant and therefore help if there were problems with machines that the other was controlling. In the visual only condition, the users were not as efficient at diagnosing what was wrong even if they knew there was a problem.

One of the biggest advantages of auditory icons is the ability to communicate meanings that listeners can easily learn and remember, other systems (for example earcons, see Section 10.6.1.1) use abstract sounds where the meanings are harder to learn. Problems did occur with some of the warning sounds used as Gaver et al. indicate: "the breaking bottle sound was so compelling semantically and acoustically that partners sometimes rushed to stop the sound without understanding its underlying cause or at the expense of ignoring more serious problems." Another problem was that when a machine ran out of raw materials its sound just stopped, users sometimes missed this and did not notice that something had gone wrong.

10.6.1.1 Design Guidelines for Auditory Icons

There have been few detailed studies investigating the best ways to design auditory icons, so there is little guidance for interaction designers. Mynatt (1994) has proposed the following basic design methodology: (1) choose short sounds that have a wide bandwidth, and where length, intensity, and sound quality are roughly equal. (2) Evaluate the identifiability of the auditory cues using free-form answers. (3) Evaluate the learnability of the auditory cues, which are not readily identified. (4) Test possible conceptual mappings for the auditory cues using a repeated measures design where the independent variable is the concept that the cue will represent. (5) Evaluate possible sets of auditory icons for potential problems with masking, discriminability, and conflicting mappings. (6) Conduct usability experiments with interfaces using the auditory icons.

10.6.2 Earcons

Blattner, Sumikawa, and Greenberg (1989) developed earcons. They use abstract, synthetic tones in structured combinations to create auditory messages. Blattner, Sumikawa, and Greenberg (1989) define earcons as "non-verbal audio messages that are used in the computer/user interface to provide information to the user about some computer object, operation, or interaction." Unlike auditory icons, there is no intuitive link between the earcon and what it represents; the link must be learned. They use a more traditional musical approach than auditory icons.

Earcons are constructed from simple building blocks called *motifs* (Blattner, Sumikawa, and Greenberg 1989). These are short, rhythmic sequences that can be combined in different ways. Blattner suggested their most important features:

Rhythm: Changing the rhythm of a motif can make it sound very different. Blattner, Sumikawa, and Greenberg (1989) describe this as the most prominent characteristic of a motif.

Pitch: There are 96 different pitches in the Western musical system, and these can be combined to produce a large number of different motifs.

Timbre: Motifs can be made to sound different by the use of different timbres, for example, playing one motif with the sound of a violin and the other with the sound of a piano.

Register: This is the position of the motif in the musical scale. A high register means a high-pitched note and a low register a low note. The same motif in a different register can convey a different meaning.

Dynamics: This is the volume of the motif. It can be made to increase as the motif plays (crescendo) or decrease (decrescendo).

Earcons can be constructed in two basic ways. The first, and simplest are *compound earcons*. These are simple motifs that can be concatenated to create more complex earcons. For example, a set of simple, one-element motifs might represent various system elements such as "create," "destroy," "file," and "string" (see Figure 10.5a), and these could then be concatenated to form earcons (Blattner, Sumikawa, and Greenberg 1989). In the figure, the earcon for "create" is a high-pitched sound that gets louder, for "destroy" it is a low-pitched sound that gets quieter. For "file," there are two long notes that fall in pitch and for "string" two short notes that rise. In Figure 10.5b, the compound earcons can be seen. For the "create file" earcon, the "create" motif is simply followed by the "file" motif. This provides a simple and effective method for building up earcons.

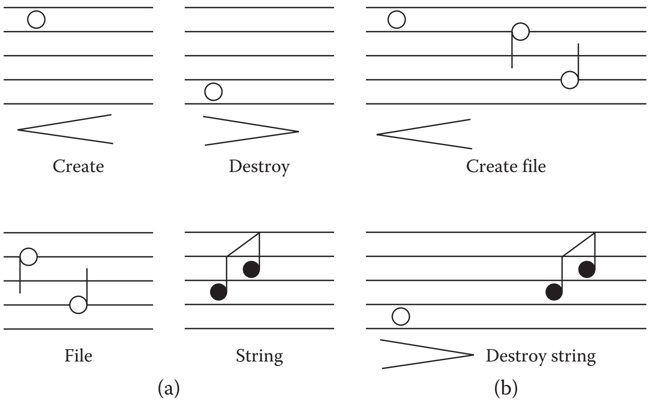


FIGURE 10.5 Compound earcons. (a) The four audio motifs "create," "destroy," "file," and "string" are shown. (b) The compound earcons "create file" and "destroy string" are shown. (From Blattner, M., D. Sumikawa, and R. Greenberg. 1989. *Hum Comput Interact* 4(1):11–44. With permission.)

Hierarchical earcons are more complex but can be used to represent more complex structures in sound. Each earcon is a node in a tree and inherits properties from the earcons above it. Figure 10.6 shows a hierarchy of earcons representing a family of errors. The top level of the tree is the family rhythm. This sound just has a rhythm and no pitch; the sounds used are clicks. The rhythmic structure of level 1 is inherited by level 2, but this time a second motif is added where pitches are put to the rhythm. At this level, Blattner et al. suggested that the timbre should be a sine wave, which produces a "colorless" sound. This is done so that at level 3 the timbre can be varied. At level 3, the pitch is also raised by a semitone to make it easier to differentiate from the pitches inherited from level 2. Other levels can be created where register and dynamics are varied.

Blattner et al. proposed the design of earcons but did not develop or test them. Brewster, Wright, and Edwards (1994) carried out a detailed evaluation of compound and hierarchical earcons based on the design proposed by Blattner, simple system beeps and a richer design based on more complex musical timbres using psychoacoustic research (see Section 10.3). In these experiments, participants were presented with earcons representing families of icons, menus, and combination of both (examples can be heard at www.dcs.gla.ac.uk/~stephen/demos.shtml). They heard each sound three times and then had to identify them when played back. Results showed that the more complex musical earcons were significantly more effective than both the simple beeps and Blattner's proposed design, with over 80% recalled correctly. Brewster et al. found that timbre was a much more important than that previously suggested, whereas pitch on its own was difficult to differentiate. The main design features of the earcons used were formalized into a set of design guidelines:

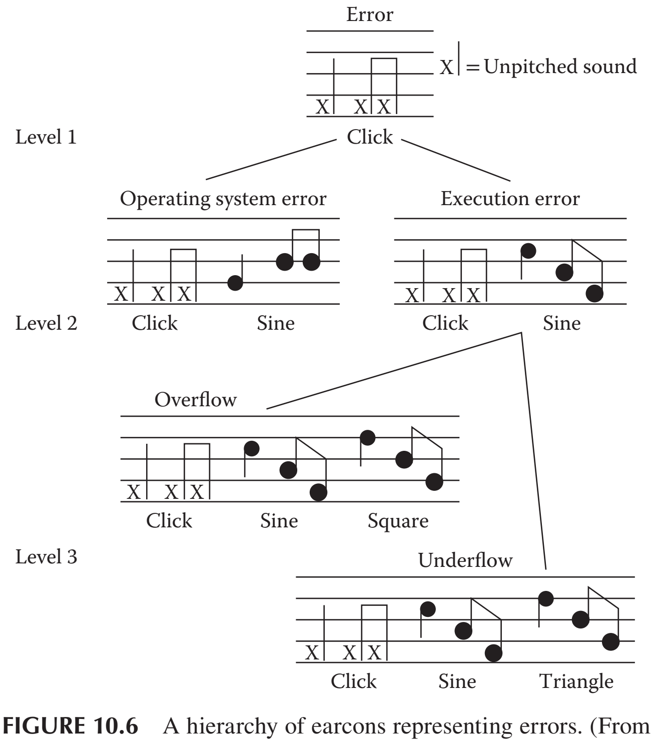

FIGURE 10.6 A hierarchy of earcons representing errors. (From Blattner, M., D. Sumikawa, and R. Greenberg. 1989. *Hum Comput Interact* 4(1):11–44. With permission.)

Timbre: This is the most important grouping factor for earcons. Use musical instrument timbres with multiple harmonics as this helps perception and can avoid masking. These timbres are more recognizable and differentiable.

Pitch and register: If listeners are to make absolute judgments of earcons, then pitch or register should not be used as a cue on its own. A combination of register and another parameter gives better rates of recall. If register alone must be used, then there should be large differences (two or three octaves) between earcons. Much smaller differences can be used if relative judgments are to be made. The maximum pitch used should be no higher than 5 kHz and no lower than 125–150 Hz so that the sounds are not easily masked and are within the hearing range of most listeners.

Rhythm, duration, and tempo: These make rhythms as different as possible. Putting different numbers of notes in each earcon is very effective. Earcons are likely to be confused if the rhythms are similar even if there are large spectral differences. Very short note lengths might not be noticed so do not use very short sounds. Earcons should be kept as short as possible so that they can keep up with interactions in the interface being sonified. Two earcons can be played in parallel to speed up presentation.

Intensity: This should not be used as a cue on its own because it is a major cause of annoyance. Earcons should be kept within a narrow dynamic range so that annoyance can be avoided (see Section 10.3 for more on this issue).

Major/minor mode: Lemmens (2005) showed that by changing from a major to minor key, he could change the affective responses of users to earcons. In Western music, the minor mode is broadly thought of as sad with the major as happy, and this can be used as a further cue to create differentiable earcons.

One aspect that Brewster also investigated was musical ability—as earcons are based on musical structures, is it only musicians who can use them? The results showed that the more complex earcons were recalled equally well by non-musicians as they were by musicians, indicating that they are useful to a more general audience of users.

In a further series of experiments, Brewster (1998b) looked in detail at designing hierarchical earcons to represent larger structures (with more than 30 earcons at four levels). These were designed based on the guidelines described earlier. Users were given a short training period and then were presented with sounds and they had to indicate where the sound was in the hierarchy.

Results were again good with participants recalling more than 80% correctly, even with the larger hierarchy used. The study also looked at the learning and memorability of earcons over time. Results showed that even with small amounts of training users could get good recall rates, and that the recall rates of the same earcons tested a week later was unchanged.

In a recent work, McGookin and Brewster (2004) have looked at presenting multiple earcons in parallel. This is problematic unless done carefully as the structures used to create earcons also cause them to overlap when played in parallel. McGookin suggested each earcon should have an onset delay and different spatial location to improve understanding. For examples of earcons in use, see the sonically enhanced widgets and Palm III work in Sections 10.7.1 through 10.7.3.

10.6.3 Sonification

Building on the work on accessibility comes from the idea of making data accessible. Sonification, or visualization in sound, can be used to present complex data nonvisually. There are many situations in which sonification can also be useful for sighted users (if they only have access to a small screen for example), or in combination with graphical feedback in multimodal visualization systems. Sonification is defined as "… the transformation of data relations into perceived relations in an acoustic signal for the purposes of facilitating communication or interpretation" (Kramer and Walker 1999). The range of sonification goes from the clicks of the Geiger counter to multidimensional information presentation of stock market data.

Mansur, Blattner, and Joy (1985) performed one of the most significant studies presenting data in sound. Their study, which laid out the research agenda for subsequent research in "sound graphs," used sound patterns to represent 2D line graphs. The value on the *y*-axis of the graph was mapped to pitch and the *x*-axis to time; this meant that a listener could hear the graph rise and fall over time in a similar way that a sighted person could see the line rising and falling. This is the basic technique used in most sonification systems.

They found that their approach was successful in allowing distinctions to be made between straight and exponential graphs, varying monotonicity in graphs, convergence, and symmetry. However, they did find that there were difficulties in identifying secondary aspects of graphs such as the slope of the curves. They suggested that a full sound graph system should contain information for secondary aspects of the graph such as the first derivative. Their suggestion was to encode this information by adding more overtones to the sound to change the timbre. They also suggested using special signal tones to indicate a graph's maxima or minima, inflection points, or discontinuities. Many other studies have been undertaken to develop this presentation technique further, most notably the studies by Flowers and Hauer (1992, 1995) and Walker (2002).

Walker and Cothran (2003) have produced the *Sonification Sandbox* to allow auditory interface designers to design sound graphs easily and rapidly. The software allows "… users to independently map several data sets to timbre, pitch, volume, and pan, with full control over the default, minimum, maximum, and polarity for each attribute." This gives the designers the chance to prototype sonifications, without having to create their own, custom-made applications. The software is freely available from http://sonify.psych.gatech.edu/research.

10.6.4 Tactons

Tactons (Brown and Brewster 2006) are structured vibrotactile messages that can be used to communicate information nonvisually. They are the tactile equivalent of earcons and visual icons, and could be used for communication in situations where vision is overloaded, restricted, or unavailable. Tactons are created by manipulating the parameters or dimensions of cutaneous perception to encode information. The most important dimensions (or parameters) are detailed below:

Locus: The body is a large area on which tactile actuators can be placed making locus (or spatial location) an important consideration. In his laboratory study, Geldard (1960) found that participants could reach levels of 100% recognition using seven actuators placed on the rib cage and the same results for five actuators on the chest. One issue that should be taken into account is the fact that, with standard vibrotactile actuators, the vibration emanates across the body and is not simply confined to underneath the actuator. Furthermore, when two or more actuators are activated simultaneously, it can often feel as though there is only one actuator.

Intensity: As mentioned in earcons, amplitude/intensity is not used as a parameter because users find loud sounds annoying and report annoyance when the volume level is out of their control. Using intensity as a parameter in tactons is equally problematic as reducing the amplitude could degrade perception of other parameters, or render the signal undetectable, while increasing it too far could cause pain (Geldard 1957). Therefore, it is best to leave amplitude under the control of the user instead of using it to encode information.

Duration: The duration parameter explored by Geldard (1957) is an extremely effective dimension. In his study, durations ranging between 0.1 and 2 seconds were used. 100% identification rates were achieved when four or five levels with intervals of at least 0.15 seconds were used. Differences in duration enable rhythmic structures to be created. However, it must be noted that stimulating an area of skin for an extended period can result in adaptation or even pain.

Frequency: As for tactile frequency, unfortunately humans cannot literally "hear through the skin" as the detectable frequency ranges for each modality are different (although with some overlap). Using frequency as a parameter has been difficult in experiments with issues rising from its influence on intensity perception. Frequency has yet to be used as a parameter in tacton research, but MacLean and Enriquez (2003) used multidimensional scaling techniques to determine how haptic icons can be created from signal parameters such as waveform, frequency, and force. They found that for the ranges of parameters that they implemented in a handheld knob, frequency played a dominant role in distinguishing between the multidimensional stimuli and that waveform and force were less helpful.

Waveform: Geldard (1957) suggested that it may be possible to distinguish between tactile waveforms provided the frequency of the stimuli is low and does not interfere. Musical composition studies have suggested that waveform can be correlated with the "texture" of tactile stimuli (Gunther, Davenport, and O'Modhrain 2002).

Rhythm: Rhythm is an extremely important parameter in earcon design and is the primary parameter used in tactons with recognition rates of over 90% achieved when three different rhythms are used (Brown, Brewster, and Purchase 2005). Rhythms can be created by grouping pulses of different durations. The rhythms used in tactons are based on Brewster's guidelines for rhythms in earcons (Brewster, Wright, and Edwards 1995).

10.6.4.1 Other Haptic Icons

Another approach to developing tactile or haptic icons involves identifying the basic elements, called haptic phonemes, and using these to create different haptic icons. With this method, Enriquez, MacLean, and Chita (2006) created a set of nine haptic icons that varied in terms of waveform and frequency. They then trained participants to associate each haptic icon with an arbitrary concept, such as the name of a fruit. They found that participants learned these associations after about 25 minutes of training and achieved higher identification rates with stimuli that varied in frequency (81% correct), compared with those that varied in waveform (73% correct).

Rovers and van Essen (2005) also mentioned the use of icons with haptic feedback. They stated that the message can be designed as a real-world signal such as a heartbeat or can be based on an abstract design. An abstract design requires the use of a set of common rules, for example, three pulses are equal to "off." In this case, variability can be represented in glyphs, for example, changing intensity based on running speed: the faster the speed, the higher the intensity.

10.6.5 Crossmodal Icons

Crossmodal interaction is a subset of multimodal interaction where the different senses are used to receive the same data. This provides a common representation of the data from both senses (in this case, audio and tactile) making them congruent informationally (Hoggan 2010b). Crossmodal use of the different senses allows the characteristics of one sensory modality to be transformed into stimuli for another sensory modality. Multimodal interaction, on the other hand, may also use the different senses to receive different information.

So, for example, in crossmodal interaction with a mobile device both the audio and tactile feedback would represent the same data, for example, an alarm. Whereas in multimodal interaction, the vibrotactile cue may indicate an alarm, the audio cue may represent a completely different type of information such as incoming messages.

The most popular example of crossmodal interaction can be seen in sensory substitution research. Sensory substitution systems take environmental data, which would normally be processed by one sensory system, and translate this data into stimuli for another sensory system (Lenay, Canu, and Villon 1997). The main application of these systems is increasing accessibility for those with sensory impairments. This class of systems includes tactile vision substitution, tactile auditory substitution, and teletouch.

Nonspeech audio and tactile displays are ideal candidates for crossmodal use because our senses of hearing and touch share several important similarities, in particular their temporal characteristics and their ability to perceive vibrations. An attribute that can communicate comparable information across modalities is considered to be amodal (Mendelson 1979). The shared temporal and spatial properties between audio and tactile mean that certain audio characteristics may be transformed into tactile stimuli (and *vice versa*) very easily (see Table 10.1). Therefore, the same data may be presented interchangeably via the two different modalities in crossmodal interaction depending on a user's particular disabilities or current situation.

Two icons may be considered to be crossmodal icons if and only if they provide a common representation of data, which is accessible interchangeably via different modalities (Hoggan 2010a).

As is the case with all types of icon including the earcons and tactons, for crossmodal icons to convey data successfully,

TABLE 10.1
Parameters Available in the Audio and Tactile Modalities

Parameter	Available in Audio?	Available in Tactile?
Rhythm	Yes	Yes
Pitch	Yes	No
Loudness (amplitude)	Yes	Yes
Timbre (texture)	Yes	Yes
Duration	Yes	Yes
Intensity	Yes	Yes
Spatial location	Yes	Yes
Rate (tempo)	Yes	Yes
Dynamics	Yes	No

there should be a mapping between the data to be communicated and the stimuli presented to the user. Crossmodal icons are structured abstract and use a symbolic approach as opposed to an iconic or indexical approach like those found in visual icons, auditory icons (William Gaver 1987), and hapticons (Mackenzie, Zhang, and Soukoreff 1999). These are not based on any preexisting understanding of the mapping between data and sound or touch. In other words, these mappings are arbitrary and require users to be trained to understand the relationship between data and sound or touch explicitly.

Crossmodal icons allow the same data to be accessible interchangeably via several different modalities. For example, a set of earcons/tactons can be considered to be crossmodal if the information represented can be encoded in both modalities so that users can move from an audio to a tactile presentation of the same data (and *vice versa*).

Multiple dimensions of data can be encoded in crossmodal icons, with each represented by a different crossmodal parameter. For example, if audio/tactile crossmodal icons were used to represent files in a computer interface, the file type could be represented by rhythm (in audio and tactile), size by duration (audio and tactile), and creation date by intensity (audio and tactile). Each file type would be mapped to a unique rhythm equivalent in both modalities. Therefore, two files of the same type and same size but different creation date would share the same audio/tactile rhythm and audio/tactile duration but would use different levels of audio/tactile intensity.

10.6.6 Comparing Feedback Types

Earcons and auditory icons are both effective at communicating information in sound. There is more formal evidence of this for earcons as more basic research has looked at their design. There is less basic research into the design of auditory icons, but the systems that have used them in practice have been effective. More detailed research is needed into auditory icons to correct this problem and to provide designers with design guidance on how to create effective sounds. It may be that each has advantages over the other in certain circumstances and that a combination of both is the best. In some situations, the intuitive nature of auditory icons may make them favorable. In other situations, earcons might be best because of the powerful structure they contain, especially if there is no real-world equivalent of what the sounds are representing. Indeed, there may be some middle ground where the natural sounds of auditory icons can be manipulated to give the structure of earcons.

The advantage of auditory icons over earcons is that they are easy to learn and remember because they are based on natural sounds and the sounds contain a semantic link to the objects they represent. This may make their association to certain, more abstract, actions or objects within an interface more difficult. Problems of ambiguity can also occur when natural sounds are taken out of the natural environment and context is lost (and people may also have their own idiosyncratic mappings). If the meanings of auditory icons must be learned then they lose some of their advantages and they come closer to earcons.

Earcons are abstract so their meaning must always be learned. This may be a problem, for example, in “walk up and use” type applications. Research has shown that little training is needed if the sounds are well designed and structured. Leplâtre and Brewster (2000) have begun to show that it is possible to learn the meanings implicitly while using an interface that generates the sounds as it is being used. However, some form of learning must take place. According to Blattner, Sumikawa, and Greenberg (1989), earcons may have an advantage when there are many highly structured sounds in an interface. With auditory icons, each one must be remembered as a distinct entity because there is no structure linking them together. With earcons, there can be a strong structure linking them that can easily be manipulated. There is not yet any experimental evidence to support this.

“Pure” auditory icons and earcons make up the two ends of a presentation continuum from representational to abstract. In reality, things are less clear. Objects or actions within an interface that do not have an auditory equivalent must have an abstract auditory icon made for them. The auditory icon then moves more toward the abstract end of the continuum. When hearing an earcon, the listener may hear and recognize a piano timbre, rhythm, and pitch structure as a kind of “catch-phrase” representing an object in the interface; he or she does not hear all the separate parts of the earcon and work out the meaning from them (listeners may also try and put their own representational meanings on earcons, even if the designer did not intend it as found by Brewster [1998b]). The earcon then moves more toward the representational side of the continuum. Therefore, earcons and icons are not necessarily as far apart as they might appear.

There are not yet any systems that use both types of sounds to their full extent and this would be an interesting area to investigate. Some parts of a system may have natural analogs in sound, and, therefore, auditory icons could be used; other parts might be more abstract or structured and earcons would be better (Figure 10.7). The combination of the two would be the most beneficial. This is an area ripe for further research.

The other major decision when choosing the type of nonvisual feedback to use is the choice of modality. If choosing audio, then Section 10.6.1 can inform the choice of earcons or auditory icons, both of which have been shown to be effective in communicating information through sound.

However, as mentioned in Section 10.2, audio feedback can be annoying if the volume is too loud or can go completely unnoticed if too quiet. Furthermore, there are social acceptability issues with audio feedback. It can be seen as rude to wear headphones when in the company of others

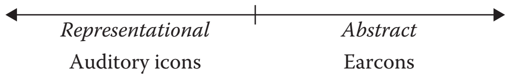

FIGURE 10.7 The presentation continuum of auditory icons and earcons.

(Hoggan and Brewster 2010). In these cases, it may be more advantageous to present feedback using the tactile modality due to its private and subtle nature.

When audio or tactile feedback is used in mobile situations, there are additional issues to consider. When the device is in a bag or pocket, tactile feedback can go unnoticed. When a user is in a noisy environment like public transport or listening to music, audio feedback can be ineffective. In these situations, there is a need for mobile devices to provide alternative presentation modalities through which information may be presented if the context requires. As the context changes, so should the feedback modality (guidelines can be found in the study by Hoggan et al. [2009]). By using concepts from crossmodal interaction and sensory substitution, mobile devices could translate data into an auditory or tactile form so that it can be presented in the most appropriate modality to suit the context. For example, alerts providing information to the user about incoming messages (for example, SMS, MMS, or phone call) could be encoded using crossmodal methods in both the audio and tactile modalities. By making these alerts available to both the auditory and tactile senses, users can receive the information in the most suitable way, without having to abandon their primary task to look at the device.

10.7 APPLICATIONS OF NONSPEECH FEEDBACK

Auditory and tactile output has been used in a wide range of different situations and applications. This section outlines some of the main areas of use and highlights some of the key papers in each area (for more uses of sound and touch, see the ICAD [www.icad.org], World Haptics [www.worldhaptics.org], or the Association for Computing Machinery international conference on Human factors in computing systems (ACM CHI) [www.acm.org/sigchi] series of conferences).

10.7.1 Graphical User Interfaces

One long-running strand of research in the area of auditory and tactile output is in the addition of sound and vibrations to standard graphical displays to improve usability. One reason for doing this is that users can become overloaded with visual information on large, high-resolution displays. In highly complex graphical displays, users must concentrate on one part of the display to perceive the visual feedback, so that feedback from another part may be missed. This becomes very important in situations where users must notice and deal with large amounts of dynamic data. For example, imagine you are working on your computer writing a report and are monitoring several on-going tasks such as a compilation, a print job, and downloading files over the Internet. The word-processing task will take up your visual attention because you must concentrate on what you are writing. To check when your printout is done, the compilation has finished, or the files have downloaded, you must move your visual attention away from the report and look at these other tasks. This causes the interface to intrude into the task you are trying to perform. If information about these other tasks were presented in sound or touch, then you could continue looking at the report but hear or feel information in the background about the other tasks.

One of the earliest pieces of work on sonic enhancement of an interface was Gaver's SonicFinder (1989). This used auditory icons to present information about the Macintosh interface redundantly with the graphical display.

Brewster (1998a) investigated the addition of sound to enhance graphical buttons. An analysis of the way buttons are used was undertaken highlighting some usability problems. It was found that the existing visual feedback did not indicate when mis-presses of a button might have occurred. For example, the selection of a graphical button is shown in Figure 10.8 (starting with 1.A and 2.A). The button highlights when it is pressed down (1.B and 2.B in Figure 10.8). There is no difference in feedback between a correct selection (1.C in Figure 10.8) and a mis-selection (2.C in Figure 10.8), where the user moves the mouse off the graphical button before the selection is complete. The user could therefore "slip off" the button, fail to press it, and get no feedback. This error can happen when the user is moving away from the button and on to some other task. For example, the user moves to a toolbar to press the "Bold" button and then moves back to the text to position the cursor to start typing. The button press and the mouse move overlap so that the button is not pressed. It is hard for the user to notice this because no feedback is given.

The problems could not easily be solved by adding more graphical feedback: The user is no longer looking at the button's location, so any feedback given there will be missed. Feedback could be given at the mouse location, but we cannot be sure that the user will be looking there either. Brewster designed a new button that used auditory feedback to indicate more about the state of the button. This was advantageous as sound is omnidirectional and the user does not need to focus attention on any part of the screen to perceive it.

Three earcons were used to improve the effectiveness of graphical buttons. An organ timbre was used for all of the sounds. When the user moved over a button, a continuous tone was played at 130 Hz at a volume just above the

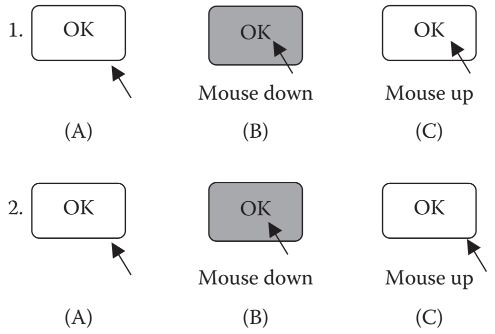

FIGURE 10.8 The visual feedback presented by a graphical button when selected. 1 shows a correct selection and 2 shows a slip-off. (From Brewster, S. A. 1998a. *Interact Comput* 11(2):211–35. With permission.)

background sound level. This informed the user the cursor was over the target (but could easily be habituated). When the mouse was pressed down over the graphical button, a continuous tone was played at 261 Hz. The third sound indicated that the graphical button had been successfully selected. This sound consisted of two short tones with a pitch of 1046 Hz and duration of 40 milliseconds. This sound was not played if a slip-off error occurred. If the user pressed the button very quickly, then only the success sound was played to avoid unnecessary feedback.

An experimental evaluation of these sounds was undertaken. Results showed that users recovered from slip-off errors significantly faster and with significantly fewer mouse clicks when sounds were present in the buttons. The users also significantly preferred the buttons with sound when asked to rate subjective preference. An interesting point to note was the fact that the use of no sound when a sound was expected could be attention grabbing. The participants could easily recognize a slip-off due to the demanding nature of the success sound *not* being played. This is important as reducing the amount of feedback presented is one way to make sure that it is not annoying.

Many other widgets have been successfully sonified. Beaudouin-Lafon and Conversey (1996) showed that nonspeech sounds could improve usability of scrollbars; Maury, Athenes, and Chatty (1999) and Marila (2002) added sounds to improve menu selections in drop-down menus. Ronkainen and Pasanen (2005) have done several studies into the design of audio feedback for buttons. Brewster and colleagues have investigated a wide range of different widgets including scroll bars, menus, progress bars, tool palettes, and drag and drop (Brewster 1998a). These widgets have been included in a toolkit (Crease, Gray, and Brewster 2000) that designers can use to add sound easily to their interfaces.

In terms of tactile feedback for widgets, Lee et al. (2004) created a system for providing tactile feedback for stylus-based touch-screen displays called the Haptic Pen. The Haptic Pen provides personal tactile feedback for multiple simultaneous users and can operate on large touch screens as well as ordinary surfaces. A pressure-sensitive stylus was combined with a small solenoid to generate a range of different tactile sensations. The tactile simulations generated by the Haptic Pen (the feedback when pressing a button appeared to feel realistic). The tactile feedback was intended to simulate the sensation of pressing a physical button or dragging a physical object. There was no formal study of the Haptic Pen so there can be few conclusions drawn but the initial findings indicate that the use of tactile feedback is an effective approach to simulating the sensation of pressing a physical button. Furthermore, the tactile feedback does not necessarily have to originate from the screen itself but can be incorporated into a stylus.

10.7.2 Users with Visual Impairments

One of the most important uses for sound and touch is in interfaces for people with visual disabilities. One of the main deprivations caused by blindness is the problem of access to information. A person with visual impairments will typically use a screen reader and a voice synthesizer to use a computer. The screen reader extracts textual information from the computer's video memory and sends it to the speech synthesizer to speak it. This works well for text but not well for the graphical components of current user interfaces. It is still surprising to find that many commercial applications used by people with visual impairments make little use of nonspeech sound or tactile feedback, concentrating on synthetic speech output. This is limiting (as discussed above) as speech is slow, can overload short-term memory, and is not good for presenting certain types of information; for example, it is not possible to render many types of images via speech so these can become inaccessible to people with visual impairments. One reason for the lack of use of sound and touch has been how to use it effectively, as Edwards (1995) says: "Currently the greatest obstacle to the exploitation of the variety of communications channels now available is our lack of understanding of how to use them." The combination of speech and nonspeech feedback such as earcons or tactons can increase the amount of information presented to the user. As long as this is done in a way that does not overload the user, then it can improve access to information. Some of the main research into the use of nonspeech interfaces for people with visual impairments will now be described (for more on perceptual impairments in general, see Chapter 38).

Soundtrack was an early attempt to create a word processor designed to be used by persons with visual impairments and was developed by Edwards (1989). It used earcons and synthetic speech as output and was designed so that the objects a sighted user would see in an interface, for example menus and dialogues, were replaced by auditory equivalents that were analogies of their visual counterparts. Its interface was constructed from auditory objects with which the user could interact. They were defined by a location, a name, a sound, and an action. They were arranged into a grid of two layers (see Figure 10.9) analogous to menus.

Each auditory object made a sound when the cursor entered it, and these could be used to rapidly navigate around the screen. Soundtrack used sine waves for its audio feedback. Chords were built-up for each menu depending on the number of menu items. For the edit menu, a chord of four notes was played because there were four menu items within it: cut, copy, paste, and find.

The base sounds increased in pitch from left to right—as in the normal representation of a musical scale (for example, on a piano), and the top layer used higher pitches than the bottom. Using these two pieces of information, a user could quickly find his or her position on the screen. If any edge of

File manu	Edit menu	Sound menu	Format menu

FIGURE 10.9 Soundtrack's main screen. (From Edwards, A. D. N. 1989. *Hum Comput Interact* 4(1):45–66. With permission.)

the screen was reached, a warning sound was played. If at any point the user got lost or needed more precise information, he or she could click on an object and it would speak its name.

The approach taken in Soundtrack was to take the visual interface to a word processor and translate it into an equivalent auditory form. The *Mercator* system (Mynatt and Edwards 1995; Mynatt and Weber 1994) took a broader approach. The designers' goal was to model and translate the graphical interfaces of X Windows applications into sound without modifying the applications (and thus create a more general solution than Soundtrack's). Their main motivation was to simulate many of the features of graphical interfaces to make graphical applications accessible to users with visual impairments and keep coherence between the audio and visual interfaces so that users with visual impairments and sighted users could interact and work together on the same applications. This meant that the auditory version of the interface had to facilitate the same mental model as the visual one. This did not mean that they translated every pixel on the screen into an auditory form; instead, they modeled the interaction objects that were present. Modeling the pixels exactly in sound was ineffective due to the very different nature of visual and auditory media and the fact that graphical interfaces had been optimized to work with the visual sense (e.g., the authors claim that an audio equivalent of overlapping windows was not needed as overlapping was just an artifact of a small visual display). Nonspeech sound was an important aspect of their design to make the iconic parts of a graphical interface usable.

Mercator used three levels of nonspeech auditory cues to convey symbolic information presented as icons in the visual interface. The first level addressed the question of "what is this object?" In Mercator, the type of an interface object was conveyed with an auditory icon. For example, touching a window sounded like tapping a piece of glass, container objects sounded like a wooden box with a creaky hinge, and text fields used the sound of a manual typewriter. Although the mapping was easy for interface components such as trashcan icons, it was less-straightforward components that did not have simple referents in reality (e.g., menus or dialogue boxes, as discussed in Section 10.7.2). In Mercator, auditory icons were also parameterized to convey more detailed information about specific attributes such as menu length. Global attributes were also mapped into changes in the auditory icons. For example, highlighting and graying-out are common to a wide range of different widgets. To represent these, Mynatt et al. used sound filters. A low-pass filter was used to make the sound of a "grayed-out" object duller and more muffled.

Sensory substitution using the sense of touch has been used by persons with visual impairments for many years in the form of Braille (Lenay, Canu, and Villon 1997). In addition, vibrotactile displays have been developed to aid persons with visual impairments in accessing visual information such as text and pictures. There have been two main approaches to encoding information in these displays. The first two devices use a pictorial representation of the data: An image is captured by a camera and is reproduced directly as a pattern by vibrating the corresponding pins or actuators in a vibrotactile array. The third system uses a more abstract, coded approach to encode the information, where there is no direct relationship between the vibrotactile stimulus and the data that it represents and, therefore, the mapping between the two has to be learned. The final system uses an encoding scheme which is somewhere between these two approaches; some pictorial elements are retained, but where this is not possible some more abstract coding occurs.

The Optacon was developed in the 1960s as a commercially available reading device for people with visual impairments and was manufactured until production ceased in 1996. A small camera was moved over any material (text or graphics) that the user wished to read. The image captured by the camera was then presented to the user's fingertips through a 6 × 24 array of metal pins. This system used a direct, pictorial representation of the data, with the pins vibrating (at 230 Hz) to create a tactile reproduction of the image captured by the camera (detailed in the study by Craig and Sherrick [1982]). The Optacon was found to be reasonably effective, with reading speeds of around 10–12 wpm (words per minute) after the initial 9-day training period, reaching 30–50 wpm after further training and experience. Although these reading speeds are significantly slower than Braille, where the average reading speed for an adult is 104 wpm, the Optacon was beneficial for people with visual impairments as it allowed them to access any text or graphics without having to wait for it to be converted into Braille or tactile diagrams. The only parameter used to encode information in the Optacon display is the spatial pattern created by the pins. The user can control the speed of presentation by varying the speed at which they move the camera, but no other parameters are varied to encode data.

The Tactile Vision Substitution System, like the Optacon, converted images captured by a camera into vibrotactile patterns presented to the user's skin, with the aim of substituting vision (see the study by Craig and Sherrick [1982]). The user sat in a chair, which had a 20 × 20 array of vibrotactile transducers built into the back of it, and objects captured by the camera were presented by stimulating the transducers to make a pattern, which represented that object. These transducers were either on or off and could, therefore, only represent light and dark (nothing in between). Users were able to distinguish horizontal and vertical lines, and pick which object was being presented from a choice of 25, but had difficulty with the internal details of objects, such as facial features.

10.7.3 Mobile and Ubiquitous Computing

One of the major growth areas in computing at the beginning of the twenty-first century has been in mobile and ubiquitous computing. People no longer just use computers while sitting at a desk. Mobile telephones, PDAs, and handheld computers are now widely used (see Chapter 13 for more on mobile and ubiquitous computing). One problem with these devices is that there is a very limited amount of screen space on which to display information: The screens are small as the devices must be able to fit into the hand or pocket to be easily carried. Small screens can easily become cluttered with information and widgets and this presents a difficult challenge for interface designers.

The graphical techniques for designing interfaces on desktop interfaces do not apply well to handheld devices. Screen resources are limited; memory and processing power are much reduced from desktop systems. However, in many cases interface designs and interaction techniques have been taken straight from standard desktop graphical interfaces (where screen space and other resources are not a problem) and applied directly to mobile devices. This has resulted in devices that are hard to use, with small text that is hard to read, cramped graphics, and little contextual information. Audio and tactile feedbacks are an important way of solving these problems.

Another reason for using sound or touch is that if users are performing tasks while walking or driving, they cannot devote all of their visual attention to the mobile device. Visual attention must remain with the main task for safety. It is therefore hard to design a visual interface that can work well under these circumstances.

Brewster developed the ideas of sonified buttons described in Section 10.7.1 and applied them to buttons on the 3Com Palm series of pen-based handheld computers (Brewster 2002). Many of the same feedback problems with buttons apply in handhelds as in desktops, but are worse as the screen is smaller (and may be hard to see when the device is moving or the sun is shining). In addition, there is the problem of the stylus (or finger) obscuring the target on the display, which makes it difficult for users to know when they are pressing in the correct place. Simple earcons were used to overcome the problems. One aim of the work was to see if adding audio could reduce the size of the widgets so that screen space could be saved and to see the effects when users were on the move.

The results in general confirmed those of the previous study. Subjective workload in the sonically enhanced buttons was reduced compared with their silent counterparts. The addition of sound allowed the participants to enter significantly more five-digit strings than in the corresponding silent treatment, with smaller sonic buttons as effective as larger silent ones. When walking, there was a 20% drop in performance overall, with the sonic interface still performing better than the standard one. Participants walked further when sound was added, and the small buttons with sound allowed as much text to be entered as the large, silent buttons. The suggested reason for this was that users did not have to concentrate so much of their visual attention on the device, as much of the feedback needed was in sound, and so could look where they were going. This would therefore allow the size of items on the display to be reduced without a corresponding decrease in usability.

Sawhney and Schmandt (1999, 2000) developed a wearable computer-based personal messaging audio system called *Nomadic Radio* to deliver information and messages to users on the move. One of the aims of this system was to reduce the interruptions to a user caused by messages being delivered at the wrong time (e.g., mobile telephone calls being received in a meeting, a PDA beeping to indicate an appointment in the middle of a conversation). In the system, users wore a microphone and shoulder-mounted loudspeakers that provide a basic planar 3D audio environment (see Section 10.4.3) through which the audio was presented. A clock-face metaphor was used with 12:00 in front of the user's nose, 3:00 by the right ear, 6:00 directly behind the head, and so on. Messages were then presented in the position appropriate to the time that they arrived. The advantage of the 3D audio presentation (as described above) is that it allows users to listen to multiple simultaneous sound streams at the same time and still be able to distinguish and separate each one (the "cocktail party" effect [Arons 1992] shows that listeners can attend one stream of sound among many, but also monitor the others in case they need attention).

The system used a context-based notification strategy that dynamically selected the appropriate notification method based on the user's focus of attention. Seven levels of auditory presentation were used from silent to full speech rendering. If the user was engaged in a task, then the system was silent and no notification of an incoming call or message would be given (so as not to cause an interruption). The next level used "ambient" cues (based on auditory icons) with sounds like running water indicating that the system was operational. These cues were designed to be easily habituated but to let the user know that the system was working. The next level was a more detailed form of auditory cue giving information on system events, task completions, and mode transitions. For example, a ringing telephone sound was used to indicate the arrival of voicemail. These were more attention grabbing than the ambient cues and would only be played if the user was not fully occupied. The next four levels of cue used speech, expanding from a simple message summary up to the full text of a voicemail message. These might be used if the person wearing Nomadic Radio was not involved in tasks that required detailed attention. The system attempted to work out the appropriate level to deliver the notifications by listening to the background audio level in the vicinity of the user (using the built-in microphone) and if the user was speaking or not. For example, if the user was speaking, the system might use an ambient cue so as not to interrupt the conversation. Users could also press a button on the device to indicate they were busy and so turn it to silent.

Three-dimensional sound has been combined with gestures to create interactions where users can point at sound sources to choose them. An early example was from Cohen (1993) who created audio windows that users could manipulate with gestures, much as windows on a desktop computer could be controlled. Brewster et al. (2003) made this idea mobile and created a soundscape of audio sources around a listener's head that presented different types of information.

Users nodded at a sound source of interest to select it. A simple study showed that users could walk and nod to select items, but that there were many issues with sound placement and feedback. Further study by Marentakis looked at different types of gestures and feedback to improve the quality of mobile 3D audio interactions (Marentakis and Brewster 2004).

There has been much work in the area of notification systems using audio for ambient displays. Carefully designed nonspeech audio can grab attention and then fade into the background. An early example was *Audio Aura* by Mynatt et al. (1998), which aimed "to provide serendipitous information, via background auditory cues, that is tied to people's physical actions in the workplace." In a similar way to Nomadic Radio, Audio Aura used auditory icons to provide background information that did not distract users.

The system used active badges so that the location of users could be identified and appropriate audio cues given, along with wireless headphones so that users could hear the sounds without distracting others. The location information from the active badges was combined with other data sources such as on-line calendars and e-mails. Changes in this information triggered audio cues sent to the user through the headphones.

Here are some examples of how the system might be used. In the first example, the user goes to the office coffee room and while entering the room he or she hears information about the number and type of e-mail messages currently waiting. This would give the user a cue whether to stay and talk to their colleagues or go back to the office to answer the messages. In the second example, a user goes to his or her colleague's office but the occupant is not there. Audio Aura would play sounds indicating if the occupant has been in recently or away for a longer period. The authors were keen to make sure the sounds were not distracting and attention grabbing—they were meant to give background information and not to be alarms. To this end, great care was taken with the cue design. They attempted to design "sonic ecologies"—groups of sounds that fitted together into a coherent whole. For example, one set of cues was based on a beach scene. The number of new e-mails was mapped to seagull cries: The more e-mails the more the gulls cried. Group activity levels were mapped to the sound of surf: The more activity going on within the group the more active the waves became. These cues were very subtle and did not grab users' attention, but some learning of the sounds would be needed as they are quite abstract.

This work was taken on and implemented in a realistic environment by Kilander and Lonnqvist (2001, 2002). They created a *Weakly Intrusive Ambient Sound scape* (WISP) where states in the computational or physical ubiquitous computing environment are presented as subtle, nonintrusive sound cues based on auditory icons, with each cue "sufficiently nonintrusive to be accepted without disturbing the focus of the task at hand, while distinctive enough to be separable from other cues." They described a meeting room scenario where devices such as handheld computers, public PCs, and clocks might all be able to make sounds and give cues for ambient awareness. The level of intrusiveness of the sounds could be varied. For low intrusiveness, a quiet sound was played with lots of reverb, making the cue sound far away and almost inaudible, whereas for high intrusiveness sharp sounds were played with no reverb.

One problem with the system was choice of sounds; users could be detected by the environment and their personal sound mappings and parameters chosen. However, these mappings could conflict with others' choices; for example, two users might use the same sound cue for different events. This could be solved to some extent with local presentation of the sounds, as in Nomadic Radio, but global cues would be more of a problem for these types of systems.

Earcons have also been used to provide previews of information. Shirazi et al. (2010) introduced the concept of audio previews of SMS. Based on a real-time analysis of the content of a message, auditory cues were provided in addition to the notification tone upon receiving an SMS. A field study showed that the use of audio-enhanced SMS affects the reading and writing behavior of users. There was a significant impact when it comes to checking messages in situations where users are engaged in other activities. For example, question marks often led users to check messages immediately.

Shengdong et al. (2007) created earPod, a touch-based menu technique with reactive auditory feedback through simple stereo audio based on time and intensity differences between the ears. The results of a user study showed that earPod is efficient to use and relatively easy to learn. For fairly large static menus, the earPod method was comparable in both speed and accuracy with an iPod-like visual menu selection technique. Furthermore, although initially slower, earPod outperformed the visual technique within 30 minutes of training.

Many mobile interfaces have also been successfully augmented with tactile feedback, which may be appropriate at times when audio feedback could go unnoticed such as in noisy environments. Nashel and Razzaque (2003) added tactile cues simulating real buttons to virtual buttons displayed on mobile devices with touch screens. Hoggan, Brewster, and Johnston (2008) also studied the use of tactile feedback for text entry in mobile environments. The experiment compared devices with a physical keyboard, a standard touch screen, and a touch screen with tactile feedback added in both static and mobile environments. The results showed that the addition of tactile feedback to the touch screen significantly improved finger-based text entry, bringing it close to the performance of a real physical keyboard. A second experiment showed that higher specification tactile actuators could improve performance even further with fewer errors and greater speeds of text entry compared with standard touchscreen keyboards without tactile feedback.

One advantage of using tactile feedback is that actuators can be placed all over the body of the user. Lee and Stamer (Lee and Thad 2010) presented Buzz wear, a tactile display for the wrist, which provides alerts for mobile users. The first experiment focused on the perception sensitivity of tactile patterns and showed that people can discriminate 24 tactile patterns on the wrist with up to 99% accuracy after 40 minutes of training. Among the four parameters (intensity, starting point, temporal pattern, and direction) that vary in the 24 patterns, intensity is the most difficult parameter to distinguish and temporal pattern is the easiest. The second experiment focused on dual-task performance, exploring users' abilities to perceive three incoming alerts from two mobile devices with and without visual distraction. The results showed that, when visually distracted, users' reactions to incoming alerts become slower for the standard mobile phone but not for the wrist-based tactile display.

10.7.4 Crossmodal Applications

Despite the fact that research has shown both audio and tactile icons to be effective means of communication, the area of crossmodal auditory/tactile displays has been studied less. Recently, Immersion Corporation has created VibeTonz (http://www.immersion.com), which could be considered crossmodal. These are vibrotactile messages that can be used, like personalized ringtones, to indicate the identity of the caller in a mobile phone. However, there have been no empirical tests conducted to determine the effectiveness of these cues or to discover the amount of information that could be encoded in the cues.

The Touch Engine by Sony is another system that could be considered crossmodal. Sony's Touch Engine has a vibrotactile screen through which users can feel images and buttons that are on the screen. In the Touch Engine, a heart icon is represented by a heartbeat sensation (Poupyrev, Rekimoto, and Maruyama 2002). Although this is not a direct translation from vision, it is an intuitive, direct translation from sound and, in fact, the sense of touch itself (as you can feel someone's heartbeat).

Chang and O'Sullivan (2005) are some of the small number of researchers who have used both the audio and tactile modalities in a mobile device. In the most basic terms, tactile feedback is added to enhance the audio feedback in a standard mobile device. The authors argue that by using integrated stimulation of the five basic senses, the sense of cognition is engaged more fully. The authors present techniques for audio manipulation to create simple vibrotactile feedback based on the fact that both the audio and tactile modalities are made up of vibrations. A filter is applied to split the sound into its constituents, that is, vibrotactile and audio. In this case, any frequencies below 300 Hz were amplified and presented through the tactile actuators. Frequencies above this level were presented through audio. Although in this case the tactile feedback is used purely as an enhancement to the audio modality, the crossmodal similarities between the modalities are exploited through the use of frequency.

Lastly, Hoggan and Brewster (2010) conducted a longitudinal summative evaluation of a touch-screen application, CrossTrainer, which uses crossmodal earcons and tactons on a mobile touch-screen device. The aim was to investigate the everyday use of crossmodal audio and tactile feedback and to study user performance and preference over time. The results of the study showed that crossmodal feedback aids users in entering answers quickly and accurately using a variety of different widgets. Furthermore, the results demonstrated that users can switch between modalities and reach 100% recognition rates of multidimensional crossmodal alerts after 2 days of regular use. Overall, the CrossTrainer study highlighted issues to consider when choosing between audio and tactile feedback for a mobile touch-screen application. The results indicated that environmental noise and vibration levels, personal preference, location, and period of use should be taken into account when choosing between nonspeech audio and tactile feedback.

10.8 CONCLUSIONS

Research into the use of nonspeech sounds and tactile feedback for information display has shown its benefits in a wide range of different applications from systems for blind people to ubiquitous computing. There are many good examples that designers can look at to see how sound or touch may be used effectively and design guidelines are now starting to appear.

Three areas are likely to be important in its future growth. The first is in combining the sound and tactile modalities with others (vision, force-feedback, etc.) to create multimodal or crossmodal displays that make the most of the all the senses available to users. This is an area ripe for further investigation, and there are many interesting interaction problems that can be tackled when multiple senses are used together. The second area in which crossmodal audio and tactile feedback could play a major role is with multitouch and tabletop interfaces. In these cases, feedback will be required for separate fingers and also separate users. Many large touch-screen computers use direct finger-based multitouch input and a 360-degree user experience. This configuration means that users should be able to use the table without restriction no matter where they are positioned around it. Both audio and tactile feedback could be advantageous over visual feedback alone. The third area in which nonspeech sound and tactile feedback has a large part to play is with mobile/wearable computing devices (again also in a multimodal or crossmodal form). Small screens cause many difficult presentation problems, and this is exactly the situation in which sound or touch has many advantages—they do not take up any precious screen space and users can hear or feel it even if they cannot look at their device. In a ubiquitous setting, there may not even be a screen at all and sound or tactile feedback can provide information on the services available in a particular environment in a nonintrusive way.

11 Network-Based Interaction

Alan Dix

CONTENTS

11.1 INTRODUCTION

In some ways, this chapter could be seen as redundant in a human–computer interaction (HCI) book—surely networks are just an implementation mechanism, a detail below the surface, and all that matters are the interfaces that are built on them. However, networked interfaces, especially the web, but increasingly also mobile devices, have changed the way we view the world and the way we view the society. Even those bastions of conservatism, the financial institutions have found themselves in sea-change and a complete restructuring of the fundamentals of businesses … just an implementation detail! Indeed networks have become so ubiquitous, so enmeshed in our day-to-day lives that it is becoming hard to distinguish to envisage interaction that is not network-based.

11.1.1 Structure

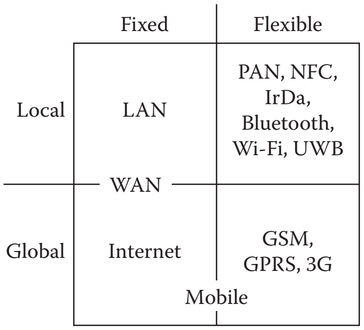
The chapter will begin with a brief overview of types of networks (Section 11.2), focused on the network as technical infrastructure. It then deals with network-based interaction under four main headings:

- Networks as enablers (Section 11.3): things that are only possible with networks
- Networks as mediators (Section 11.4): issues and problems because of networks
- Networks as subjects (Section 11.5): understanding and managing networks
- Networks as platforms (Section 11.6): algorithms and architectures for distributed interfaces

In addition, there will be a section (Section 11.7) that takes a broader view of the history and future of network interaction and the societal effects and paradigm changes engendered, especially by more recent developments in global and wireless networking.

11.2 ABOUT NETWORKS

The word network will probably make many think of accessing the Internet and the web. Others may think of a jumble of Ethernet wires between the PCs in their office, maybe broadband router at home, or Wi-Fi hotspots in cafes. In fact, the range of networking standards including physical cabling (or lack of cabling) and the protocols that computers use to talk down those cables is extensive. Although most of the wire-based networks have been around for some time, they are in a state of flux as a result of increases in scale and the demands of continuous media. In the wireless world, things are changing even more rapidly with new generations of data service being introduced every few years.



As an aid to seeing the broader issues surrounding these changing (and, in some cases potentially ephemeral) technologies, we can use the following two dimensions to classify them:

- Global versus local
  - How spatially distant are the points connected—ranging from machines in the same room (IrDa, Bluetooth), through those in a building/site (local area network [LAN]) to global networks (Internet, mobile-phone networks).

- Fixed versus flexible
    - How permanent are the links between points of the network, from physically fixed machines, to self-reconfiguring devices that recognize other devices in their vicinity.

The fixed versus flexible dimension is almost, but not quite terrestrial versus wireless. The “not quite” is because fixed networks increasingly involve wireless links. Also, it is often possible, when visiting another organization, to plug a portable computer into a (wired) Ethernet network and find you have access to the local printers, Internet connections, and so on—flexible wire-based networking.

Let us look at a few network technologies against these dimensions. Traditional office LANs are squarely in the local-fixed category, whereas the Internet is largely global-fixed category. Corporate wide area networks, connecting offices within the same national or international company, sit somewhere between. Sometimes these corporate networks use dedicated lines for security, but more often now use virtual private networks (VPNs) layered on top of the Internet.

Mobile phones have been placed within the global-fixed category as well. This may seem strange—the phone can go anywhere. However, the interconnections between phones are fixed and location independent. If two mobile phones are in the same room, it is no easier to connect between them than if they are at opposite ends of the earth (bar a shorter lag time perhaps).

Similarly, the Internet although increasingly accessible through mobile devices and phones is largely based on fixed domain names, Internet Protocol (IP) numbers, and URLs.

Given the placement of mobile phones is a little ambiguous, and it is possible to detect the location of phones and thus deliver location-based content, some of the phone technologies have been listed in the global-flexible category: Global System for Mobile Communications (GSM), General Packet Radio Service (GPRS), and 3G. There is obviously a steadily increasing data rate and third-generation services are able to cope with heavy media content including live video. A few years ago, it seemed like the “killer app” to sell these services would be live sports highlights, but actually it is users’ viewing and uploading of their own content: videos to YouTube and photos to Flickr or Facebook that are the main use of this bandwidth. Perhaps, the most significant changes in mobile telecoms have been in the charging and connectivity model. With GSM you are connected when required to the Internet, and this was treated like any other telephone call, usually meaning pay per minute while connected. In contrast, second- and third-generation services are based on sending small packets of data (the P in the GPRS acronym). The connection to the Internet is treated as “always on” and packets of data are sent to or from the phone as required. Charging is also typically by data use or by fixed charge.

In the local-flexible category, there is a host of existing and emerging technologies. At the most mundane are the now ubiquitous Wi-Fi networks and hotspots (based on the 802.11 Protocol) (IEEE 2001). These merely treat the machine the same as if it were plugged into the local fixed network. At a more local scale, infrared (IrDa)-enabled devices can talk to one another if their infrared sensors are within line-of-sight and Bluetooth (Bluetooth 2001) or emerging wireless technologies such as ZigBee or ultra wideband (Zigbee 2006; WiMedia 2006) allows flexible connections between personal devices. With these a laptop can use a mobile-phone modem, or a Bluetooth hands-free headset can connect to a phone without having to plug in with a piece of wire.

These same technologies can also be used to establish local connections with printers or other devices or even track people using the unique addresses that are often broadcast continually. Thus they offer both the opportunities of accessing fixed public equipment through personal devices, but also the threat of surveillance and hacking everywhere!

Also operating at very close range are various forms of near-field communication technology and radio-frequency identification tags. These are often operated by very close contact, such as touching a train pass to a reader, or wheeling a shipping trolley full of tagged goods near a reader.

Finally, research in wearable computers has suggested using the body itself as the connection between worn devices in a personal area network (Zimmerman 1996). The future is networked and we will become the network.

On the whole, we have seen in the last 10 years the main focus of network-based interaction has moved anticlockwise in this picture from fixed/local networks (mainly LAN), through fixed global networks (the Internet and web explosion), through global mobile networks (mostly phone-based, but including Wireless Application Protocol [WAP], i-mode, etc.) and moving toward flexible local connections between devices. In both the local and global spaces, there has also been a growth of less centrally-controlled networking with peer–peer services establishing decentralized applications over the Internet and wireless ad hoc networks allowing machines to establish networks with no fixed infrastructure.

11.3 NETWORKS AS ENABLERS: THINGS THAT ARE ONLY POSSIBLE WITH NETWORKS

It can be the case that the network is no more than an implementation detail—for example, using a networked disk rather than a local one. However, there are also many applications, like videoconferencing, which are only possible because the network is there. The key feature of networks is the access to remote resources of some kind or other.

11.3.1 Remote Resources

Four kinds of remote things are made accessible by networks:

- People
- Physical things
- Data
- Computation

These may be remote because they are far away from where you normally are, or because you are yourself on the move and hence away from one's own resources (colleagues, databases etc.). Thus mobility can create a need for any or all the above.

11.3.1.1 People

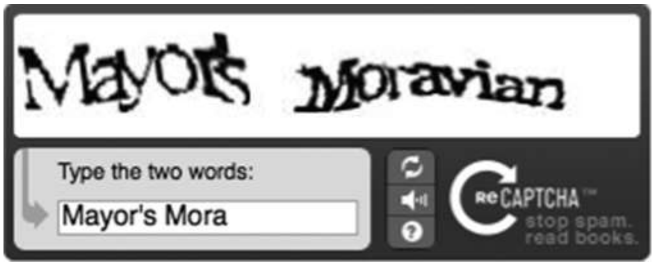
Networks mean we can communicate and work with others in distant places. This is often a direct action, such as e-mailing someone or engaging in a videoconference. These are all the normal study of computer-supported cooperative work (CSCW) and groupware (see Chapter 29).

Interaction with remote people may also be indirect. Recommender systems gather information about people's preferences and use this to suggest further information, services, or goods based on their own preferences and those of others who have similar tastes (Resnick and Varian 1997; Konstan 2004; Riedl and Dourish 2005). Because the people making recommendations are in different locations from each other, the data on who selected what must be stored centrally, or at least with some central control. If you have been suggested books at Amazon, you have experienced a recommender system.

Collaborative virtual environments, such as Second Life, also offer the ability for remote people to interact, but by embedding them within an apparently local virtual reality world. Although the people you are dealing with may be half a world away, their avatar (a virtual presence, perhaps a cartoon character, photo, or robot-like creature) may seem only a few yards or meters away in the virtual world.

Networking has made remote working possible for many years both telecommuting from home and also more nomadic teleworkers such as sales representatives on the road or in hotels (Denbigh 2003). These are largely traditional working relationships, simply freed from the constraints of the office desk. However, networks have made possible a number of more radical remote working styles. Amazon's Mechanical Turk (Amazon 2010) and similar marketplaces allow small pieces of work to be requested, executed, and paid where the person wanting the work and the person doing it have no contact or knowledge of each other except through the website.

More radical are various forms of human computation (also known as crowd sourcing), where substantial tasks are achieved through the small actions of many people, often in the form of a game or puzzle. The most well-known of these is reCaptcha, which is used as a way to ensure users of a web page or service are human and not an automated agent (von Ahn et al. 2008). reCaptcha shows slightly distorted words, which the user needs to type in correctly in order to proceed in the site (see Figure 11.1). However, unlike many schemes where the words are algorithmically distorted from known text, in reCaptcha, the text displayed comes from documents where optical character recognition (OCR) has failed. One of the words is known, but the other is unknown, so that the user is effectively reading the unrecognized word and so slowly increasing the corpus of known text.



Type the two words:

Mayor's Mora

FIGURE 11.1 reCaptcha interface (usually embedded in a web page).

Technology often favors those who are already more materially well off, disadvantaging the poor, the old, and those in countries with a less well-developed technical infrastructure. However, there are some systems which counter this trend.

One is the Net Neighbors scheme in York (Blythe and Monk 2005). Many supermarkets have Internet-based shipping services delivering directly to the home. This would be a great benefit to the elderly, especially those who are house bound or with limited mobility, but these are precisely those least likely to have access to the Internet or be able to use it. Net Neighbors pairs an elderly client with a volunteer. The client telephones the volunteer and dictates a shopping list. The helper then goes to the supermarket site and fills in the online order for delivery direct to the client's doorstep.

Possibly more revolutionary is txteagle (Eagle 2009; txteagle 2009). Txteagle is rather like Mechanical Turk, sending small tasks to independent workers who have registered willingness to perform small tasks. However, the workers in this case are largely illiterate and the tasks (e.g., translation of short phrases) are delivered through mobile phones.

11.3.1.2 Physical Things

We can also view and control remote things at a distance. For example, live webcams in public places allow us to see things (and people) there. Similarly the cameras mounted around rockets as they prepare to take off (and then usually destroyed during the launch) allow the mission controllers to monitor critical aspects of the physical system as do the numerous telemetry sensors, which will also be related through some sort of closed network. And of course the launch command itself will be relayed to the rocket by the same closed network as will the ongoing mission, perhaps the Mars robots, through wireless links.

In the rocket example, it would be dangerous to be in the actual location; in other circumstances, it is merely expensive or inconvenient. Telescopes are frequently mounted in distant parts of the world where skies are clearer than those above the laboratories to which they belong. In order to avoid long international trips to remote places, some of these now have some form of remote control and monitoring using the Internet (Lavery, Kilgourz, and Sykeso 1994).

At a more personal level, the systems within certain high-end cars are controlled using a within car network (called controller-area network (AN)). Even an adjustable heated seat may require dozens of control wires, but with a network, only one power and one control cable is needed. The engine management system, lighting assemblies, radio, CD player, windscreen wipers, each have a small controller that talks through the network to the drivers console (although critical engine systems will usually have a separate circuit).

Many household appliances are now being made Internet-ready. In some cases, this may mean an actual interface—for example, an Internet fridge that can scan the bar-codes of items as you put them in and out and then warn you when items are getting out of date, generate a shopping list of items for you, and even order from your favorite store (Electrolux 1999). Others have instead, or in addition, connectivity for maintenance purposes, sending usage and diagnostic data back to the manufacturer so that they can organize service or repair visits before the appliance fails in some way.

Although these appliances have been available for some years, they are still extremely rare as the benefits for end users rarely seem to justify the substantial price tags. This may change as the environment around becomes increasingly networked. For example, large numbers of consumer items are seen expected to be tagged using near-field communication. The purpose of this is to help stock control and speed up checkouts in shops. However, this will mean that an intelligent refrigerator will be able to identify its contents, know when they were purchased, by-passing the bar-code scanning of first-generation Internet refrigerators.

Another example, that is already with us is the use of iPhones in the home to control (suitable enabled) Hi-Fi equipment, or to remotely program satellite TV receivers. The latter is interesting as the TV receivers already have telephone connections to download program information, so are already "networked" and the iPhone also has semipermanent network connectivity; furthermore the benefit, being able to decide to record a program when not at home, is substantial. We are beginning to see signs of the synergy possible between networked devices.

In some ways, Internet shopping can also be seen in this light. While at one level it is merely a transfer of data, the ultimate end is that you receive physically the ordered goods. This interaction with the remote physical goods is often two-way as you track its progress, and sometimes its physical location through a web interface.

Perhaps most important in a world facing global warming is the potential for the additional information available through networks to improve energy usage. Smart network technologies are already routinely used for very fine grain monitoring of industrial processes and utilities (mqtt.org 2009), and in the home, the smart refrigerator may not only detect when your food is out of date, but also more intelligently monitor power use, making use of periods of low-demand (Anslow 2009). In the past, utilities have managed power production to match consumption, but as renewable energies such as wind-power make power production less controllable, transferring this information down to devices makes managed consumption possible.

11.3.1.3 Data

Anyone using the web is accessing remote data. Sometimes, data is stored remotely purely for convenience, but often data is necessarily stored remotely because

- It is shared by many remote people.
- Central storage helps maintain control, security, or privacy.
- It is used by a single user at different locations (web e-mail).
- It is too extensive to be stored locally (e.g., large databases and thin client).

In the case of the web, the data is remote because it is accessed by different people at different locations, the author(s) of the material, and all those who want to read it.

Even the web is quite complex: We may perceive a web page as a single entity, but in fact it exists in many forms (Figure 11.2). The author of the page will typically have created it offline on his or her own PC. They then upload the page (which effectively means copying it) onto the web server. Any changes the author makes after uploading the page will not be visible to the world until it is next uploaded. When you want to see the page and enter a URL or click on a link, the browser asks the web server for the file which is then copied into the browser's memory and displayed to the user. You can tell the browser has a copy as you can disconnect from the Internet and still scroll within the file. If you access the same page again quite soon, your browser may choose to use the copy it holds rather than going back to the web server, again potentially meaning you see a slightly out-of-date copy of the page. Various other things may keep their own cached copies including web proxies and firewalls.

This story of copied data in various places is not just about the web, but true to some extent or other of all shared networked data. With people or physical things, we do not expect to have the actual person or thing locally, just a representation. This is equally true for shared data, except that the representation is so much like the "real thing;" it is far less obvious to the user.

For shared networked data even the "real thing" may be problematic—there may be no single "golden copy," but instead many variants all with equal right to be called "the real data."

FIGURE 11.3 Apple iDisk—cloud data on the desktop.

You do not even escape networking issues if you only access data locally on your own PC—networking issues may still arise if your data is backed-up over the network, and with cloud data services, virtual disks on the desktop may in fact be simply links to a network that is distributed across the world. For example, in MacOSX, an iDisk is stored remotely on Apple servers, but appears similar to an ordinary folder or local disk (Figure 11.3).

As well as having multiple copies of data, distributed sources and computation can sometimes make it hard for the user to know what the data actually is. For example, when a web page is generated at the server, there may be no "page" at all until data is assembled from a database or web sources at the point of creation, and for a web page created dynamically from AJAX sources, the page delivered, as in Figure 11.2, may be very different than the page viewed by the user.

11.3.1.4 Computation

Sometimes it is remote computational resources that are accessed over the network. The most obvious example of this is large supercomputers. These have enormous computational power, and scientists wishing to use them will often prebook time slots to perform particularly intensive calculations such as global weather simulations, analysis of chemical structure, stress calculations, and so on. Because these machines are so expensive, programs for them are typically developed on other less powerful computers and then uploaded over the network when the supercomputer is available.

If the data required as input or output for the calculation is not too great, "fairly simple" means can be used to upload the programs and data. However, some calculations work on large volumes of data—for example, data from microwave readings of the upper atmosphere to probe the ozone hole generate terabytes (millions of millions of bytes) of data per second. High-capacity networks are being created in many countries to enable both high-volume data for this sort of application and also the expected data required for rich media (Foster 2000; Foster and Kesselman 1999; GRID 2001).

The ease with which data and results can be shipped back and forth across the Internet has enabled the growth of web services: web applications designed to be accessed by other programs supplying services or data. In addition to more scientific or heavy commercial uses of these, they have become a standard part of many consumer-oriented applications, for example, del.icio.us has a standard API accessible through the web allowing third-party applications to interact with it.

Sometimes calculations need to be performed centrally, not because the central computer is powerful, but because the local device is a computational lightweight. For example, one may want to create a remote analysis package where engineers in the field enter data into a personal digital assistant (PDA) or phone interface, but where complex stress calculations are carried out on a small server back in the office. The data on materials and calculations involved may not be extensive by supercomputer standards, but may still be too much for a handheld device.

Because transporting large volumes of data is not always practical, calculations are often performed where the data is. (In performing any computation program, data and computational engine must all be in the same place. If they are not together, then one or the other must be moved or copied to bring them together [Ramduny and Dix 1997].) For example, when you perform a database access, the request for the data is usually transmitted to the database server as an SQL query, for example, "SELECT name, salary FROM payroll WHERE salary > 70000." In principle, the complete contents of the payroll database could be downloaded to your PC and the selection of appropriate records carried out locally; however, it would be more costly to transmit the data, hence the calculation is effectively transmitted to the database server. In a similar vein, Alexa allow third parties to run programs on their servers through their Web Search Platform (AlexaWSP 2006); this allows the programs to access a 100-TB web crawl that would be impractical (and commercially unacceptable) to transfer to clients.

Even when the volume of data is not large or the frequency of access would make it cost effective to transmit it, security or privacy reasons may prevent the download of data. For example, some datasets are available to search to a limited degree on the web, but charge for a download or CD of the complete dataset. My own http://hcibook.com site (Dix et al. 1998) is rather like this, allowing searching of the book's contents online and displaying portions of the text, but not allowing a full download, as readers are expected to buy the book!

Security considerations may also prohibit the distribution of programs themselves if they contain proprietary algorithms. Also if the source of the program is not fully trusted, one may not want to run these programs locally. The latter is the reason that Java applets are run in a software "sandbox" confining the ability of the applet to access local files and other potentially vulnerable resources.

For those who have not come across it, the Search for Extra-Terrestrial Intelligence (SETI) project is analyzing radio signals from outer space looking for patterns or regularities that may indicate transmissions from an alien civilization. You can download a SETI screensaver that performs calculations for SETI when you are not using your machine. Each SETI screensaver periodically gets bits of data to analyze from the central SETI servers and then returns results. This means that the SETI project ends up with the combined computational resources of many hundreds of thousands of PCs.

SETI is an interesting example of remote computation (SETI@home 2001). Normally remote computation involves a device of low-computational power asking a central computer to do work for it. In the case of SETI, large calculations are split up and distributed over large numbers of not particularly powerful computers.

The same technique is used in "PC farms." These are when large numbers of PCs are networked together to act as a form of supercomputer. For example, in CERN (the home of the web), data from high-energy collisions may consist of many megabytes of data for each event, with perhaps hundreds of significant events per second (CERN 2001). The data from each event is passed to a different PC, which then performs calculations on the data. When the PC finishes, it stores its results and then adds itself back to a pool of available machines.

During coming years, we are likely to see both forms of remote computation. As devices become smaller and more numerous, many will become simply sensors or actuators communicating with central computational and data servers (although central here may mean one per room, or even one per body). However, inspired by SETI, several companies are pursuing commercial ways of harnessing the spare, and usually wasted, computational power of the millions of home and office PCs across the world.

If the network is fast enough, it no longer matters where computation happens, hence the growth of cloud computing turning processing into a commodity—if you have a certain amount of computation to do, instead of buying a dedicated machine, you pay for it to happen "somewhere." However, the exception is for highly time-critical tasks and in particular rapid feedback from user interaction. We shall discuss this more in Section 11.4.2, but the crucial thing is that for many interactions, response times of less than a second or in some cases closer to 100 milliseconds are required; hence the move for highly interactive websites to using JavaScript running in the browser rather than server-side computation.

11.3.2 Applications

The existence of networks, particularly the global networks offered by the Internet and mobile-phone networks, have made many new applications possible and changed others.

Several of the more major application areas made possible by networks are discussed in their own chapters: groupware (Chapter 29), online communities (Chapter 30), mobile systems (Chapter 32), e-commerce (Chapter 39), telecommunications (Chapter 40), and of course, the web (Chapter 37).

In addition, networking impinges on many other areas. Handheld devices (Chapter 32) can operate alone, but are increasingly able to interact with one another and with fixed networks through wireless networking. Similarly wearable computers (Chapter 33) are expected to be interacting with one another through short-range networks, possibly carried through our own bodies (makes mobile phones seem positively safe!) and information appliances (Chapter 38) will be Internet connected to allow remote control and maintenance. In the area of government and citizenship (Chapter 41), terms such as e-democracy and e-government are used to denote not just the technological ability to vote or access traditional government publications online, but a broader agenda whereby citizens feel a more intimate connection to the democratic process. Of course, education, entertainment, and game playing are also making use of networks.

Throughout the chapter, we will also encounter broader issues of human abilities, especially concerned with time and delays, involving aspects of virtually all of Part II (human perception, cognition, motor skills, etc.). Also we will find networking raises issues of trust and ethics (Chapters 62 and 65), and of course, the global network increases the importance of culturally and linguistically accessible information and interfaces (Chapter 23).

Networking has already transformed many people's working lives allowing telecommuting, improving access to corporate information while on the move and enabling the formation of virtual organizations. Networks are also allowing whole new business areas to develop, not just the obvious applications in e-shopping and those concerned with web-design.

The Internet has forced many organizations to create parallel structures to handle the more direct connections between primary supplier and consumer (disintermediation).

This paradoxically is allowing more personalized (if not personal) services and often a focus on customer–supplier and customer–customer communication (Siegal 1999; Light and Wakeman 2001). This restructuring may also allow the more flexible businesses to revolutionize their high street (or mall) presence—allowing you to buy shoes in different sizes, or next day fitting services for clothes (Dix 2001b).

The complexity of installing software and the need to have data available anywhere at any time has driven the application service provider sector. You do not install software yourself, but use software hosted remotely by providers who charge on a usage rather than once-off basis. By storing the data with third parties, an organization can off-load the majority of its backup and disaster management requirements.

This process has accelerated with the growth of cloud computing. Providers of these services store and deliver data anywhere in the world using networks of servers, but without it being apparent where on the net the data is stored. More critical computation is available at one of many servers, again without the client needing to be concerned where and when the computation is occurring. For web-based services, this has allowed far more scalable applications, as the provider of the cloud platform will have capacity to allow for a sudden surge in activity. Furthermore, the fact that these services are often charged on a usage basis significantly reduces the barriers to entry for new businesses.

For the individual user, the ubiquity of Internet access for many has enabled many personal information management applications such as e-mail, calendars, bookmark lists, and address books. These things that would once have been seen as personal are being not only accessed through the web, but in many cases also shared. These web communities are no longer the province of geeks, but have become part of day-to-day life of many engendering whole new ways of finding out and getting to know including social bookmarking, blogs, photoblogs (or photologs or phlogs) and social networking sites. New issues arise as personal data becomes distributed over different websites. Who owns it? How do you know what is there? Can you take it with you between sites? The DataPortability Project, is one initiative in this area attempting to create standards and influence industry attitudes so that it is easier to move personal data between sites (DataPortability 2010).

The "personal" device has not become redundant, though, in this web-orientation of applications. In addition to being an access point to global services, it is also a potential interaction device for things close by. For example, in an installation by .:thePooch:. (thePooch 2006) in an arts event the attendees were encouraged to send SMS texts to Andrine, a huge face projected high on the wall. The texts were analyzed using natural language-processing techniques and depending on the content the face took on different emotions: happy, sad, shocked (Lock, Rayson, and Allanson 2003). The cameras in phones are also being used to enable them to be used as location-finding devices (Sarvas et al. 2004), to enable the embedding of SpotCodes or other visual codes in paper posters (Toye et al. 2004; Semacode 2006) and for real-time manipulation of large public displays (Rohs, Sheridan, and Ballagas 2004). Some of these applications use local networking such as Bluetooth, others paradoxically use the "global" connectivity through SMS or WAP to enable local interactions.

11.3.3 Virtual Networks

The word "network" has two meanings: There is the technical communication infrastructure of wired and wireless connections between machines, but atop this various virtual networks of web pages, social networks, and linked data.

The web itself is a network in the sense that each page links to others, creating a network of connections. Of course, it is possible to imagine such networks without there being an underlying communications network. Indeed this was precisely the nature of most early hypertext systems, such as Notecards, which ran on early Xerox Lisp machines (Halasz et al. 1986). However, the fact that the web sits on top of the Internet means it can have a scale beyond anything one would normally consider in a single machine. In fact, this scale is not so much the information capacity; the crawled web is less than a petabyte and can fit in a rack of disks the size of a filing cabinet (Dix 2005). The crucial thing is that a distributed web can be updated in many places my many people, it is the underlying network of people who are connected through the Internet that makes the knowledge embodied in the web possible.

When in 2005 Tim O'Reilly wrote down some of the characteristics of the then emerging web2.0 (O'Reilly 2005), one of the key aspects was "Harnessing Collective Intelligence." In some ways, this creative power of distributed people was already evident in even the earliest web. However, in second-generation web systems such as Wikipedia this became far more clear, as the distributed collective knowledge was brought together. That is, it is the power of the communications network to connect people combined with its power to connect data that makes both the original web and the second generation web2.0 possible.

This interconnecting of people is at the heart of the social networks, which are now part of so many people's lives. Sociologists study the networks of connections between people where there are no computers or telecommunications. However, it is clear that social network sites such as Facebook, Hi5, and MySpace, and microblogging such as Twitter have created something new. Sometimes this is merely another mode of communication for existing nonweb interactions and some social network sites, such as Facebook, are oriented primarily toward this reinforcement of existing connections. Others are more oriented toward forging new connections.

Computer readable data is at the centre of the semantic web (Berners-Lee et al. 2001), which seeks to add explicit semantics to existing web resources … and ultimately everything! The semantic web centers on a number of key technologies. One of the most important is resource description framework (RDF), which is effectively a way of discussing the relationships between "resources," where a "resource" is anything for which you can create a uniform resource identifier (URI). This was initially web pages or parts of them, but over time URIs were defined for nonweb resources such as books, places, and people. This graph of resources and relationships forms another network, but in early semantic web, applications were largely about the web, but each graph of RDF existed separately.

However, the emerging “web of data” or “linked data” is harnessing the communications infrastructure of the web to allow distributed yet interconnected RDF data (Bizer, Heath, and Berners-Lee 2009). The key idea that makes this possible has been to make URIs of nonweb resources actually be dereferenceable—that is, being web documents that describe the resource. For example, the URI http://www.alandix.com/rdf/alandix_xml links to a FOAF (friend-of-a-friend) file (FOAF 2000), which describes some facts about me in RDF (see Figure 11.4). Because of this, the web of knowledge in the linked data world can bridge between individual repositories, if a URI is encountered, it can be looked up to find more information about it, and from it further resources can be accessed. Figure 11.5 shows a map of linked data available in July 2009 including Dbpedia, Wikipedia data represented in RDF. However, since this time, the U.K. government has released vast amounts of data at http://data.gov.uk and other governments around the world are doing the same.

For the user interface, this creates new challenges; how to represent this machine-formatted data effectively to the user? However, there are also enormous opportunities, as massive amounts of data are available to augment user interactions (Dix et al. 2010).

11.4 NETWORKS AS MEDIATORS: ISSUES AND PROBLEMS BECAUSE OF NETWORKS

This section takes as a starting point that an application is networked and looks at the implications this has for the user interface. This is most apparent in terms of timing problems of various kinds. This section is really about when the network is largely not apparent except for the unintended effects it has on the user.

We will begin with a technical introduction to basic properties of networks and then see how these affect the user interface and media delivery.

11.4.1 Network Properties

11.4.1.1 Bandwidth and Compression

The most commonly cited network property is bandwidth—how much data can be sent per second. Those who have used dial-up connections will be familiar with 56-K modems, and those with better memory or those using mobile-phone modems may recall 9.6-K modems or less. The “K” in all of these refers to thousands of bits (0/1 value) per second (strictly Kbps) rather than bytes (single character) that are more commonly seen in disk and other memory sizes. A byte takes 8 bits, and considering a small amount for overhead, you can divide the bits per second by 10 to get bytes per second.

Faster networks between machines in offices are more typically measured in megabits per second (again strictly Mbps but often just written M)—for example, the small “telephone cable” Ethernet is rated at either 10 Mbps or 100 Mbps.

As numbers these do not mean much, but if we think about them in relation to real data, the implications for users become apparent.

A small word processor document may be 30 Kb (kilo bytes). With a 9.6-K GSM modem, this will take approximately half a minute, on a 56-K modem this is reduced to 5 seconds, for a 10-Mb Ethernet this is 30 milliseconds. A full screen web quality graphic may be 300 Kb taking 5 minutes of 9.6-K modem, less than a minute on a 56-K modem, or

```

FIGURE 11.4 Fragment of resource description framework at http://www.alandix.com/rdf/alandix.xml.

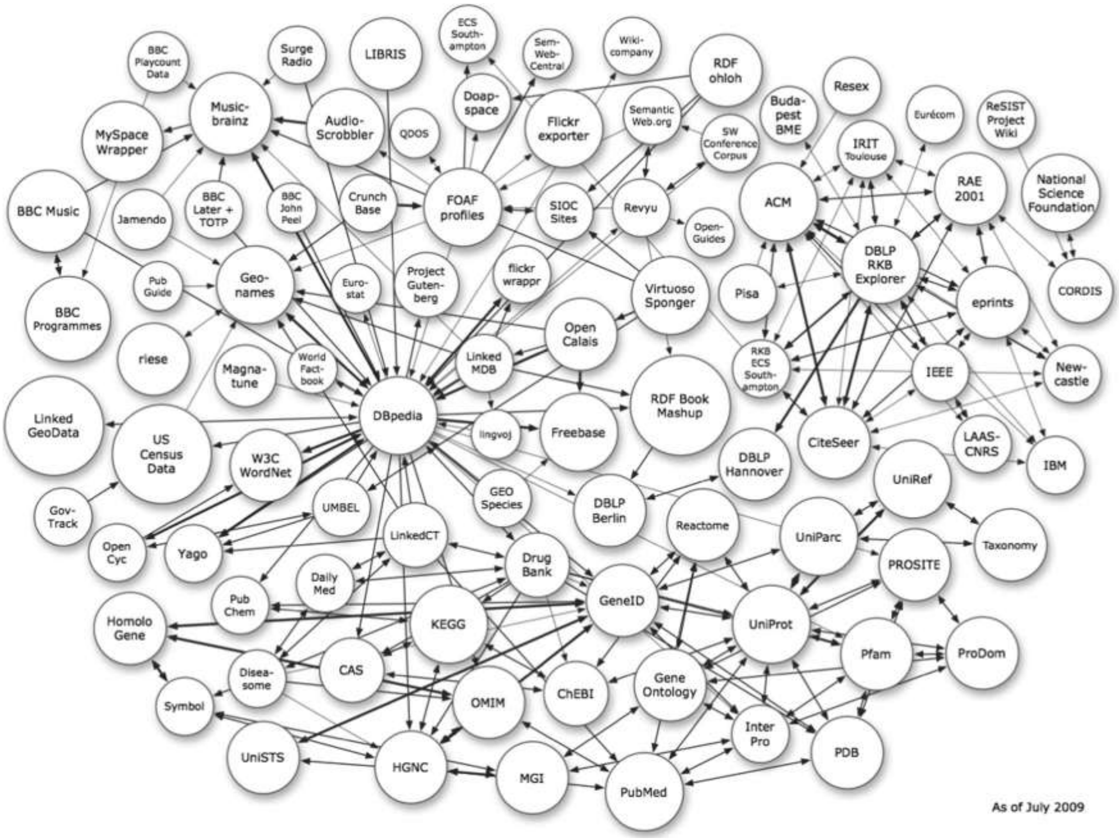

FIGURE 11.5 Linked data as of July 2009 (http://richard.cyganiak.de/2007/10/lod/).

Note that I am using the formula:

$$\text{download time } T = \frac{F \times 10}{M}$$

where F is the size of file in bytes, 10 is the number of raw bits per byte, and M is the modem speed in bits per second.

1/3 second on a 10-Mb Ethernet. (N.B. these are theoretical minimum times if there is nothing else using the network.)

Rich media such as sound or video put a greater load again. Raw, uncompressed Hi-Fi quality sound needs more than 200 Kbps and video tens of Mbps. Happily there are ways to reduce this, otherwise digital AV would be impossible over normal networks.

Real media data has a lot of redundant information—areas of similar color in a picture, successive frames in a video are similar, sustained notes in music. Compression techniques use this similarity to reduce the actual amount of data that needs to be sent (e.g., rather than sending a whole new frame of video, just send the differences from the last frame). Also some forms of compression make use of human perceptual limits: For example, MP3 stores certain pitch ranges with greater fidelity than others as the human ear's sensitivity is different at different pitches (MPEG 2001), also JPEG images give less emphasis to accurate color hue than the darkness/lightness (JPEG 2001). Between them these techniques can reduce the amount of information that needs to be transferred significantly, especially for richer media such as video. Thus the actual bandwidth and the effective bandwidth, in terms of the sorts of data that are transmitted may be very different.

11.4.1.2 Latency and Start-Up

Bandwidth measures how much data can be transferred—latency is how long each bit takes (see Figure 11.6). In terms of a highway, bandwidth would be how many lanes and latency is the time it takes to travel the length of the highway. The latency is due to two factors. The first is the speed of transmission of electricity through wires or light through optical networks. This may seem insignificant, but for a beam of light to travel across the Atlantic would take 20 milliseconds and in practice this hop takes more like 70 milliseconds. For satellite-based communications, the return trip to and from a geostationary satellite takes nearly a second; think about the typical delay you can hear on a transcontinental telephone call. The second factor contributing to latency is that every electronic switch or computer router has to temporarily store, and then decide what to do with the signal before passing it on to the next along the chain. Typically, this is a more major factor, and in practice, trans-Atlantic Internet traffic will take nearly 250 milliseconds from source to final destination, most of which in various computer centers at one end or the other.

Latency is made worse by set-up time. Every time you establish an Internet connection, a conversation is established between your computer and the machine hosting the web server:

> "hello are you there,"
> "yes I'm here what do you want,"
> "I'd like to send you some data,"
> "great I'm waiting,"
> "OK here it is then" (this is called handshaking).

Each turn in this conversation involves a round trip, network latency on both outward and return paths and processing by both computers. And this is before the web server proper even gets to look at your request. Similar patterns happen as you dial a telephone call.

Latency and set-up time are critical as they often dominate the delay for the user except for very large files or streaming audio/visual media. Early web design advice (by those concerned about people with slow connections, but who clearly had never used one!) used to suggest having only as much text that would fit on a single screen. This was intended to minimize the download time. However, this ignores set-up times. A long text page does not take long to load even on a slow connection, once the connection to the web server has been established. Then it is far faster to scroll in the browser than to click and wait for another small page to load. A similar problem is the practice of breaking large images up into a jigsaw of small pieces. There are valid reasons for this—allowing rollover interaction or where parts of the image are of different kinds (picture/text)—however, it is also used without such reasons and each small image requires a separate interaction with the server encountering latency and set-up delays.

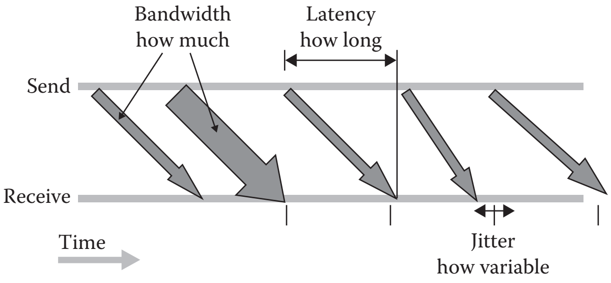

FIGURE 11.6 Bandwidth, latency, and jitter.

11.4.1.3 Jitter and Buffering

Suppose you send letters to a friend every 3 days and the postal service typically takes 2 days to deliver letters (the average latency in network terms). Your friend will receive letters every 3 days, just delayed from when you sent them. Now imagine that the postal system is a little variable, sometimes letters take 2 days, but occasionally they are faster and arrive the next day, and sometimes they are slower and take 3 days. You continue to send letters every 3 days, but if a slow letter is followed by a fast one, your friend will receive them only one day apart, if on the other hand a fast letter is followed by a slow one, the gap becomes 5 days. This variability in the delay is called jitter. (Note that the fast letters are just as problematic as the slow ones—a fast letter followed by a normal speed one still gives a 4-day gap.)

Jitter does not really matter when sending large amounts of data, or when sending one-off messages. However, it is critical for continuous media. If you just played video frames or sound when it arrived, jitter would mean that the recording would keep accelerating and slowing down (see Figure 11.7a and b).

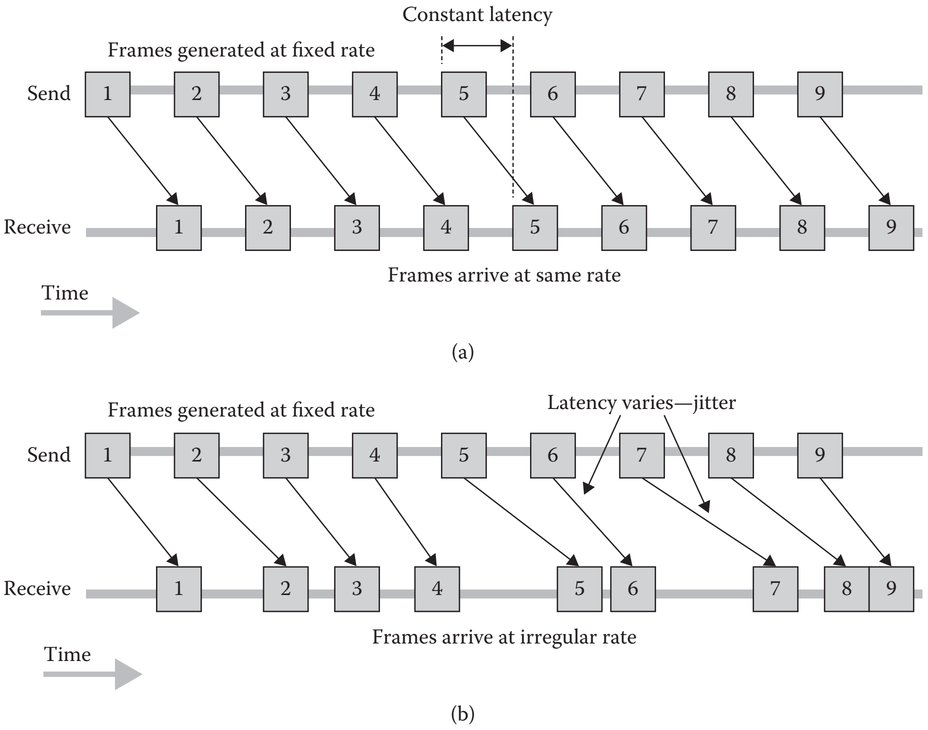

FIGURE 11.7 (a) No jitter—no problem. (b) Jitter causes irregular reception.

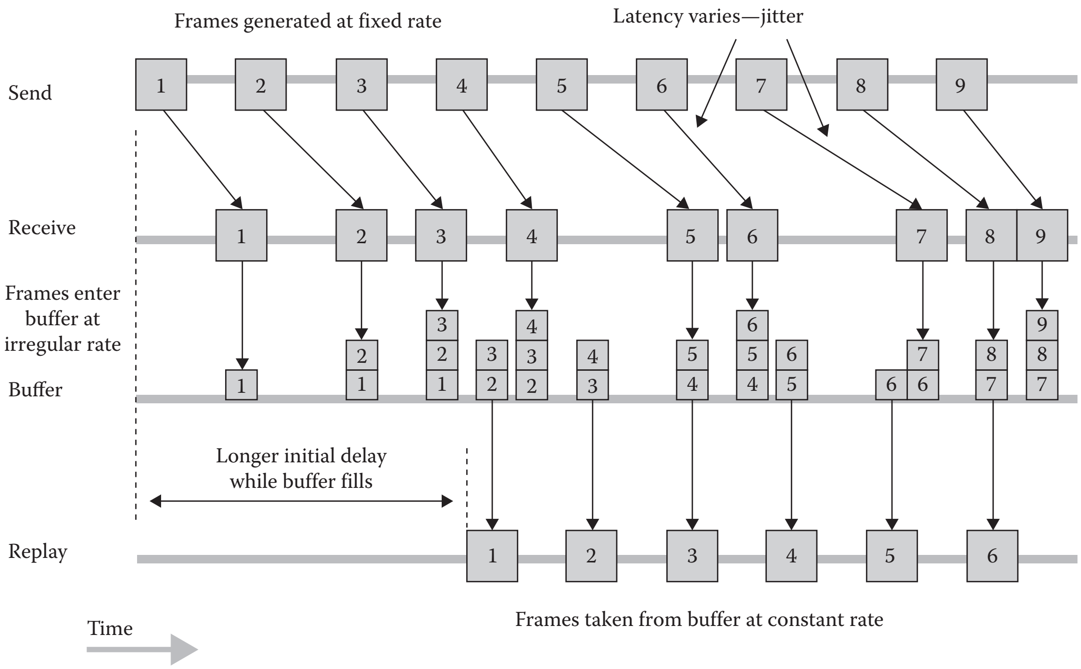


Frames generated at fixed rate
Latency varies—jitter
Send
Receive
Frames enter buffer at irregular rate
Buffer
Longer initial delay while buffer fills
Replay
Time
Frames taken from buffer at constant rate

FIGURE 11.8 Buffering will smooth the jitter, but adds delay.

Jitter can be partially alleviated by buffering. Imagine your friend's postman holds back one letter for 3 days and then starts giving letters to your friend one every third day. If your mail always arrives in exactly 2 days, the postman will always hold exactly one letter as mail will arrive as fast as he passes it on. If however a letter arrives quickly, he will simply hold 2 letters for a few days and if it is slow, he will have a spare letter to give. Your friend's mail is now arriving at a regular rate, but the delay has increased to (a predictable) 5 days. Buffering in network multimedia behaves exactly the same holding back a few seconds audio/video data and then releasing it at a constant rate (see Figure 11.8).

11.4.1.4 Reliability and Loss, Datagram and Connection-Based Services

Virtually all networks are designed on the principle that there will be some loss or damage to data en-route. This arises for various reasons—sometimes there is electrical interference in a wire, and sometimes the internal computers and routers in the network may have too much traffic to cope with. This is normal and network software is built to detect damaged data and cope with lost data.

Because of this, the lowest layers of a network are assumed to be lousy. Any data damaged in transit are discarded, and computers and hardware en-route can choose to discard data if they get busy. So when one computer sends a packet of data to another, it can assume that if the packet of data arrives it will be intact, but it may never arrive at all.

Some network data, in particular certain forms of real-time multimedia data are deliberately sent in this unreliable, message-at-a-time, form (called datagrams).

However, it is usually easier to deal with reliable channels, so higher levels of the network create what are called connection-based services on top of the unreliable lower level service. Internet users may have come across the term Transmission Control Protocol (TCP)/IP. IP is the name of an unreliable low-level service that routes packets of data between computers. TCP is a higher level connection-based service built on top of an IP. The way TCP works is that the computer wanting to make a connection contacts the other and they exchange a few (unreliable IP) messages to establish the link. Once the link is established, the sending computer tags messages it sends with sequence data. Whenever the receiving computer has all the data up to a certain point, it sends an acknowledgement. If the sending computer does not get an acknowledgement after a certain time, it resends the data (Stevens 1998, 1999).

With TCP, the receiving computer cannot send a message back, and when it notices a gap, it has to wait for the sending computer to resend after the timeout. While it is awaiting the resend, it cannot process any of the later data. Notice that this means reliability is bought at the price of potential delays.

11.4.1.5 Quality-of-Service and Reservation

The above properties are not just determined by a raw network's characteristics, such as the length of wires, types of routers, modems, and so on. They are also affected by other traffic—its volume and nature. If 10 PCs are connected to a single 10-Mbps network connection and require high-volume data transfers (perhaps streaming video), then there is only, on average, 1 Mbps available for each. If you are accessing a network service that requires trans-Atlantic connections during peak hours, then intermediate routers and hubs in the network are likely to become occasionally overloaded leading to intermittent packet loss, longer average delays, and more variability in delay, hence jitter. In the past, when the capacity of Internet backbones was lower, it was very obvious in the United Kingdom when the United States "woke up" as the web ground to a crawl!

For certain types of activity, in particular real-time or streaming rich-media, one would like to be able to predict or guarantee a minimum bandwidth, maximum delay and jitter, and so on. These are collectively called quality-of-service (QoS) issues (Campbell and Nahrstedt 1997). Some network protocols allow applications to reserve a virtual channel with guaranteed properties; however, the most common large-scale network, the Internet, does not have such guarantees, and it operates solely on a best endeavor basis. Upgrades to the underlying protocol (called by the catchy name IPv6), allow some differentiation of different types of traffic. This may allow routers to make decisions to favor time-critical data, but it will still not be able to reserve guaranteed capacity. However, in practice, the increased capacity of Internet backbones is allowing large-scale Voice-over-Internet services, such as Skype, with acceptable end-to-end service (FCC 2006; Skype 2006).

11.4.1.6 Encryption, Authentication, and Digital Signatures

Some networks, such as closed office networks, offer no greater worries about security of information than talking together (both are capable of being bugged, but with similar levels of difficulty). However, more open networks such as the Internet, or phone networks, mean that data is travelling through a third party and public infrastructure to get to its recipients. Increasing use of wireless devices also means that it is easier for the data sent between devices to be monitored or interfered with by third parties. One option is to only use physically secure networks, but for economic reasons, this is often not an option.

Furthermore, solutions that do not rely on the network itself being secure are more robust. If you rely on, for example, a private dedicated line between two offices and assume it is secure, then if someone does manage to tap into it, all your interoffice communication is at risk.

The more common approach now is to assume the networks are insecure and live with it. This gives rise to two problems:

secrecy—how to stop others from seeing your data
security—how to make sure data is not tampered with

The first problem is managed largely by encryption methods—ensuring that even if someone reads all your communications they cannot understand them (Schneier 1996). The "https" in some URLs is an example of this denoting that the communication to the web server is encrypted.

The second problem, security, has various manifestations. Given communications are through a network, how do you know that you are talking to the right person/machine. Authentication mechanisms deal with this. In various ways, they allow one machine to verify (usually by secret information that can only be known by the true intended party) that it is talking to the right party.

Even if you know that you are talking to the right person/machine, how do you know that the data you receive has not been changed? This is like receiving a signed letter, but, unbeknownst to you, someone has added some lines of text above the signature, although it really comes from the person you think, the message is not as was sent. If data is being encrypted then this may often implicitly solve this problem as any tampered data is uninterpretable by a third party, who therefore cannot alter it in a meaningful way.

If secrecy is not an issue however, encryption is an unnecessary overhead and instead digital signatures generate a small data block that depends on the whole of the message and secret information known to the sender. It is possible for the recipient to verify that the signature block corresponds to the data sent and the person who is supposed to have sent it. One example of this are "signed applets" where the Java code is digitally signed so that you can choose to only run Java programs from trusted parties.

The choice between different forms of secure network is complex. For example, the U.K. National Health Service installed a dedicated network called N3 to every hospital, family doctor, surgery, and pharmacy in order to support a variety of services including an electronic prescription service (EPS). However other countries introducing EPS (e.g., Bulgaria, Gibraltar) are using standard Internet technology such as VPNs. There were clearly reasons behind the U.K. NHS decision, but interviews with pharmacists suggest problems with the N3 network, and the introduction of EPS seems to have been far slower than those countries adopting a more lightweight approach (Griffiths and Dix 2008).

11.4.2 UI Properties

11.4.2.1 Network Transparency

One of the goals of many low-level network systems is to achieve transparency—that is to make it invisible to the user where on the network a particular resource lays. When you access the web, you use the same kind of URL and same kind of interface whether the web server is in Arizona, Australia, or Armenia. I know that when at home I send an e-mail between two machines less than 2 m apart, the message actually goes all the way across the Atlantic and back—but this is only because I have quite a detailed understanding of the computers involved—as a user I press "send mail" on one machine and it arrives near instantaneously on the other. Cloud storage also creates this sense of transparency, giving access to data from anywhere in the world without caring where the data is actually stored.

Although network transparency has many advantages to the user—you do not care about routes through the network, and so on, there are limits to its effectiveness and desirability. Some years ago, I was at a Xerox lab in Welwyn Garden City in the United Kingdom. Randy Trigg was demonstrating some new features of Notecards (an early hypertext system [Halasz, Moran, and Trigg 1987]). The version was still under development and every so often would hit a problem and a LISP debugger window would appear. After using it for a while, it suddenly froze—no debugger window, no error message, just froze. After a few embarrassing seconds, he hit a control key and launched the debugger. A few minutes of frantic scanning through stack dumps, program traces, and so on, and the reason became clear to him. He had demonstrated a feature that he had last used on his workstation at Palo Alto. The feature itself was not at fault, but required an obscure font that he had on his own workstation, but not on the machine there in Welwyn. When Notecards had requested the font, the system might have thrown up an error window, or substituted a similar font. However, in the spirit of true network transparency, the location of the font should not matter. Having failed to find it on the local machine, it proceeded to interrogate machines on the local network to see if they had it, it then proceeded to scan the Xerox U. K. network, and world network. Eventually, if we had waited long enough, it would have been found on Randy's machine in Palo Alto. Network transparency rarely extends to timing!

Transparency has also been critiqued for CSCW purposes (Mariani and Rodden 1991). It may well be very important to users where resources and people are. For mobile computing also, an executive takes a laptop on the plane only to discover that the files needed are residing on a network file server rather than on the machine itself. If the interface hides location how can one predict when and where resources will be available?

In Section 11.5.3, we will discuss recent work where the presence of intermittent connections, limited range, and variable signal strength is being used as a deliberate feature in interfaces.

11.4.2.2 Delays and Time

As is evident, one of the issues that arises again and again when considering networks is time—how long are the delays, how long to transfer data, how variable, and so on. Networking is not the only reason for delays in applications, but is probably one of the most noticeable—the web has often been renamed the "world-wide wait." There is a longstanding literature on time and delays in user interfaces. This is not as extensive as one might think, largely because for a long time, the prevailing perception in the HCI community was that temporal problems would go away (with some exceptions) leading to what I called the "myth of the infinitely fast machine" (Dix 1987).

One of the earlier influential articles was Ben Shneiderman's review of research findings on delays (Shneiderman 1984)—mainly based on command line interfaces. Since then, there have been a number of workshops and special journal issues on issues of time, sparked largely by web delays (Johnson and Gray 1996; Clarke et al. 1997; Howard and Fabre 1998; Hildebrandt, Dix, and Meyer 2004).

There are three main timescales that are problematic for networked user interfaces:

100 milliseconds —Feedback for hand–eye coordination tasks needs to be less than 100–200 milliseconds to feel fluid. This is probably related to the fact that there are delays of this length in our motor-sensory system anyway. For aural feedback, the timescales are slightly tighter again.

1 second—Timescale for apparent cause–effect links such as popping a window after pressing a button. If the response is faster than this, the effect seems "immediate." This is related to a period of about 1 second that the brain regards as "now."

5–10 seconds—Waits longer than these engender annoyance and make it hard to maintain task focus. This may be related to short-term memory decay.

The 100-millisecond time is hard to achieve if the interaction involves even local network traffic. The 1-second time is usually achievable for local networks (and is assumed by X-Windows systems), but more problematic for long haul networks. The 5- to 10-second time is in principle achievable for even the longest transcontinental connections, but when combined with bandwidth, limitations or overload of remote resources may become problematic. This is especially evident on web-based services where the delay between hitting a link and retrieving a page (especially a generated page) may well exceed these limits, even for the page to begin to draw.

The lesson for UI designers is to understand the sort of interaction required and to ensure that parts of the user interface are located appropriately. For example, if close hand–eye coordination is required, it must run locally on the user's own machine—in the case of the web in an applet, in JavaScript code, and so on. If the nature of the application is such that parts of the application cannot reside close enough to the user for the type of interaction required, then, of course, one should *not* simply have a slow version of (say) dragging an icon around, but instead change the overall interaction style to reflect the available resources.

Two of the factors that alleviate the effects of longer delays are predictability of the delay and progress indicators. Both factors give the user some sense of control or understanding over the process, especially if users have some indication of expected delays before initiating an action (Johnson' 1997). The many variable factors in networked systems make predicting delays very difficult, increasing the importance of giving users some sense of progress. The psychological effect of progress indicators is exploited (cynically) by those web browsers that have progress bars that effectively lie to the user, moving irrespective of any real activity (try unplugging a computer from the network and attempting to access a web page, some browsers will hit 70% on the progress bar before reporting a problem). Other network applications use recent network activity to predict remaining time for long operations (such as large file downloads). Other solutions include generating some sort of intermediate low quality or partial information while the full information is being generated or downloaded (e.g., progressive image formats or splash pages of Flash movies). If a progress bar only is available, research has shown that manipulations of the way it is presented (e.g., pulsating patterns on the bar) can significantly change the perceived wait time (Harrison, Yeo, and Hudson 2010).

For virtual reality using head-mounted displays, as well as hand–eye coordination tasks, we also have issues of the coordination between head movements and corresponding generated images. The timescales here are even tighter as the sensory paths are faster within our bodies, hence less tolerant of external delays. The brain receives various indications of movement: the position and changes of neck and related muscles, the balance sensors in the inner ear, and the visual feedback. Delays between the movement of the generated environment and head movement lead to dissonance between these different senses and have an effect rather like being at sea, with corresponding disorientation and nausea. Also any delays reduce the sense of immersion—being there within the virtual environment. Early studies of VR showed that users' sense of immersion was far better when they were given very responsive wire frame images than when they were given fully rendered images at a delayed and lower frame rate (Pausch 1991).

11.4.2.3 Coping Strategies

People are very adaptable. When faced with unacceptable delays (or other user interface problems) users develop ways to work around or ameliorate the problem—coping strategies. For example, web users may open multiple windows so that they can view one page while reading another (McManus 1997) and users of "telnet" for remote command line interfaces may type "test" characters to see whether the system has any outstanding input (Dix 1994).

Coping strategies may hide real problems, so it is important not to assume that just because users do not seem to be complaining or failing that everything is all right. However, we can also use the fact that users are bright and resourceful by building interface features that allow users to adopt coping strategies where it would be impossible or impractical to produce the interface response we would like. For example, where we expect delays we can ensure that continual interaction is not required (by perhaps amassing issues requiring user attention in a "batch" fashion), thus allowing users to more easily multitask. Unfortunately, this latter behavior is not frequently seen—the "myth" lives on and most networked programs still stop activity and await user interaction whenever problems are encountered.

11.4.2.4 Timeliness of Feedback/Feedthrough, Pace

Although feedback is one of the most heavily used terms in HCI, we may often ignore the complex levels of feedback when dealing with near instantaneous responses of GUI interfaces. In networked systems with potentially long delays, we need to unpack the concept. We have already discussed some of the critical timescales for feedback. For hand–eye coordination getting feedback of less than the 100-millisecond threshold is far more important than fidelity—quickly moving wire frames or simple representations are better than dragging an exact image with drop shadow.

For longer feedback cycles, such as pressing a button, we need to distinguish:

- Syntactic feedback—the system has recognized your action
- Intermediate feedback—the system is dealing with the request implied by your action (and if possible progress toward that request)
- Semantic feedback—the system has responded and the results obtained

The direct manipulation metaphor has led to identification and hence confusion between these levels, and many systems provide little in the way of syntactic or intermediate feedback relying solely on semantic feedback. In networked systems where the semantic feedback includes some sort of remote resource, it is crucial to introduce specific mechanisms to supply syntactic and intermediate feedback, otherwise the system may simply appear to have ignored the user's action (leading to repeated actions with potentially unforeseen consequences) or even frozen or crashed.

This also reminds us of a crucial design rule for slow systems: Wherever possible make actions idempotent—that is, invoking the same action twice, where possible, should have the same effect as a single action. This means that the "try again" response to a slow system does not lead to strange results.

For collaborative systems or those involving external or autonomous resources (remote-controlled objects, environmental sensors, software agents), we must also consider feedthrough. Feedback is experiencing the effect of one's own actions; feedthrough is the effect of one's own actions on other people and things and experiencing the effects of their actions themselves. For example, in an online chat system, you type a short message and press "send" and your message appears in your transcript—feedback—then sometime later it also appears in the transcript of the other chat participants—feedthrough.

Feedback is needed to enable us to work out whether the actions we have performed are appropriate, hence (typically) need to be much quicker than feedthrough responses. This is fortunate as feedthrough by its very nature usually requires network transmission and ensuing delays. The exception to the rule that feedthrough can afford to be slower is where the users are attempting to perform some close collaborative task (e.g., positioning some items using direct manipulation) or where there is a second-fast communication channel (e.g., on the telephone, user A says to user B "see the red box," but the relevant item has not appeared yet on B's screen).

Potentially more important to users of collaborative systems than bandwidth or even raw delays is pace—the rate at which it is possible to interact with a remote resource or person. This is partly determined by lower level timings, but is also heavily influenced by interface design. For example, you know that someone is sitting at his or her desk and you send him or her an urgent e-mail. The time that it takes to get a response will be hardly affected by the raw speeds between your machine and your colleague, and more determined by factors such as how often the e-mail client checks the server for new e-mail and whether it sounds an alert when new e-mail arrives, or simply waits there until your colleague chooses to check the inbox.

11.4.2.5 Race Conditions and Inconsistent Interface States

Alison and Brian are using an online chat program.

Alison writes "It's a beautiful day. Let's go out after work" and then begins to think about it.

Brian writes "I agree totally" and then has to leave to go to a meeting.

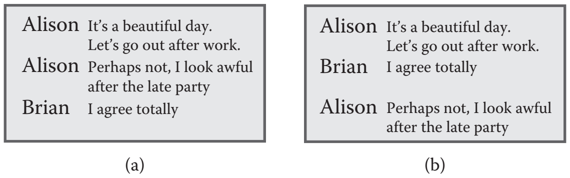
At almost the same time, Alison writes "Perhaps not, I look awful after the late party"

Unfortunately the messages are so close to simultaneous that both Alison and Brian's machines put their own contribution first so Alison sees the chat window as in Figure 11.9a, and Brian sees it as in Figure 11.9b. Brian thinks for a few moments, and then he writes "No you look lovely as ever," but unfortunately Alison never sees this as she takes one look at Brian's previous remark and shuts down the chat program.

This type of incident where two events happen so close together that their effects overlap is called a race condition. Race conditions may lead to inconsistent states for users as in this example, or may even lead to the software crashing. Although in principle race conditions are possible however fast the underlying network, the likelihood of races occurring gets greater as the network (and other) delays get longer.

Even some of the earliest studies in collaborative systems have shown the disorienting effects of users seeing different views of their shared information space, even when this is simply a matter of seeing different parts of the same space (Stefik et al. 1987).

Consistency becomes an even greater problem in mobile systems where wireless connections may be temporarily lost, or devices may be unplugged from fixed networks while on the move. During these periods of disconnection, it is easy for several people to be updating the same information leading to potential problems when their devices next become network connected.



Alison It's a beautiful day.
Let's go out after work.
Alison Perhaps not, I look awful
after the late party
Brian I agree totally

(a)

Alison It's a beautiful day.
Let's go out after work.
Brian I agree totally
Alison Perhaps not, I look awful
after the late party

(b)

FIGURE 11.9 Consistency breakdown. (a) Alison's chat window. (b) Brian's chat window.

In Section 11.6, we will discuss mechanisms and algorithms that can be used to maintain consistency even when delays are long and race conditions likely to occur.

11.4.2.6 Awareness

Returning to Alison and Brian, after Brian has typed his response, he may not know that Alison has not seen his second contribution.

Awareness of who is around and what they are doing is a major issue in CSCW (e.g., Dourish and Bellotti [1992] and McDaniel and Brinck [1997]). It has various forms:

- Being able to tell easily, when you want to know, what other people are doing
- Being made aware (through alerts, very salient visual cues, etc.) when significant events occur, for example, a new user arrives, someone makes a contribution
- Having a peripheral awareness of who is around and what they are up to

Awareness is not just about other people. In any circumstance where the environment may change, but not through your own direct action, you may need to know what the current state is and what is happening. This is not confined to networked applications, but applies to any hidden or invisible phenomena, for example, background indexing of your hard disk contents. In networked applications, anything distant is invisible unless it is made visible (audible) in the interface.

One of the earlier influential experiments to demonstrate the importance of peripheral awareness was ArKola (Gaver, Smith, and O'Shea 1991). This was a simulated bottling factory where two people worked together in maintaining the factory, supplying, maintaining the process, and so on. The participants could not see the entire factory at once, so relied on the sounds produced to be aware of its smooth running or if there are any problems. For example, the sound of breaking glass might suggest that the end of the production line has run out of crates, but if it immediately stopped, one would assume that the other participant had sorted out the problem.

The numerous forms of shared video and audio spaces are another example of this—several people, usually in distant offices establish these long-term, always-on audio, video, or audio–video links between their offices (Buxton and Moran 1990; Olson and Bly 1991). Sometimes these are used for direct communication, but most of the time they just give a peripheral awareness that the other person is there and the sort of activity they are doing. This can be used for functional purposes (e.g., knowing when the other person is interruptible), but also for social purposes—feeling part of a larger virtual office. Other systems have allowed larger numbers of, usually deliberately low quality and so less intrusive, webcam views of colleagues' offices and shared areas (Roussel 1999, 2001). The aim is the same, to build social cohesion, to allow at-a-glance reading of one another's situation, and to promote "accidental" encounters.

A form of awareness mechanism is now common on the web with buddy-lists that tell you when friends are online (ICQ 2001), microblogging such as Twitter feeds and "status" on social network sites such as Facebook. I still know of no examples of rich media experiments in a domestic environment, for example, a virtual kitchen shared with your elderly mother in Minnesota. However, various forms of domestic sharing through the Internet are becoming more common including the early Casablanca project at Interval (Hindus et al. 2001) using shared electronic sketch pads in the home and more recent projects (CASIDE 2005; Taylor et al. 2006). Some of these applications are fairly standard "computer" interfaces, some are soft surveillance, such as monitoring an elderly relative; however, there is also a stream of research looking at more intimate ways of sharing presence including pads that glow or warm when a far-away loved one touches them, or Jenny Tillotson's "Scent Whisper," a pair of Internet connected brooches which emit a pleasant scent when the loved one whispers on the other end (Tillotson 2005).

Trying to capture all this information within a computer display can be distracting, use up valuable screen space, and of course assumes that the computer is there and switched on. For this reason, several projects have looked at ambient interfaces, which in various ways make the physical environment reflect the virtual. These interfaces monitor various events in the electronic worlds and then change things in the physical environment: lights on the wall, moving strings hung from the ceiling, even a shaking potted plant (Lock, Allanson, and Phillips 2000). Again, this is not fundamentally limited to networked environments, but is of course not very useful when the relevant activity is close at hand anyway.

The other side of this is finding out what people are doing in order to signal this to others. For computer activity—are you logged on? have you been typing recently? what web page are you viewing?—this is in principle available, although the various layers of software may make it hard for an awareness service to discover. For noncomputer aspects, this is more problematic—are you in the room, busy, with other people—and may require a range of sensors in the environment: ultrasound, video, and so on, with corresponding privacy issues (see for example Bellotti [1993]). Monitoring of everyday objects is another way to achieve this, for example, one experiment used electronic coffee cups with sensors to tell when they were picked up and moved around (Gellersen, Beigl, and Krull 1999). As more and more devices become networked, it may be that we do not need special sensors, just use the combined information from those available, although the privacy issues remain.

In collaborative virtual reality environments, knowing that other people are around (as avatars) is as important as in a physical world, but harder due to limited senses (usually just vision and sound), limited field of view. Furthermore, there are computational costs in passing information such as audio or even detailed positional information around the network when there are tens, hundreds, or thousands of users. Various spatial models have been developed to analyze and implement the idea of proximity in virtual space (Benford et al. 1994; Rodden 1996; Sandor, Bogdan, and Bowers 1997; Dix et al. 2000, 2005; Dix 2009). These seek to formalize concepts of (1) where your focus of attention is within the virtual world and thus whether you require full quality audio and visual representation of others; (2) broader areas where you would expect some peripheral awareness where potentially degraded information can be used; and (3) those parts of the space for which you need no awareness information.

11.4.3 Media Issues

When describing the intrinsic network properties, issues for continuous media were mentioned several times. This is because, with the possible exception of close hand–eye coordination tasks, continuous media put some of the tightest requirements on the underlying networks.

11.4.3.1 Interactive Conversation and Action

Most demanding of all are audio–visual requirements of interactive conversation. Anyone who has had a transcontinental telephone conversation will have some feeling for the problems a delay of a second or two can cause. While actually speaking, the delays are less significant; however, turn-taking becomes very problematic. This is because the speaker in a conversation periodically (and subconsciously) leaves short (200–300 milliseconds) gaps in the flow of speech. These moments of silence act as entry points for the other participant who is expected to either acknowledge with a "go on" sound, such as "uhm," or perhaps a small nod of the head, or can use to break in with their own conversation. Entries at other points would be seen as butting in and rude, and lack of feedback responses can leave the speaker uncertain as to the listener's understanding. The 200–300 milliseconds is again almost certainly related to the time it takes for the listener's sensory system to get the relevant aural information to the brain, and for the brain to signal the relevant nod, acknowledgement, or start to speak. Clearly our conversational system is finely tuned to the expected intrinsic delays of face-to-face conversation.

When network delays are added, it is no longer possible to respond within the expected 200–300-millisecond window. The speaker therefore gets no responses at the appropriate points, and it is very hard for the listener to break into the flow of speech without appearing rude (by the time they hear the gap and speak, the speaker has already restarted). Some telephone systems are half-duplex; that is, they only allow conversation in one direction at a time, and this means that the various vocalizations ("uhu," "hmm," etc.) that give the speaker feedback will be lost entirely while the speaker is actually talking. It is not uncommon for the speaker to have to resort to saying "Are you there?" due to a loss of sense of presence.

These effects are similar, whether one is dealing with pure audio stream (as with the telephone), video streams (as with desktop conferencing), or distributed virtual environments. One VR project in the United Kingdom conducted all its meetings using a virtual environment in which the participants were represented by cuboid robot-like avatars (called blockies) (Greenhalgh 1997). The project ended with an online virtual party. As the music played the participants (and their avatars) danced. Although they were clearly enjoying, the video of the party showed an interesting phenomenon. Everyone danced alone! There are various reasons for this, for example, it was hard to determine the gender of a potential dancing partner. However, one relates directly to the network delays. Although everyone hears the same music, they all were hearing it at slightly different time; furthermore, the avatars for other people will be slightly delayed from their actual movements. Given popular music rhythms operate at several beats per second, even modest delays means that your partner appears to dance completely out of time! In more recent work, predictive algorithms have been used to create "ghost" figures showing the "best guess" location of people and things in collaborative virtual environments (Gutwin et al. 2004).

11.4.3.2 Reliability

As well as delays, we noted in Section 11.4.1 that network connections may not always be reliable—that is, information may be lost. Video and audio streams behave very differently in the presence of dropped information. Imagine you are watching a film on a long air flight. The break in the sound when the pilot makes an announcement is much more difficult than losing sight of the screen for a moment or two as the passenger in front stands up. At a smaller scale, a fraction of a second loss of a few frames of video just makes the movie seem a little jerky, and a smaller loss of even a few tens of milliseconds of audio signal would make an intrusive click or distortion. In general, reliability is more important for audio than video streams and where resources are limited, it is typically most important to reserve the QoS for the audio stream.

11.4.3.3 Sound and Vision

Why is it that audio is more sensitive than video? Vision works (largely) by looking at a single snapshot—try walking around the room with your eyes shut, but opening them for glances once or twice a second. Apart from the moment or two as your eyes refocus, you can cope remarkably well. Now turn a radio on with the sound turned very low and every second turn the sound up for a moment and back to silent—potentially an interesting remixing sound, but not at all meaningful. Sound more than vision is about change in time. Even the most basic sounds, pure tones, are measured in frequencies—how long between peaks and troughs of air pressure. For more complex sounds, the shape of the sound through time—how its volume and frequency mix changes—is critical. For musical instruments, it is hard to hear the difference between instruments if they are playing a continuous note, but instantly differentiable by their attack—how the note starts. (To get some idea of the complexity of sound, see the review in Mitsopoulos' thesis [Mitsopoulos 2000], and for an insight into the way different senses affect interaction, see my own AVI'96 article [Dix 1996].)

11.4.3.4 Compression

As we discussed in Section 11.4.1, it is possible to produce reliable network connections, but this introduces additional delays. Compression can also help by reducing the overall amount of audio–visual data that needs to be transmitted, but again may introduce additional delays. Furthermore, simple compression algorithms require reliable channels (both kinds of delays). Special algorithms can be designed to cope with dropped data, making sure that the most important parts of the signal are replicated or "spread out" so that dropped data leads to a loss in quality rather than interruption.

11.4.3.5 Jitter

As noted in Section 11.4.1, jitter is particularly problematic for continuous media. Small variations in delay can lead to jerky video play back, but is again even worse for audio streams. First of all, a longer than normal gap between successive bits of audio data would lead to a gap in the sound just like dropped data. And perhaps even more problematic, what do you do when subsequent data arrives closer together—play it faster? Changing the rate of playing audio data does not just make it jerky, but changes the frequency of sound rendering it meaningless.

(Aside: Actually, there are some quite clever things you can do by digitally speeding up sound but not changing its frequency. These are not useful for dealing with jitter, but can be used to quickly overview audio recordings, or catch up on missed audio streams [Arons 1997; Stifelman, Arons, and Schmandt 2001].)

For real-time audio streams, such as videoconferencing or Voice over IP, it is hard to do anything about this, and the best one can do is drop late data and do some processing of the audio stream to smooth out the clicks this would otherwise generate.

11.4.3.6 Broadcast and Prerecorded Media

Where media is prerecorded or being broadcast but where a few seconds delay are acceptable, it is possible to do far better. Recall that in several places we saw that better quality can be obtained if we are prepared to introduce additional delays.

If you have used streaming audio or video broadcasts, you will know that the quality is quite acceptable and does not have many of the problems described in Sections 11.4.3.1 through 11.4.3.5. This is partly because of efficient compression, meaning that video is compressed to a fraction of a percent of its raw bandwidth and so can fit down even a modem line. However, this would not solve the problems of jitter. To deal with this, the player at the receiving end buffers several seconds of audio–visual data before playing it back. The buffering irons out the jitter giving continuous quality.

Try it out for yourself—tune onto a radio channel and simultaneously listen to the same broadcast over the Internet with streamed audio. You will clearly hear up to a minute delay between the two.

Fast and free Internet connections have enabled the sharing and distribution of high-quality media for storing and playing later initially through illegitimate file-sharing including the pre-lawsuit Napster and many current peer–peer applications, but also increasingly through paid-for services such as the current Napster and Apple iTunes (Wikipedia contributors 2006). In addition to forcing existing media publishers to revisit their business models, the rise of web-distributed MP3 and Podcasting has enabled would-be artists and broadcasters to bypass the traditional distribution channels.

11.4.4 Public Perception: Ownership, Privacy, and Trust

One of the early barriers to consumer e-commerce was distrust of the transaction mechanisms—especially giving credit card details over the web. Arguments that web transactions are more secure than phone-based credit cards transactions or even using a credit card at your local restaurant (which gets both card number and signature) did little to alleviate this fear. This was never as major a barrier in the United States as it was, for example, in Europe, but across the world was a concern, slowing down the growth of e-shopping (or really e-buying, but that is another story [Dix 2001a]).

It certainly is the case that transactions through secure channels can be far more secure than physical transactions, where various documents can be stolen or copied en route and are in a format much more easy to exploit for fraud. However, knowing that a transaction is secure is more than the mechanisms involved, it is about human trust. Do I understand the mechanisms well enough, and the people involved well enough, to trust my money to it?

In fact, with a wider perspective, this distrust is very well founded. Encryption and authentication mechanisms can ensure that I am talking to a particular person or company and that no-one else can overhear. But how do I know to trust that person? Being distant means I have few of the normal means available to assess the trustworthiness of my virtual contact. In the real world, I may use the location and appearance of a shop to decide whether I believe it will give good service. For mail order goods, I may use the size, glossiness, and publication containing an advert to assess its expense and again use this to give a sense of quality of the organization. It is not that these physical indicators are foolproof, but that we are more familiar with them. In contrast, virtual space offers few intrinsic affordances. It is easy and quite cheap to produce a very professional web presence, but it may be little more than a facade. This is problematic in all kinds of electronic materials, but perhaps most obvious when money is involved.

As a designer, it is important not just to assure your users that your site is trustworthy, but also to make sure you do not create habits in your users that may be dangerous in the future. For example, e-mail "phishing" attacks often have links to sites at different domains from the sender address of the e-mail, but some e-mails from banks do exactly the same—they may be safe, but they create patterns of use that may mean you end up giving away your bank log-in information to another party. For e-mails on sites that need to be secure, it is often the best policy to simply ask users to go to your website and enter some form of quick access code rather than a clickable link.

Even if I trust the person at the other end, how do I know whether the network channel I am using is of a secure kind? Again the affordances of the physical world are clear: in a closed office versus in the open street versus in a bar frequented by staff of a rival firm. We will say different things depending on the perceived privacy of the location. In the electronic world, we rely on "https" at the beginning of a URL (how many ordinary consumers know what that means?), or an icon inserted by the e-mail program to say a message has been encrypted or signed. We need to trust not only the mechanisms themselves, but also the indicators that tell us what mechanisms are being used (Millett, Friedman, and Felton 2001; Fogg et al. 2001).

In nonfinancial transactions, issues of privacy are also critical. We have already seen several examples where privacy issues occur. As more devices become networked, especially through wireless links and our environment and even our own bodies become filled with interlinked sensors, issues about who can access information about you become more significant. This poses problems at a technical level—ensuring security among devices, at an interface level—being able to know and control what or who can see specific information, and at a perception level—believing in the privacy and security of the systems. There are also legal implications. For example, in the United Kingdom, in 2001, it was illegal for mobile telecoms operators to give location information to third parties (Sangha 2001).

The issue of perception is not just a minor point, but also perhaps the dominant one. Networks, and indeed computer systems in general, are by their nature hidden. We do not see the bits travelling down the wires or through the air from device to device, but have to trust the system at even the most basic level. As HCI specialists, we believe ourselves a little above the mundane software engineers who merely construct computer systems, as we take a wider view and understand that the interaction between human and electronic systems has additional emergent properties and that it is this complete socio-technical unit that achieves real goals. For networked systems, this view is still far too parochial.

Imagine if the personal e-mail of millions of people was being sucked into the databanks of a transnational computer company, and only being released when accessed through the multinational's own web interface. The public outcry! Imagine Hotmail, Yahoo! mail, and so on. How is it that although stored on distant computers, perhaps half the world away, millions of people feel that it is "their" mailbox and trust the privacy of web mail more than perhaps their organization's own mail system. This feeling of ownership of remote resources is more than the technology that protects the security of such systems; it is a cultural phenomenon and a marketing phenomenon. The web mail "product" is not just technology, or interface, but formed by every word that is written about the product in ads, press releases, and media interviews (Dix 2001a).

11.5 NETWORKS AS SUBJECTS: UNDERSTANDING AND MANAGING NETWORKS

When using a networked application, you do not really care what kind of network is being used, whether the data is sent over copper wires, fiber optic, microwave, or satellite. All you care about is that the two ends manage to communicate and the effects that any of the above have on the end-to-end network properties, such as bandwidth discussed in the previous section. However, there are times when the network's internals cannot be ignored.

Those involved in installing or managing networks need to understand the internal workings of the network in order to optimize performance and find faults. For ordinary users, when things go wrong in a networked application, they effectively become a network manager and so understanding something of the network can help them to deal with the problem. Even when things are working, having some awareness of the current state of the network may help one predict potential delays, avoid problems, and minimize costs. In some cases, this can even be used as a positive part of the interactive experience.

We will start this section by looking at some of the technical issues that are important in understanding networks. This parallels Section 11.4.2, but is focused on the internal properties of the network. We will then look at the interface issues for those managing networks and the ways in which interfaces can make users aware of critical network state. Finally, we will look briefly at the way models of networks can be used as a metaphor for some of the motor and cognitive behaviors of humans.

11.5.1 Network Models

11.5.1.1 Layers

Networking is dominated by the idea of layers—lower levels of the network offer standard interfaces to higher levels so that it is possible to change the details of the lower level without changing the higher levels. For example, imagine you are using your laptop to access the Internet while in a train (see Figure 11.10). The web browser establishes a TCP/IP connection to the web server, requests a web page, and then displays it. However, between your laptop and the web server, the message may have travelled through a Bluetooth link to your mobile phone, which then used a cell-based radio to send it to a mobile-phone station, and then through a microwave link to a larger base station onto a fiber-optic telephone network backbone and through various copper wires to your telecom service provider. Your service provider is then connected into another fiber-optic Internet backbone and eventually through more fiber-optic, copper, and microwave links to the web server. To complicate things even further, it may even be that the telephone and Internet backbones may share the same physical cabling at various points. Imagine if your poor laptop had to know about all of this.

In fact, even your PDA will know about at least five layers:

- Bluetooth—how the laptop communicates to the phone
- Modem—how the laptop uses the phone to link to your Internet service provider (ISP)
- IP—how your laptop communicates to the web server computer
- TCP—how data is passed as a reliable connection-based channel between the right program on your PDA and the web-server computer
- HTTP—how the browser communicates to the web server

Each of these hides most of the lower levels, so your browser needs to know nothing about IP, the modem, or the infrared connection while accessing the web page.

The nature of these layers differs both between different types of network, for example WAP, for sending data over mobile phones and devices, has five defined layers (Arehart et al. 2000), the ISO OSI reference model has seven layers (see Figure 11.11) (ISO/IEC7498 1994).

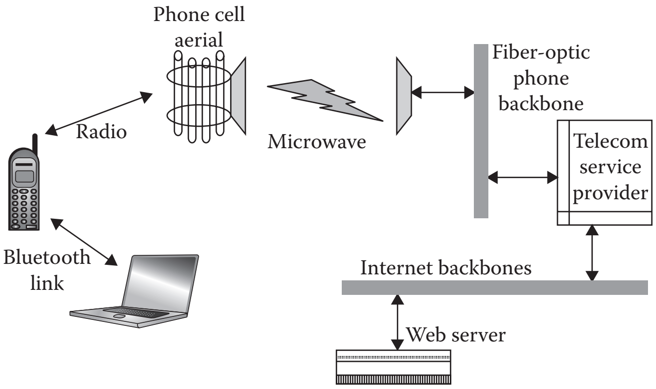


FIGURE 11.10 The long path from laptop to web.

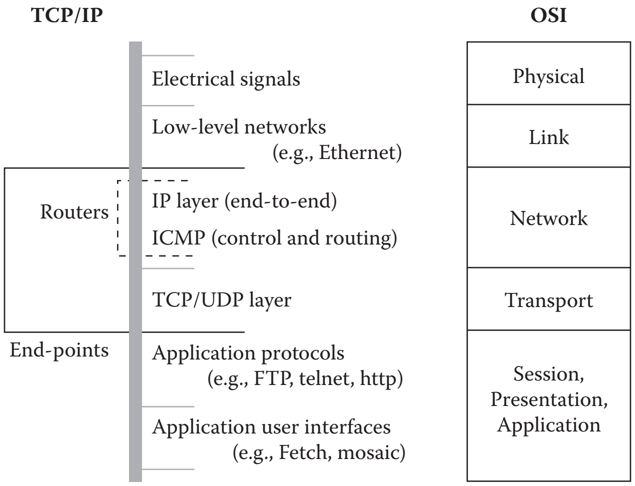

FIGURE 11.11 OSI seven layers and TCP/IP.

Mail program says	SMTP server replies
HELO mypc.mydomain.com	220 mail.server.net ESMTP
MAIL From:<myself@mydomain.com>	250 mail.server.net Hello mypc.mydomain.com[100.0.1.7], pleased to meet you
RCPT To: <a-friend@theirdomain.com>	250 <myself@mydomain.com>… Sender ok
DATA	250 <a-friend@theirdomain.com>… Recipient ok
	354 Enter mail, end with "." on a line by itself

to address	from address	info	data length	data …..

FIGURE 11.13 Typical network packet format (simplified).

Ethernet header			Ethernet body			
			IP header			IP body
Ethernet to addr.	Ethernet from addr.	IP flag data len. etc.	IP to addr.	IP from addr.	Other header IP info	Internet data…..

FIGURE 11.14 Internet IP packet inside Ethernet packet.

11.5.1.2 Protocols

Systems at the same layer typically require some standard language to communicate. This is called a protocol. For higher levels, this may be quite readable. For example, to send an Internet e-mail message, your mail program connects to a simple mail transfer protocol (SMTP) server (a system that relays messages) using TCP/IP and has the exchange shown in Figure 11.12.

At lower levels, data is usually sent in small packets, which contain a small amount of data plus header information saying where the data is coming from, where it is going to, and other bookkeeping information such as sequence numbers, data length, and so on.

Even telephone conversations, except those using predigital exchanges, are sent by chopping up your speech into short segments at your local telephone exchange, sending each segment as a packet and then reassembling the packets back into a continuous stream at the other end (Stevens 1998, 1999).

11.5.1.3 Internetworking and Tunneling

This layering does not just operate within a particular network standard, but between different kinds of networks too. The Internet is an example of an internet (notice little "i") that is a network which links together different kinds of low-level network. For example, many PCs are connected to the Internet through an Ethernet cable. Ethernet sends its own data in packets like those of Figure 11.13. The IP also has packets of a form like Figure 11.13. When you establish an Internet connection through Ethernet, the IP packets are placed in the data portion of the Ethernet packet, so you get something a bit like Figure 11.14.

This placing of one kind of network packet inside the data portion of another kind of network is also used in VPNs in a process called tunneling. These are used to allow a secure network to be implemented using a public network like the Internet. Imagine a company has just two offices, one in Australia and the other in Canada. When a computer in the Sydney office sends data to a computer in the Toronto office, the network packet is encrypted, put in the data portion of an Internet packet, and sent through the Internet to a special computer in the Toronto office. When it gets there, the computer at the Toronto office detects it is VPN data, extracts the encrypted data packet, decrypts it and puts it onto its own local network where the target computer picks it up. As far as both ends are concerned, it appears as if both offices are on the same LAN and any data on the Internet is fully encrypted and secure.

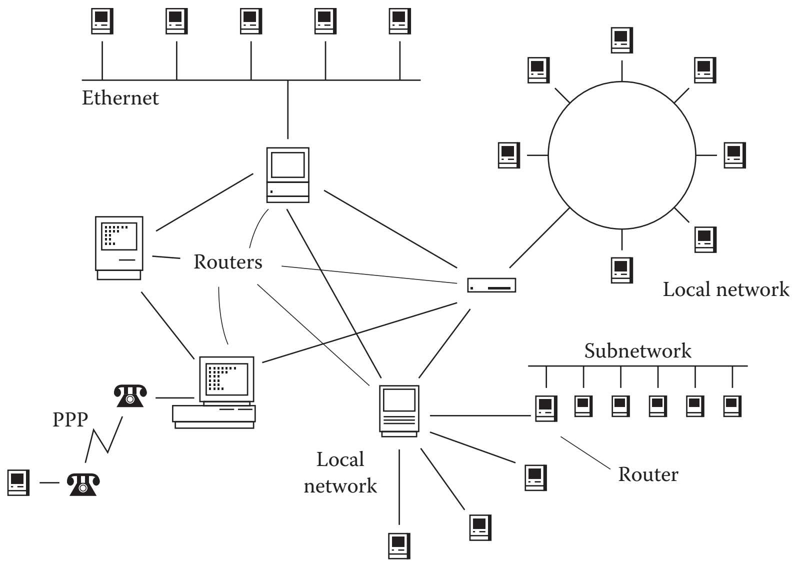

FIGURE 11.15 Routers send messages in the right direction through complex networks.

11.5.1.4 Routing

If two computers are on the same piece of physical network, each can simply listen out for packets that are destined for them, so sending messages between them is easy. If however messages need to be sent between distant machines, for example, if you are dialed into an ISP in the United Kingdom and are accessing a web server in the United States, the message cannot simply be broadcast to every machine on the Internet (Figure 11.15). Instead at each stage, it needs to be passed in the right direction between different parts of the network. Routers perform this task. They look at the address of each packet and decide where to pass it to. If it is a local machine, this might be to simply put it onto the relevant local network, but if not it may need to pass it on to another intermediate machine.

Routers may be standalone boxes in network centers, or may be a normal computer. Often a file server acts as a router between a LAN and the global network.

Besides routers, networks are also linked by hubs and switches, which make several different pieces of physical network behave as if they were one local network, and gateways that link different kinds of network. The details of these are not important, but they add more to the sheer complexity of even small networks.

11.5.1.5 Addresses

In order to send messages on the Internet or any other network, you need to have the address of where they are to go (or at least your computer needs it). In a phone network, this is the telephone number, and on the Internet, it is an IP number. The IP number is a 32-bit number, normally represented as a group of four numbers between 0 and 255 (e.g., 212.35.74.132), which you will have probably seen at some stage when using a web browser or other Internet tool. It is these IP numbers that are used by routers to send Internet data to the right place.

> The 32-bit IP number space allows for 4 billion addresses. This sounds like quite a lot; however, these have been running out because of the explosive growth in the number of Internet devices and "wasted" IP numbers due to the way ranges of numbers get allocated to subnetworks. The new version of TCP/IP, IPv6, which is being deployed, has 128-bit addresses, which requires 16 numbers (IPng 2001). This allows sufficient unique IP addresses for every phone, PDA, Internet-enabled domestic appliance, or even electronic paper clip.

However, with any network, there is a problem of how you get to know the address. With phone numbers, you simply look up the person's name in a telephone directory or by phoning the operator. Similarly, most networks have a naming scheme and some way to translate these into addresses. In the case of the Internet, domain names (e.g., acm.org, www.hcibook.com. magisoft.co.uk) are the naming system. There are so many of these and they are changed relatively rapidly, so there is no equivalent of a telephone directory, but instead special computers called domain name servers (DNS) act as the equivalent of telephone directory enquiries operators. Every time an application needs to access a network resource using a domain name (e.g., to look up a URL), the computer has to ask a DNS what IP address corresponds to that domain name. Only then can it use the IP address to contact the target computer.

The DNS system is an example of a "white pages" system. You have an exact name and want to find the address for that name. In addition, there are so-called "yellow pages" systems where you request, for example, a color postscript printer and are told of addresses of systems supplying the service. Sometimes, this may be mediated by brokers who may attempt to find the closest matching resource (e.g., a non-PostScript color printer) or even perform translations (e.g., the Java JINI framework [Edwards and Rodden 2001]).

This latter form of resource discovery system is most important in mobile systems and ubiquitous computing where we are particularly interested in establishing connections with other geographically close devices.

A final piece in the puzzle is how one gets to know the address of the name server, directory service, or brokering service. In some types of network, this may be managed by sending broadcast requests to a network "is there a name server out there." In the case of the Internet, this is normally explicitly set for each machine as part of its network settings.

11.5.1.6 All Together…

If you are in your web browser and you try to access the URL http://www.meandeviation.com/qbb/, the following stages happen:

1. Send IP-level request to DNS asking for www.meandeviation.com.
2. Wait for reply.
3. DNS sends reply 64.39.13.108.
4. Establish TCP level connection with 64.39.13.108.
5. Send HTTP request ("GET/qbb/HTTP/1.1").
6. Web server sends the page back in reply.
7. Close TCP connection.

Most of these stages are themselves simplified, all will involve layering on top of lower level networks and most stages involve several substages (e.g., establishing a TCP-level connection requires several IP-level messages).

The basic message is that network internals are multilevel, multistage, and pretty complicated.

11.5.1.7 Decentralizing: Peer–Peer and Ad Hoc Networks

Traditional Internet and web applications tended to work through client–server paradigms where a user's client application accesses a well-known such as a web server. However, there has been a growth of more decentralized models at both higher and lower protocol levels (Androutsellis-Theotokis and Spinellis 2004).

At an application level, peer–peer file sharing works by having clients running on users' own PCs talk directly to one another broadcasting requests for particular files by name or type to all connected clients. These then forward the requests to their connected nodes until some maximum hop count is hit. Often semi-centralized services are used to establish initial connections, but thereafter everything is done at the "edges" of the network. These protocols and applications have some technical strength, but their origins are rooted in legal disputes on the distribution of copyright material. Recent research has also shown that the anonymity of peer–peer file sharing also allows "deviant" subgroups sharing illicit material (Hughes et al. 2006).

At a lower level, ad hoc networks build more structured higher level networks for computers that have point-to-point connections, often through wireless connectivity. This can be used to set up a network in a meeting, or at a larger level could even allow everyone in a pop festival to have Internet access through a small number of wireless hot spots. In an ad hoc network, the low-level software works out what machines are connected where and routes messages from end to end even if the two end point computers do not have direct access. The difficult thing in an ad hoc network is not just setting up this routing information, but the dynamics: dealing with the fact that machines constantly move around, perhaps going out of range of one another, may be turned off, and join the network late.

11.5.2 Network Management

Those most obviously exposed to this complexity are the engineers managing large national and international networks, both data networks, such as the main Internet backbones, and telecoms networks. The technical issues outlined in Section 11.5.1 are compounded by the fact that the different levels of network hardware and network management software are typically supplied by different manufacturers. Furthermore, parts of the network may be owned and managed by a third party and shared with other networks. For example, a trans-Atlantic fiber optic cable may carry telecoms and data traffic from many different carriers.

When a fault occurs in such a network, it is hard to know whether it is a software fault or a hardware fault, where it is happening and who is responsible for it. If you send engineers out to the wrong location, it will cost both their time and also increase the time the service is unavailable. Typically, the penalties for inoperative or reduced quality services are high—you need to get it right fast.

This is a specialized and complex area, but clearly of increasing importance. It poses many fascinating UI challenges: How to visualize complex multilayered structures, and how to help operators trace faults in these. Although I know that it is a topic being addressed by individual telecoms companies, published material in the HCI literature is minimal. The exception is visualization of networks, both physical and logical, which is quite extensive (Dodge and Kitchin's Atlas of Cyberspace and associated website [Dodge and Kitchin 2001] is the comprehensive text in this area).

Ordinary systems administrators in organizations face similar problems albeit on a smaller scale. A near universal experience of misconfigured e-mail systems, continual network failures, and performance problems certainly suggests this is an area ripe for effective interface solutions, but again there is very little in the current HCI literature.

Finally, it appears that everyone is now a network administrator; even a first-time home PC user must manage modem settings, name server addresses, SMTP and POP servers, and more. It is interesting that for most such users, the interface they use is identical to that supplied for full systems administrators. Arguably this may ease the path for those who graduate from single machines to administering an office or organization, perhaps less than 5% of users. Unfortunately, it makes life intolerable for the other 95%! The only thing that makes this possible at all is that the "welcome" disks from many ISPs and the Wizards shipping with the OS offer step-by-step instructions or may automatically configure the system. These complications are compounded if the user wishes to allow access through more than one ISP, or connect into a fixed network. As many home users now have several PCs and other devices that need to be networked, this is not a minor issue.

In the first edition of this handbook, I wrote "If we look at the current state of the two most popular PC systems, Microsoft Windows and Mac OS, the picture is not rosy." Sadly things have not improved dramatically—you only have to watch a room full of computer scientists at a meeting trying to sort out wireless connections.

Some things have got better, for example, on MacOSX pretty much all settings are in one place under "Network Settings." Changing locations with a laptop is simply a matter of selecting "Location …" from the main menu. Similarly, the iPhone connects and reconnects largely seamlessly. However, ease of user brings its own problems as it can be very difficult to diagnose problems when they occur; the interfaces hide irrelevant detail to make life easier, but that "irrelevant" detail often becomes crucial in order to fix problems. Where information is available, it is buried in dialog boxes full of technical networking language.

These problems serve partly to emphasize the intrinsic complexity of networking—yes it does involve multiple logically distinct settings, many of which relate to low-level details. However, it also exposes the apparent view that those involved in network administration are experts who understand the meaning of various internal networking terms. This is not the case even for most office networks and certainly not at home.

And this is just initially setting up the system to use. For the home user, debugging faults has many of the same problems as large networks. You try to visit a website and get an error box … Is the website down? Are there problems with the wireless LAN, the broadband modem, the phone line, the ISP's hardware? Are all your configurations settings right? Has a thunderstorm 3000 miles away knocked out a vital network connection? Trying to understand a multilayered, nonlocalized and, when things work, largely hidden system is intrinsically difficult and where diagnostic tools for this are provided, they assume an even greater degree of expertise.

One example on the iPhone is that, when available, it uses Wi-Fi to connect to Internet service in preference to mobile broadband. This is done in order to speed up access and reduce load on the mobile network, both improving user experience and reducing the telecom operator's costs. When this works, it is fine, but sometimes applications such as the Facebook app simply fail "No Internet Connection" even though the phone appears to have full mobile broadband connectivity. One reason for this is when there is a Wi-Fi network available, which appears to be open, but actually has a web form requesting a log-in (and/or payment). If you are attempting to browse the web, this is immediately obvious and so you can either log-in/pay or go to the phone settings and turn off the Wi-Fi. However, when apps attempt to access the network, they are blocked and simply fail.

The promise of devices that connect up to one another within our homes and about our bodies is going to throw up many of the same problems. Some old ones may ease as explicit configuration becomes automated by self-discovery between components, but this adds further to the hiddenness and thus difficulty in managing faults, security, and so on. You can imagine the scenario—the sound on my portable DVD stops working and produces a continuous noise—why? There are no cables to check of course (wireless networking), but hours of checking and randomly turning devices on and off narrows the problem down to a fault in the washing machine which is sending continuous "I finished the clothes" alerts to all devices in the vicinity.

11.5.3 Network Awareness

One of the problems noted in Section 11.5.2 is the concealment of networks. This causes problems when things go wrong as one does not have an appropriate model of what is going on, but also sometimes even when things are working fine.

We discussed in Section 11.4.1 some of the network properties that may affect usability: bandwidth, delay, jitter, and so on. These are all affected to some extent by other network load, the quality of current network connections, and so on. So predicting performance (and knowing whether or not to panic if things appear to go slow) needs some awareness of the current state of the network.

PCs using wireless networks usually offer some indication of signal strength (if one knows where to look and what it means) although this is less common for line quality for modems. As wireless devices and sensors become smaller, they will not have suitable displays for this and explicitly making users aware of the low-level signal strength of an intelligent paper clip may not be appropriate. However, as interface designers, we do need to think how users will be able to cope and problem solve in such networks.

Only more sophisticated network management software allows one to probe the current load on a network. This does matter. Consider a small home network with several PCs connected through a single modem. If one person starts a large download, they will be aware that this will affect the performance of the rest of their web browsing. Other members of the household will just experience a slowing down of everything and not understand why. If the cause is a file-sharing utility such as Gnutella, even the person whose computer is running it may not realize its network impact. In experiments at MIT, the level of network traffic has been used to "jiggle" a string hanging from the ceiling so that heavy traffic leads to a lot of movement (Wisneski et al. 1998). The movements are not intrusive so give a general background awareness of network activity. Although supplying a ceiling-mounted string may not be the ideal solution for every home, other more prosaic interface features are possible.

Cost awareness is also very important. In the United Kingdom, the first-generation GSM mobile data services are charged by connection time. So knowing how long you have been connected and how long things are likely to take becomes critical. If these charges differ at peak hours of the day, calculating whether to read your e-mail now, or do a quick check and download the big attachments later can become a complex decision. The move to data-volume-based charging means the user needs to estimate the volume of data that is likely to be involved in initiating an action versus the value of that data—do you want to click on that link if the page it links to will include large graphics, perhaps an applet or two? Terrestrial broadband networks have largely shifted to fixed monthly fees, and this has dramatically changed the way people perceive the Internet from smash-and-grab interactions to surf-and-play. However, when roaming abroad, the charging regimes are still often usage-based and so this very free use of mobile Internet is still not ubiquitous.

11.5.3.1 Network Confusion

If the preceding does not sound confusing enough, the multilayered nature of networked applications means that it is hard to predict the possible patterns of interference between things implemented at different levels or even at the same level. Again this is often most obvious when things go wrong, but also because unforeseen interactions may mean that two features that work perfectly well in isolation may fail when used together.

This problem, feature interaction, has been studied particularly in standard telecoms (although certainly not confined to it). Let us look at an example of feature interaction. Telephone systems universally apply the principle that the caller, who has control over whether and when the call is made, is the person who pays. In the exceptions (free-phone numbers, reverse charges) special efforts are made to ensure that subscribers understand the costs involved. Some telephone systems also have a feature whereby a caller who encounters a busy line can request a call-back when the line becomes free. Unfortunately at least one company implemented this call-back feature so that the charging system saw the call-back as originating from the person who had originally been called. Each feature seemed to be clear on its own, but together meant you could be charged for calls you did not want to make.

With N features, there are $N(N-1)/2$ possible pairs of interactions to consider, $N(N-1)(N-2)/6$ triples, and so on. This is a well-recognized (but not solved) problem with considerable efforts being made using, for example, formal analysis of interactions to automatically detect potential problems. It is worth noting that this is not simply a technical issue; the charging example shows that it is not just who pays that matters, but the perceptions of who pays. This particular interaction would have been less of a problem if the interface of the phone system had, for example, said (in generated speech) "you have had a call from XXX press call back, you will be charged for this call." Although this issue has been most widely recorded in telecoms (Calder et al. 2003), these sorts of problems are likely to be found increasingly in related areas such as ubiquitous computing and resource discovery.

11.5.3.2 Exploiting the Limitations: Seamfulness and Virtual Locality

Some companies cynically exploit this user confusion over network charging, and in the United Kingdom, there have been some high-profile news stories about teenagers running up thousands of pounds of debt after innocently signing up to ring-tone delivery services.

Happily there are also more positive uses of the limitations of networks. Given suitable awareness mechanisms for network strength and connectivity, people are very resourceful in exploiting these. You will have experienced the way mobile phone users get to know the sweet spots for their networks when in areas of poor coverage, learning to get out of doors, away from big buildings or up hills. This can get sophisticated. One mixed-reality experiment, part of the Equator project, consisted of an outside game where real players running in the street were pitted against virtual characters manipulated remotely. The "real" players learned to hide in the global positioning system shadow of buildings so that their location could not be detected by the virtual participants (Benford et al. 2003). Similar effects have been seen in Wi-Fi-based games where participants get to know the regions of good and bad coverage and may use these to seek out or avoid remote interactions.

These are ways in which users do more than cope but actively exploit the limitations of networks and sensing. The Pirates game did this with RF technology; RF beacons represent islands in an ocean the locality of the RF signals corresponding to the limited land area of the island (Björk et al. 2001). This notion of exploiting network limitations has led to the idea of seamful games—deliberately designing so that variations in Wi-Fi coverage and connectivity are part of the gameplay (Chalmers et al. 2005).

Even more strange is a recent game "hitchers." In this, you pick up and drop off hitchers with your phone, just like you might pick up a hitch-hiker on the road. You can only pick up a hitcher in the same mobile cell as the last person dropped the hitcher off. The hitchers are actually stored and managed centrally, but the effect is as if the hitchers were only accessible in a small region. Here, even though there is no real limitation of access, a limitation is constructed to make a more interesting game—virtual locality. You can imagine virtual locality being used in synchronous applications, for example, allowing a phone user to broadcast to people in their vicinity apparently as if it were a limited range transmission, whereas in reality, it is centrally managed, based on global positioning system or phone cell location.

11.5.4 Network Within

So far the story is pretty bleak from a user interface viewpoint—a complex problem, of rapidly growing importance, with relatively little published work in many areas. One good thing as a HCI practitioner about understanding the complexity of networks is that they help us understand better the workings of the human cognitive and motor system.

For at least five decades, computational models have been used to inspire cognitive. Also, of course, cognitive and neurological models have been used to inspire computational models in artificial intelligence and neural networks. However, our bodies are not like a single computer, but in various ways more like a networked system.

First, the body is like a networked system because several things can happen at once. The interacting cognitive subsystems model from APU Cambridge (Barnard and May 1995) considers looking at various parts of the cognitive system, the conversions between representations between these parts and the conflicts that arise if the same part is used to perform different tasks simultaneously. Similarly, the very successful PERT-style goals, operators, methods, and selection rules analysis used on the NYNEX telephone operators interface used the fact that the operator could be doing several things simultaneously with no interfering parts of their bodies and brains (John 1990; Gray, John, and Atwood 1992).

We are also like a networked system in that signals take an appreciable time to get from our senses to our brains and from our brains to our muscles. The famous homunculus from Card, Moran, and Newell's (1983) Model Human Processor makes this very clear with timings attached to various paths and types of mental processing. In fact, the sorts of delays within our bodies (from 50–200 milliseconds on different paths) are very similar to those found on international networks.

In industrial control, one distinguishes between open-loop and closed-loop control systems (see Figure 11.16). Open-loop control is where you give the machine an instruction and assume it does it correctly (like a treasure map—"ten steps North, turn left, three steps forward and dig"). This assumes the machine is well calibrated and predictable. In contrast, closed-loop control uses sensors to constantly feedback and modifies future actions based on the outcomes of previous ones (e.g., "follow the yellow brick road until you come to the emerald city"). Closed-loop control systems tend to be far more robust, especially in uncontrolled environments, like the real world.

Not surprisingly our bodies are full of closed-loop control systems (e.g., the level of carbon dioxide in your lungs triggers the breathing reflex). However, closed-loop control can become difficult if there are delays—you have not received feedback from the previous action when starting the next one. Delays either mean one has to slow down the task or use some level of prediction to determine what to do next, based on feedback of actions before the last one. This breakdown of closed-loop control in the face of (especially unexpected) delays is one of the reasons hand–eye coordination tasks, such as mouse movement, breakdown if delays exceed a couple of hundred milliseconds (Section 11.4.2). The feedback loops in our bodies for these tasks assume normal delays of around 200 milliseconds and are robust to variations around this figure, but adding delays beyond this start to cause breakdown.

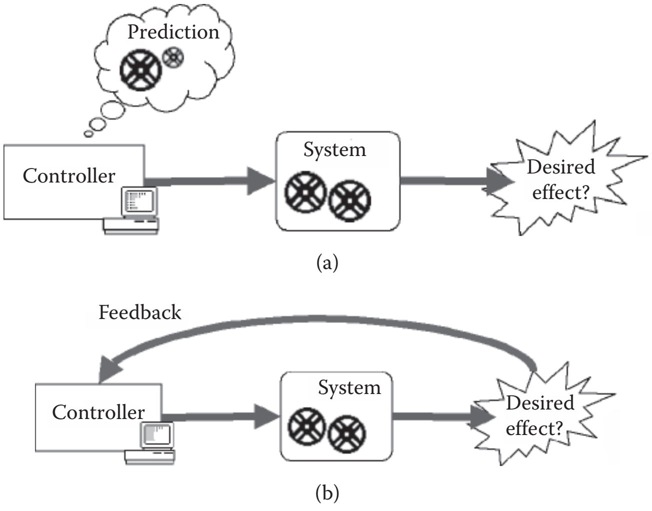

FIGURE 11.16 (a) Open-loop control. (b) Closed-loop control.

The delays inside our bodies cause other problems too. The path from our visual cortex into our brain is far faster (by 100 milliseconds or so) than that from our touch and muscle tension sensors around our bodies. If we were designing a computer system to use this information, we might consider having a short 100-millisecond tape loop, so that we could store the video input until we had the appropriate information from all senses. However, the sheer volume of visual information means that our brains do not attempt to do this. Instead, there is a part of our brains that predicts where it "thinks" our bodies are and what it is feeling based on previous nerve feedback and what it knows the muscles have been asked to do. The same bit of the brain then monitors what actually did happen (when the nerve signals have made their way up the spinal column to the brain) and gives either an uncomfortable or shocked sensation when a mismatch occurs. For example, you go to pick something up, but because of poor light or a strange shaped object, you touch it earlier or later than you would expect. Tickling is also connected with this lack of ability to predict the sensations (this is why it is difficult to tickle yourself).

Race conditions also occur within this networked system of our bodies—for example, getting letter inversions while typing where signals to the two hands get processed in the wrong order. Dix and Brewster (1994) also used race conditions to understand what goes wrong in certain kinds of mis-hits of onscreen buttons. In certain circumstances, two almost simultaneous "commands" from our brain to our hand to release the mouse button and to our arm to move to a new mouse location can get out of order meaning the mouse moves out of the target before it is released. This analysis allowed us to design an experiment that forced this very infrequent error to occur much more frequently and therefore make it easier to assess potential solutions.

11.6 NETWORKS AS PLATFORMS: ALGORITHMS AND ARCHITECTURES FOR DISTRIBUTED INTERFACES

User interfaces are hard enough to construct on a single machine, concurrent access by users on networked machines is a nightmare!

Happily, appropriate algorithms, architectures, toolkits, and frameworks can help … a bit.

11.6.1 Accessing Shared Objects

We saw in Section 11.4.2 how race conditions within networked systems can lead to inconsistencies within the user interface and within the underlying data structures. Fortunately, there are a range of techniques for dealing with this.

11.6.1.1 Locking

The standard technique, used in databases and file systems, for dealing with multiple accesses to the same data object is locking. When a user's application wants to update a particular database record, it asks the database manager for a lock on the record. It can then get a copy of the record and send back the update knowing that nothing else can access it in the meantime. Users are typically unaware that locking is being performed; the act of opening a file or opening an edit screen for a database record establishes the lock and later, when the file or the edit form is completed and closed, the lock is released.

Although this is acceptable for more structured domains, there are problems in more dynamic domains such as shared editing. Locking a file when one user is editing it is no good as we want several people to edit the same file at the same time. In these cases, more lightweight forms of locking can be used at finer granularities: at paragraph, sentence, or even per character level. For example, the act of clicking over a paragraph to set a text entry position may implicitly request a paragraph lock, which is released when you go on to edit another paragraph. However, implicit and informal locks, because they are not apparent, can lead to new problems. For example, a user may click on a paragraph, do some changes, but before moving on to another part of the document gets interrupted. No one else can then edit the paragraph. To avoid this, the more informal locks are often time limited or can be forcibly broken by the server if another user requests a lock on the same object.

11.6.1.2 Replication

In collaboration systems such as Lotus Notes/Domino or source code systems such as Subversion (SVN), users do not lock central copies of data, but instead each user (or possibly each site) has their own replica of the complete Notes database/SVN tree. Periodically, these replicas are synchronized with central copies or with each other. Updates can happen anywhere by anyone with a replica. Conflicts may, of course, arise if two people edit the same note between synchronizations. Instead of preventing such conflicts, the system (and software written using it) accepts that such conflicts will occur. When the replicas synchronize, conflicts are detected and various (configurable) actions may occur: flagging the conflicts to users adding conflicting copies as versions, and so on.

This view of replicate and worry later is essential in many mobile applications as attempts to lock a file while disconnected would first of all require waiting until a network connection could be made, and, worse, if the network connection is lost while the lock is still in operation could lead to files being locked for very long periods. Other examples of replication in research environments have included CODA at Carnegie Mellon University, which allows replication of a standard UNIX file system (Kistler and Satyanarayanan 1992) and Liveware, a contact information system that replicates and synchronizes when people meet in a manner modeled after the spread of computer viruses (Witten et al. 1991).

Commercial products offering data synchronization on PDAs and mobile phones has been common for many years, for example, HotSync was a key element of Palm OS since the mid-1990s. Now not only is this found on mobile devices to enable them to synchronize with desktop computers, but also on desktop applications synchronizing with large central servers or cloud data services to enable "anywhere" access to data; for example, FireFox Weave allows you to access shared bookmarks and other FireFox data from browsers on different machines (Mozilla Labs 2010).

Despite so many years of research and use, data synchronization still has significant problems. One example is in MacOSX, which has a very well-developed mechanism for third-party applications to synchronize between desktop machines and the iPhone, and also with the MobileMe cloud service (Apple 2010). However, if one attempts a three-way synchronization by enabling synchronization both directly between iPhone–desktop and through MobileMe, the algorithms used fail dramatically duplicating address book items and calendar events.

It is also interesting that commercial synchronization solutions rarely deal actively with conflicting updates, usually simply taking the last update as canonical. This may be because of technical reasons, if applications do not store fine-grained information about update and synchronization times, but also probably because it is difficult to design user interfaces to offer users the ability to decide between conflicts.

11.6.1.3 Optimistic Concurrency for Synchronous Editing

The "do it now and see if there are conflicts later" approach is also called optimistic concurrency, especially in more synchronous settings. For example, in a shared editing system, the likelihood of two users editing the same sentence at the same time is very low. An optimistic algorithm does not bother to lock or otherwise check things when the users start to edit in an area, but in the midst or at the end of their edits checks to see if there are any conflicts and attempts to fix them.

There are three main types of data that may be shared:

Orthogonal data—where the data consists of attributes of individual objects/records that can all be independently updated

Sequential data—particularly text, but any form of list where the order is not determined by an attribute property

Imagine two users, Adonis and Beatrice.

They are working using a shared editor and their current document reads as follows:

```
Adonis is ⊤ and Beatrice is ⊤ .
          A                 B
```

The sentence is partial and both users are about to type in their prime personal characteristic in order to complete it.

Adonis' insertion point is denoted by the boxed $\boxed{A}$ and Beatrice's insertion point is the boxed $\boxed{B}$.

Beatrice types first yielding the following:

```
Adonis is⊤and Beatrice is beautiful⊤.
         A                         B
```

Adonis then types "adorable", but unfortunately the implementor of the group editor was not very expert and the resulting display was:

```
Adonis is adorable⊤and Beatrice is ⊤ beautiful.
                  A                B
```

Beatrice's insertion point followed the thirty-sixth character before Adonis' insertion, and followed the thirty-sixth character after.

Reasonable but wrong! The actual text should clearly read as follows:

```
Adonis is adorable⊤and Beatrice is beautiful⊤.
                  A                         B
```

This correct behaviour is called a dynamic pointer as opposed to the static pointer "character position 36".

FIGURE 11.17 Dynamic pointers from Dix (1995).

Complex structural data—such as directory trees, taxonomic categories, etc.

In terms of complexity for shared data, these are in increasing difficulty.

Orthogonal data, although by no means trivial, is the simplest case. There is quite a literature on shared graphical editors, which all have this model—independent shapes and objects with independent attributes such as color, size, and position. When merging updates from two users, all one has to do is look at each attribute in turn and see whether it has been changed by only one user, in which case the updated value is used, or if it has been changed by both, in which case either the last update is used or the conflict is flagged.

Structured data is most complicated—What do you do if someone has created a new file in directory D, but at the same time someone else has deleted the directory? I know of no optimistic algorithms for dealing effectively with this in the CSCW literature. CODA deals with directory structures (normal UNIX file system) but takes a very simple view of this, as it only flags inconsistencies and does not attempt to fix them.

Algorithms for shared text editing sit somewhere between the two and have two slightly different problems, both relating to race conditions when two or more users are updating the same text:

Dynamic pointers—If user A is updating an area of text in front of user B, then the text user B is editing will effectively move in the document.

Deep conflict—What happens if user A's and user B's cursors are at the very same location and they perform insertions/deletions?

Figure 11.17 shows an example of the first of these problems. The deeper conflict occurs when both cursors are at the same position; say after the "Y" in "XYZ." Adonis types "A" and at the same time Beatrice types "B" should we have "XYABZ" or "XYBAZ" or perhaps even loose one or other character? Or if Adonis types "A" and Beatrice presses "delete" should we have "XYZ" or "XAZ"?

A number of algorithms exist for dealing with this (Sun and Ellis 1998; Mauve 2000; Vidot et al. 2000) including a retrofit to Microsoft Word called CoWord (Xia et al. 2004). Most of these stem from the dOPT algorithm used in the Grove editor (Ellis and Gibbs 1989). These algorithms work by having various operation transformations that allow you to reorder operations. For example, if we have two insertions (labeled a and b) performed at the same time at different locations:

a. Insert texta at location n
b. Insert textb at location m

but decide to give insert a preference, then we have to transform b to b' as follows:

b'. if (m < n) insert textb at location m (i)
if (m = n) insert textb at location m (ii)
if (m > n) insert textb at location m + length(texta) (iii)

Case (i) says that if the location of insert "b" is before insert "a" you do not have to worry. Case (iii) says that if it is after insert "a" you have to shift your insert along accordingly. Case (ii) is the difficult one where a conflict occurs and has to be dealt with carefully to ensure that the algorithm generates the same results no matter where it is. The version above would mean that B's cursor gets left behind by A's edit. The alternative would be to make case (ii) the same as case (iii), which would mean B's cursor would be pushed ahead of A's.

In early work in this area, I proposed regarding dynamic pointers as first class objects and using these in all representations of actions (Dix 1991, 1995). This means that rules like case (i) and case (iii) happen "for free," but the deep conflict case still needs to be dealt with specially.

Although operation transform methods have been in the research literature for many years, they have mainly been used in research systems. However, Google Wave uses operation transformation to enable fine-grained remote collaboration (Wang and Mah 2010), so this technology is eventually entering the mainstream.

11.6.1.4 Groupware Undo

The reason that undo is complicated in groupware is similar to the problems of race conditions in optimistic concurrency.

In the case of optimistic concurrency, user A has performed action a, and user B has performed action b, both on the same initial state. The problem is to transform user B's action into one b' that can be applied to the state after action a yet still mean the "same things" as the original action b (see Figure 11.18 left).

In the case of groupware undo, we may have the situation where user A has performed action a, followed by user B performing action b, and then user A decides to undo action a. How do we transform action b so that the transformed b' means the same before action a as b did after (see Figure 11.18 right).

Similar, but slightly different transformation rules can be produced for the case of undo and also dynamic pointers can be used for most cases.

As with optimistic concurrency, there is slightly more work on group undo in shared graphical editors where the orthogonal data makes conflicts easier (Berlage and Spenke 1992).

11.6.1.5 Real Solutions?

Although these various algorithms can ensure there is no internal inconsistency and that all participants see the same thing, they do not necessarily solve all problems. Look again at the case of Alison and Brian's chat in Section 11.4.2. Certainly in the case of group undo, when Abowd and Dix (1992) published the first article on the topic, we proposed various solutions, but also recommended that besides an explicit undo button, systems ought to provide sufficient history to allow users to recreate what they want to without using the undo button. This is not because it is impossible to find a reasonable meaning for the undo button, but because in the case of group undo, there are several reasonable meanings. Choosing the meaning a user intends is impossible, and so it may sometimes be better not to guess.

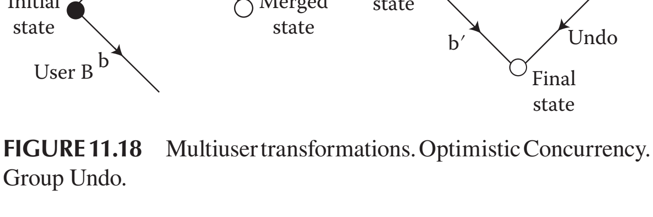

FIGURE 11.18 Multiuser transformations. Optimistic Concurrency. Group Undo.

11.6.2 Architectures for Networked Systems

Software architecture is about choosing what (in terms of code and functionality) goes where. For applications on a single machine these are often logical distinctions between parts of the code. For networked systems, "where" includes physical location, and the choice of location makes an enormous difference to the responsiveness of the system.

The simplest systems are almost always centralized client–server architectures, where the majority of computation and data storage happens in the central server. Many of the problems of race conditions and potential inconsistencies disappear. However, this means that every interaction requires a network interaction with the server meaning that feedback may be very slow. At the opposite extreme are replicated peer–peer architectures, where all the code is running on users' own PCs and the PCs communicate directly with one another. Feedback can now be instantaneous, but the complexity of algorithms to maintain consistency, catch-up late joiners, and so on can be very complex. Most systems operate somewhere between these two extremes with a central "golden copy" of shared data, but with some portion of the data on individual PCs, mobile phones, or other devices in order to allow rapid feedback. A notable exception to this is peer–peer sharing networks such as Gnutella where the only central resource is a sort of switchboard to allow client programs to contact one another. The reason for this is largely legal as these are often used to share copyright media! One reason this works is that the data is static, "Yesterday" is the same now as when it was first recorded in 1965 … although given it has the greatest number of covers of any song, perhaps not the best example!

In web applications, options are constrained by the features allowed in HTML and web browsers. Note that even a web form is allowing some local interaction (filling in the form) as well as some centralized interaction (submitting it). Applets allow more interaction, but the security limitations mean that they can only talk back to the server where they originated. Thus true peer–peer architectures are impossible on the web, but can be emulated by chat servers and similar programs that relay messages between clients. For Intranets, it is easier to either configure browsers so that they accept applets as trusted and thus with greater network privileges, or include special plug-in components to perform more complicated actions.

Mobile systems have yet more issues as they need to be capable of managing disconnected operation (when they have no physical or wireless connection to the network). A number of mechanisms have been developed over the years to allow local caching of network data, especially web pages. As applications, such as web mail and Google docs, shifted more functionality into network applications, this became more urgent leading to first vendor-specific technology such as Google Gears (Google 2010) and now standardized methods in HTML5 for creating and accessing local data for offline use of "web" applications (W3C 2010a,b).

For native applications also, smartphones often have replicated architectures with major resynchronization when connected through cheap/fast connection. For example, the iPhone SDK includes mechanisms for third parties to add synchronizable data.

11.6.3 Supporting Infrastructure

In order to help manage networked applications, various types of supporting infrastructure are being developed.

11.6.3.1 Awareness Servers

These keep track of which users are accessing particular resources (e.g., visiting a particular web page) so that you can be kept informed as to whether others are "near" you in virtual space, or whether friends are online and active (Palfreyman and Rodden 1996; ICQ 2001; SUN Microsystems 2001).

11.6.3.2 Notification Servers

These serve a similar role for data allowing client programs to register an interest in particular pieces of shared data. When the data is modified or accessed, the interested parties are "notified." For example, you may be told when a web page has changed or when a new item has been added to a bulletin board. Some notification servers also manage the shared data (Patterson, Day, and Kucan 1996) while others are "pure," just managing the job of notification (Ramduny, Dix, and Rodden 1998).

11.6.3.3 Event/Messaging Systems

These allow different objects in a networked environment to send messages to one another in ways which are more convenient than that allowed by the raw network. For example, they may allow messages to be sent to objects based on location-independent names, so that objects do not have to know where each other are.

11.6.3.4 Resource Discovery

Systems such as the Java JINI framework and Universal Plug-and-Play allow devices to find out about other devices close to them, for example, the local printer, and configure themselves to work with one another. As ubiquitous and mobile devices multiply, this will become increasingly important.

11.6.3.5 Web Service and Remote Procedure Call

Web service frameworks such as SOAP (Simple Object Access Protocol) or XML (extensible markup language)–RPC or nonweb remote procedure mechanisms such as Java's RMI or common object request broker architecture (CORBA) allow applications on different machines to easily connect to one another even though they may be written in different programming languages and run on different operating systems. In all cases, the parameters or arguments have to be serialized into a binary or ASCII test stream to be sent. As Figure 11.19 shows these are designed to be read by machines, not people!

```
<SOAP-ENV:Envelope
  xmlns:SOAP-ENV = "http://schemas.xmlsoap.org/soap/envelope/"
  xmlns:xsi = "http://www.w3.org/1999/XMLSchema-instance"
  xmlns:xsd = "http://www.w3.org/1999/XMLSchema">
   <SOAP-ENV:Header>
   </SOAP-ENV:Header>
   <SOAP-ENV:Body>
      <ns1:sayHelloTo
         xmlns:ns1 = "Lookup"
      SOAP-ENV: encodingStyle = "http://schemas.xmlsoap.org/soap/
 encoding/">
         <name xsi:type = "xsd:string">Hello World</name>
      </ns1:sayHelloTo>
   </SOAP-ENV:Body>
</SOAP-ENV:Envelope>
```

FIGURE 11.19 SOAP XML encoding of Lookup ("Hello World").

Because of the complexity of SOAP and other RPC mechanisms, many web APIs now use representational state transfer (REST)-based protocols (Fielding 2000). REST takes a more data-oriented view of intercomponent communications compared with a function/method paradigm of RPC. Instead of defining bespoke operations, REST uses the native HTTP methods GET, POST, PUT, and DELETE often in combination with standard HTTP authentication and content negotiation. REST-based APIs often make use of JavaScript Object Notation encoding of the return results, which was originally designed as a lightweight way to return results to JavaScript web pages (suing AJAX or similar techniques), but has now become common as a cross-language format (Crockford 2010).

11.7 HISTORY, PARADIGM SHIFT, AND FUTURES

11.7.1 History

Timeline—key events for the Internet:

1968—First proposal for ARPANET–military and government research contracted to Bolt, Beranek & Newman

1971—ARPANET enters regular use

1973–1974—Redesign of lower level protocols leads to TCP/IP

1983—Berkeley TCP/IP implementation for 4.2BSD—public domain code

1980s—Rapid growth of NSFNET–broad academic use

1990s—WWW and widespread public access to the Internet

2000—WAP on mobile phones web transcends the Internet

Given the anarchic image of the web, it is strange that the Internet began its development as a U.S. military project. The suitability of the Internet for distributed management and independent growth stems not from an egalitarian or anticentralist political agenda, but from the need to make the network resilient to nuclear attack with no single point of failure.

In the 1970s when the Internet was first developing, it and other networks were mainly targeted at connecting together large computers. It was during the 1980s, with the rise of personal computing that local networks began to become popular.

However, even before that point, very local networks at the lab-bench level had been developed to link laboratory equipment, for example, the IEEE488 designed originally to link Hewlett Packard's proprietary equipment and then becoming an international standard. Ethernet, too, began life in commercial development at Xerox before becoming the de facto standard for local networking.

Although it is technical features of the Internet (decentralized, resilient to failures, hardware independent) that have made it possible for it to grow, it is the web that has made it become part of popular consciousness. Just as strange as the Internet's metamorphosis from military standard to anarchic cult is the web's development: from medium of exchange of large high-energy physics data sets to e-commerce, home of alternative web pages and online sex!

11.7.2 Paradigm Shift

During the 1970s through to the mid-1990s, networking was a technical phenomenon, enabling many aspects of business and academic life, but with very little public impact. However, this has changed dramatically over the last five years and now we think of a networked society. The Internet and other network technologies, such as SMS text messages, are not only transforming society, but at a popular and cultural level defining an era.

International transport, telecommunications, and broadcasting had long before given rise to the term global village. However, it seems this was more a phrase waiting for a meaning. Until recently the global village was either parochial—telephoning those you already know, or sanitized—views of distant cultures through the eyes of the travel agent or television camera. It is only now that we see chat rooms and web home pages allowing new contacts and friendship around the world—or at least among those affluent to get Internet access.

Markets too have changed due to global networks. It is not only the transnational that can trade across the world, and even my father-in-law runs a thriving business selling antiques through eBay.

Marketing has also had to face a different form of cross-cultural issue. Although selling the same product, a hoarding in Karachi may well be different from an ads in a magazine in Kentucky, reflecting the different cultural concerns. Global availability of web pages changes all that. You have to create a message that appeals to all cultures—a tall order. Those who try to replicate the targeting of traditional media by having several country-specific websites may face new problems—the global access to even these country-specific pages means that the residents of Kentucky and Karachi can compare the different ads prepared for them, and in doing so see how the company views them and their cultures.

Economics drives so much of popular as well as business development of networked society. One of the most significant changes in the United Kingdom was because of the changes in charging models. In the United States, local calls had long been free and hence so were Internet connections to local points of presence. The costs of Internet access in the United Kingdom (and even more important the perception of the cost) held back widespread use for many years. The rise of free or fixed-charge unmetered access changed nearly overnight the acceptability and style of use. Internet access used to be like a lightening guerrilla attack into the web territory, quick in and out before the costs mounted up, but became a full-scale occupation.

The need for telecom companies across the world to recover large investments in wireless band franchises combined with use rather than connection-based charging made possible by GPRS and third-generation mobile services, is now enabling a similar growth in mobile access to global networked information and services.

In an article in 1998, I used the term PopuNET to refer to a change in society that was not yet there, but would come. PopuNET is characterized by network access: everywhere, everywhen by everyone

This pervasive, permanent, popular access is similar to the so-called Martini principle applied more recently to mobile networking—anytime, anyplace, anywhere. Of course, Martini never pretends to be anything but exclusive, so not surprisingly these differ on the popular dimension! "Anyplace, anywhere" does correspond to the pervasive "everywhere" and "anytime" to the permanent "everywhen." However, there is a subtle difference, especially between "anytime" and "everywhen." "Anytime" means that at any time you choose you can connect. "Everywhen" means that at all places and all times you are connected. When this happens, one ceases to think of "connectedness" and it simply becomes part of the backdrop of life.

The combination of high-bandwidth networks, changes in charging models and always-on mobile connectivity have brought the goal of "everywhen" closer. However, in even the most developed nations, move out of major cities and bandwidth and connectivity rapidly begin to fall. So for the urban smartphone user, PopuNET is here, but as a truly pervasive experience "everywhen" is still coming.

PopuNET demands new interfaces and products, not just putting web pages on TV screens or spreadsheets on fridge doors. What these new interfaces will be is still uncertain, but the explosion of apps on the iPhone and similar platforms such as JIL (2010) shows one direction.

In fact many applications effectively assume constant connectivity; for example, many of the help pages are delivered as web pages. This can lead to problems when disconnected—especially in the case when looking for help to get connected! However, it also means that documentation can be easily updated. Similarly, most software now includes automatic updates meaning that you have the latest security fixes, but with the downside that as "essential" security update of 200 Mb may take a long time if you do not have a broadband connection. We will increasingly see an erosion of the distinctions between network and computer, symbolized by the popularity of the NetBook.

11.7.3 Futures (Near)

It is dangerous to predict far into the future in an area as volatile as this. One development that is already underway, which will make a major impact on user interfaces, is short-range networking, which will enable various forms of wearable and ubiquitous networks. Another is the introduction of network appliances, which will make the home "alive" on the network.

We have considered network aspects of continuous media at length. The fact that the existing Internet TCP/IP protocols do not enable guaranteed quality-of-service will put severe limits on its ability to act as an infrastructure for services such as video-on-demand or video sharing between homes. The update to TCP/IP which has been under development for several years, IPv6, will allow prioritized traffic; it falls short of real guaranteed QoS (IPng 2001).

It seems that this is an impasse. One of the reasons that IPv6 has taken so long is not the technical difficulty, but backwards compatibility and the problems of uptake on the existing world-wide infrastructure. Although most computers and routers do have IPv6 support, it is rare to see it actually used, and consequently, evolutionary change is hard. However, revolutionary change is also hard: One cannot easily establish a new parallel international infrastructure overnight. Or perhaps one can.

Mobile-phone services started with an infrastructure designed for continuous voice and are, through a series of quite dramatic changes, moving this toward a fully mixed media/data service. And it is a global network. Furthermore, more and more nonweb-based Internet services are using HTTP, the web protocol, to talk to one another in order to be "firewall friendly." In principle, a device could be web connected without being Internet connected.

In earlier editions, I suggested that possibly this may mean that *n*th-generation mobile networks effectively supplant the Internet allowing both web and voice traffic, and maybe being used as the bases of new wire-based standards. However, predictions are dangerous and this was completely wrong. Although phones themselves do still make use of separate voice and data channels, the movement across voice and media on wired and Wi-Fi connections has been exactly the opposite with Voice over IP services, notably Skype acting as a replacement for telephones, and various forms of on-demand video sitting alongside or even replacing terrestrial or satellite television.

One challenge that is certainly emerging, and a safe prediction, is the rise of the mobile phone as the most common (or only) form of Internet connectivity (and indeed computing) across many parts of the world including much of China, India, and Africa. Indeed, by the time of the next edition of this book, it is likely that mobile-phone web-access will already have overtaken conventional computing.

Man businesses are looking toward the "Next Billion" in these emerging markets (NextBillion 2010), who so far have been technologically disenfranchised. HP Labs are expecting that these Next Billion customers, many of whom may be illiterate or use languages with non-Latin character sets, may never have used a standard computer, but will access computation and information solely through a mobile-phone handset; and (HPL 2010). The applications and patterns of use that have arisen in desktop environments or even for Western urban youth may not be the most appropriate for this new market (Dix and Subramanian 2010).

12 Wearable Computers

Daniel Siewiorek, Asim Smailagic, and Thad Starner

CONTENTS

12.1 INTRODUCTION

Computers have become a primary tool for office workers, allowing them to access the information they need to perform their jobs; however, accessing information is more difficult for mobile users. With current computer interfaces, the user must focus both physically and mentally on the computing device instead of the environs. In a mobile environment, such interfaces may interfere with the user's primary task. However, many mobile tasks could benefit from computer support. (Smailagic and Siewiorek 1993; Siewiorek et al. 1998; Lyons and Starner 2001.) Our focus is the design of wearable computers that augment, instead of interfere, with the user's tasks. Carnegie Mellon University's (CMU) VuMan 3 project provides an example of how the introduction of wearable computing to a task can reap many rewards.

12.2 MAINTENANCE INSPECTION USING A VUMAN 3 WEARABLE COMPUTER

Many maintenance activities begin with an inspection in which problems are identified. Job orders and repair instructions are generated from the results of the inspection. The VuMan 3 wearable computer was designed for streamlining Limited Technical Inspections (LTI) of amphibious tractors for the U.S. Marines at Camp Pendleton, California (Smailagic et al. 1998). The LTI is a 600-element, 50-page checklist that usually takes 4–6 hours to complete. The inspection includes an item for each part of the vehicle (e.g., front left track, rear axle, windshield wipers, etc.). VuMan 3 created an electronic version of this checklist. The system's interface was arranged as a menu hierarchy and a physical dial, and selection buttons controlled navigation. The top level consisted of a menu that gave a choice of function. Once the inspection function was chosen, the component being inspected was selected by its location on the vehicle. At each stage, the user could go up one level of the hierarchy.

The inspector selects one of four possible options about the status of the item: (1) serviceable, (2) unserviceable, (3) missing, or (4) on equipment repair order. Further explanatory comments about the item can be selected (e.g., the part is unserviceable due to four missing bolts).

The LTI checklist consists of a number of sections, with approximately 100 items in each section. The user sequences through each item by using the dial to select "next item," or "next field." A "smart cursor" helps automate some of the navigation by positioning the user at the next most likely action.

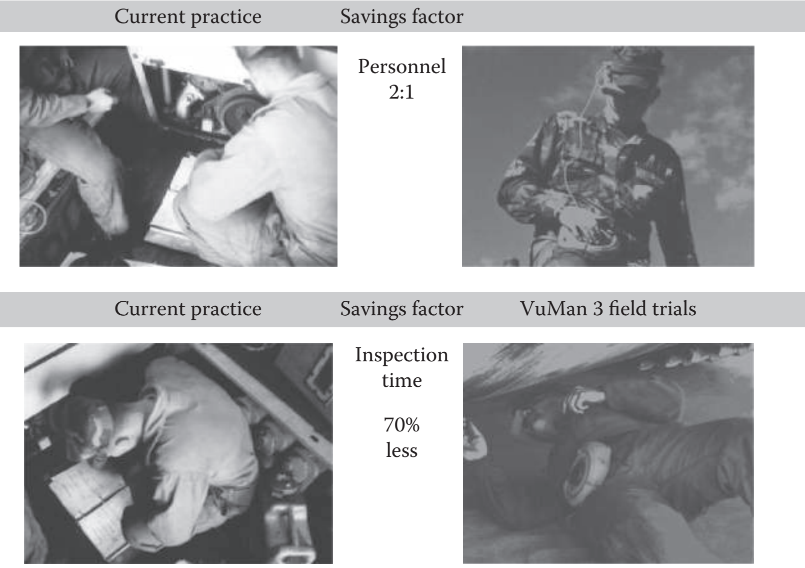

FIGURE 12.1 VuMan 3 savings factors.

As part of the design process, a field study was performed. In typical troubleshooting tasks, one marine would read the maintenance manual to a second marine who performs the inspection. With the VuMan 3, only one marine is needed for the task as he has the electronic maintenance manual with him. Thus, the physical manual does not have to be carried into hard-to-reach places.

The most unanticipated result was a 40% reduction in inspection time. The bottom right image of Figure 12.1 demonstrates the reason for this result. Here, the marine is on his side looking up at the bottom of the amphibious tractor. In such places, it is hard to read or write on the clipboard typically used for inspections. The marine constantly gets into position, crawls out to read instructions, crawls back into position for the inspection, and then crawls out again to record the results. In addition, the marine tends to do one task at a time when he might have five things he has to inspect in one place. This extra motion has a major impact on the time required to do a task. By making information truly portable, wearable computers can improve the efficiency of this application and many other similar ones.

The second form of time savings with the VuMan 3 occurred when the inspection is finished. The wearable computer requires a couple of minutes to upload its data to the logistics computer. The manual process, however, required a typist to enter the marine's handwritten text into the computer. Given that the soldier may have written his notes in cold weather while wearing gloves, the writing may require some interpretation. This manual process represents another 30% of the time.

Such redundant data entry is common when users are mobile (Starner et al. 2004). There are numerous checklist-based applications including plant operations, preflight checkout of aircraft, inventory, and so on, that may benefit from a form-filling application run on a wearable computer. In the case of the VuMan 3 project, the results were striking. From the time the inspection was started until the data was entered into the logistics computer, 70% of the time was saved by using the wearable. There was a potential saving by reducing maintenance crews from two to one. Finally, there was also a savings in weight over paper manuals.

12.3 FACTORS IN WEARABLE COMPUTER DESIGN

Designing wearable computer interfaces requires attention to many different factors due to their closeness to the body and their use while performing other tasks. For the purposes of discussion, we have created the "CAMP" framework, which consists of the following factors:

Corporal: Wearables should be designed to interface physically with the user without discomfort or distraction.

Attention: Interfaces should be designed for the user's divided attention between the physical and virtual worlds.

Manipulation: When mobile users lose some of the dexterity assumed by desktop interfaces, controls should be quick to find and simple to manipulate.

Perception: A user's ability to perceive displays, both visual and audio, is also reduced while mobile. Displays should be simple, distinct, and quick to navigate.

Power, heat, on-body and off-body networking, privacy, and many other factors also affect on-body computing (Starner 2001). Many of these topics are the subjects of current research, and much work will be required to examine how these factors interrelate. Due to space constraint, we will concentrate mainly on CAMP principles and practice in the remainder of this chapter.

12.4 CORPORAL: DESIGN GUIDES FOR WEARABILITY

The term “wearable” implies the use of the human body as a support environment for the object described. Society has historically evolved its tools and products into more portable, mobile, and wearable form factors. Clocks, radios, and telephones are examples of this trend. Computers are undergoing a similar evolution. Simply shrinking computing tools from the desktop paradigm to a more portable scale does not take advantage of a whole new context of use. While it is possible to miniaturize keyboards, human evolution has not kept pace by shrinking our fingers. There is no Moore’s Law for humans. The human anatomy introduces minimal and maximal dimensions that define the shape of wearable objects, and the mobile context also defines dynamic interactions. Conventional methods of interaction, including keyboard, mouse, joystick, and monitor, have mostly assumed a fixed physical relationship between user and device. With wearable computers, the user’s physical context may be constantly changing. Symbol’s development of a wearable computer for shipping hubs provides an example of how computing must be adapted for the human body.

As a company, Symbol is well known for its bar code technology. However, it is also one of the first successful wearable computer companies, having sold over 100,000 units from its WSS 1000 line of wearable computers (see Figure 12.2). The WS-1000 consists of a wrist-mounted wearable computer that features a laser bar code scanner encapsulated in a ring worn on the user’s finger. This configuration allows the user to scan bar codes while keeping both hands free to manipulate the item being scanned. Because the user no longer has to fumble with a desk-tethered scanner, these devices increase the speed at which the user can manipulate packages and decrease the overall strain on the user’s body. Such features are important in shipping hubs, where millions of packages are scanned by hand every year. Symbol spent over US$5 million and devoted 40,000 hours of testing to develop this new class of device, and one of the major challenges was adapting the computer technology to the needs of the human body (Stein et al. 1998).

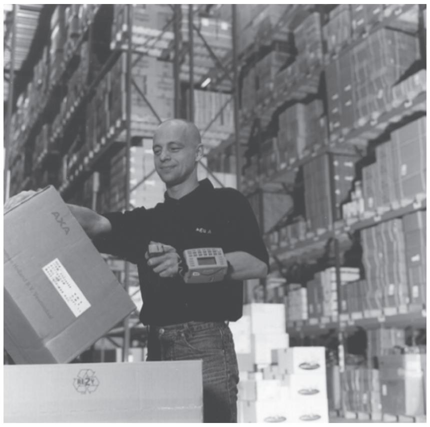

FIGURE 12.2 Symbol’s WSS 1000 series wrist-mounted wearable computer with ring scanner.

One of the first observations made was that users may be of widely varying shapes and sizes. Specifically, Symbol’s scanner had to fit the fingers of both large men and small women. Similarly, the wrist unit had to be mounted on both large and small wrists. Even though the system’s wires were designed to be unobtrusive, the system must be designed to break away if entangled and subjected to strain. This policy provided a safeguard for the user.

Initial testing discovered other needs that were obvious in hindsight. For example, the system was strapped to the user’s forearm while the user exerted himself in moving boxes. Soon, the “soft-good” materials, which were designed for the comfort of the user, became sodden with sweat. After one shift, the user was expected to pass the computer to the operator on the next shift. Not only was the sweat-laden computer mount considered “gross,” it also presented a possible health risk. This problem was solved by separating the computer mount from the computer itself. Each user received his own mount, which he could keep adjusted to his own needs. After each shift, the computer could be removed from the user’s mount and placed in the replacement user’s mount.

Another unexpected discovery is that the users tended to use the computer as body armor. When a shipping box would begin to fall on the user, the user would block the box with the computer mounted on his forearm, as that was the least sensitive part of his body. Symbol’s designers were surprised to see users adapt their work practices to use the rigid forearm computer to force boxes into position. Accordingly, the computer’s case was designed out of high-impact materials. However, another surprise came with longer term testing of the computer.

Employees in the test company’s shipping hubs constantly reached into wooden crates to remove boxes. As they reached into the crates, the computer would grind along the side. After extended use, holes would appear in the computer’s casing, eventually damaging the circuitry. Changing the composition of the casing to be resistant to both abrasion and impact finally fixed the problem.

After several design cycles, Symbol presented the finished system to new employees in a shipping hub. After a couple of weeks’ work, test results showed that the new employees felt the system was cumbersome, whereas established employees who had participated in the design of the project felt that the wearable computer provided a considerable improvement over the old system of package scanning. After consideration, Symbol’s engineers realized that these new employees had no experiential basis for comparing the new system to the past requirements of the job. As employees in shipping hubs are often short-term, a new group of employees were recruited. For two weeks, these employees were taught their job using the old system of package scanning: the employee would reach into a crate, grasp a package, transfer it to a table, grasp a handheld scanner, scan the package, replace the scanner, grasp the package, and transfer it to its appropriate conveyer belt. The employees were then introduced to the forearm-mounted WS-1000. With the wearable computer, the employee would squeeze his index and middle finger together to trigger the ring-mounted scanner to scan the package while reaching for it, grasp the package, and transfer it to the appropriate conveyer belt in one fluid motion. These employees returned very positive scores for the wearable computer.

This lesson—that perceived value and comfort of a wearable computer is relative—was also investigated by Bodine and Gemperle (2003). In short interviews, users were fitted with a backpack or armband "wearable" and told that the system was either a police monitoring device (similar to those used for house arrest), a medical device for monitoring health, or a device for use during parties. The subjects were then asked to rate the devices on various scales of desirability and comfort. Not surprisingly, the police "wearable" was considered the least desirable. However, the police function elicited more negative *physical* comfort ratings, and the medical function elicited more positive physical comfort ratings even though they were the same device. In other words, perceived comfort can be affected by the supposed function of the device.

Researchers have also explored wearability in more general terms. Wearability is defined as the interaction between the human body and the wearable object. Dynamic wearability includes the human body in motion. Design for wearability considers the physical shape of objects and their active relationship with the human form. Gemperle et al. explored history and cultures including topics such as clothing, costumes, protective wearables, and carried devices (Gemperle et al. 1998; Siewiorek 2002). They studied physiology, biomechanics, and the movements of modern dancers and athletes. Drawing upon the experience of CMU's wearable's group over two dozen generations of machines representing over a hundred person years of research, they codified the results into guidelines for designing wearable systems. These results are summarized in Table 12.1.

This team also developed a set of wearable forms to demonstrate how wearable computers might be mounted on the body. Each of the forms was developed by applying design guidelines and followed a simple pattern for ensuring wearability. The pods were designed to house electronic components. All of the forms are between 3/8 in. and 1 in. thick, and flexible circuits can fit comfortably into the 1/4 in.-thick flex zones. Beginning with acceptable areas and the humanistic form language, the team considered human movement in each individual area. Each area is unique, and some study of the muscle and bone structure was required along with common movements. Perception of size was studied for each individual area. For testing, minimal amounts of spandex was stretched around the body to attach the forms. The results are shown in Figure 12.3.

These studies and guidelines provide a starting point for wearable systems designers. However, there is much work to be done in this area. Weight was not considered in these

TABLE 12.1
Design for Wearability Attributes

Attribute	Comments
Placement	Identify where the computer should be placed on the body. Issues include identifying areas of similar size across a population, areas of low movement/flexibility, and areas large in surface area.
Humanistic form language	The form of the object should work with the dynamic human form to ensure a comfortable fit. Principles include inside surface concave to fit body, outside surface convex to deflect objects, tapering sides to stabilize form on body, and radiusing edges/corners to provide soft form.
Human movement	Many elements make up a single human movement: mechanics of joints, shifting of flesh, and the flexing and extending of muscles and tendons beneath the skin. Allowing for freedom of movement can be accomplished in one of two ways: (1) by designing around the more active areas of the joints or (2) by creating spaces on the wearable form into which the body can move.
Human perception of size	The brain perceives an aura around the body. Forms should stay within the wearer's intimate space, so that perceptually they become a part of the body. The intimate space is between zero and 5 in. off the body and varies with position on the body.
Size variations	Wearables must be designed to fit many types of users. Allowing for size variations is achieved in two ways: (1) static anthropometric data, which details point-to-point distances on different sized bodies and (2) consideration of human muscle and fat growth in three dimensions using solid rigid areas coupled with flexible areas.
Attachment	Comfortable attachment of forms can be created by wrapping the form around the body, rather than using single-point fastening systems such as clips or shoulder straps.
Contents	The system must have sufficient volume to house electronics, batteries, and so on, that, in turn, constrains the outer form.
Weight	The weight of a wearable should not hinder the body's movement or balance. The bulk of the wearable object weight should be close to the center of gravity of the human body minimizing the weight that spreads to the extremities.
Accessibility	Before purchasing a wearable system, walk and move with the wearable object to test its comfort and accessibility.
Interaction	Passive and active sensory interaction with the wearable should be simple and intuitive.
Thermal	The body needs to breathe and is very sensitive to products that create, focus, or trap heat.
Esthetics	Culture and context will dictate shapes, materials, textures, and colors that perceptually fit the user and their environment.

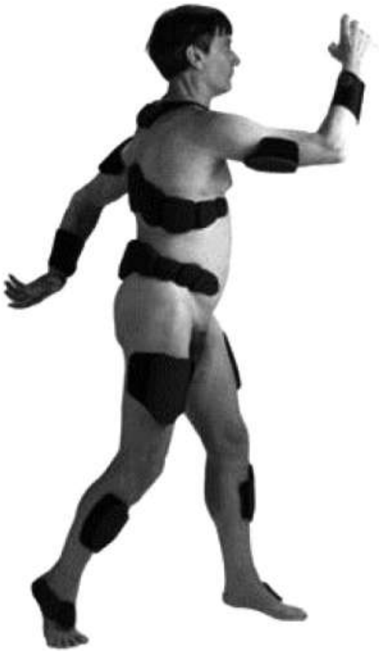

FIGURE 12.3 Forms studied for wearability.

studies, nor was the long-term physiological effects such systems might have on the wearer's body. Similarly, fashion can affect the perception of comfort and desirability of a wearable component. As wearable systems become more common and are used for longer periods of time, it will be important to test these components of wearability.

12.5 ATTENTION

Humans have a finite and nonincreasing capacity that limits the number of concurrent activities they can perform. Herb Simon observed that human effectiveness is reduced as they try to multiplex more activities. Frequent interruptions require a refocusing of attention. After each refocus of attention, a period of time is required to reestablish the context prior to the interruption. In addition human short-term memory can hold seven plus or minus two (i.e., five to nine) chunks of information. With this limited capacity, today's systems can overwhelm users with data, leading to information overload. The challenge to human computer interaction design is to use advances in technology to preserve human attention and to avoid information saturation.

In the mobile context, the user's attention is divided between the computing task and the activities in the physical environs. Some interfaces, like some augmented realities (Azuma 1997) and Dual Purpose Speech (Lyons et al. 2004), try to integrate the computing task with the user's behavior in the physical world. The VuMan 3 interface did not tightly couple the virtual and real worlds, but the computer interface was designed specifically for the user's task and allowed the user to switch rapidly between a virtual interface and his hands-on vehicle inspection.

However, office productivity tasks, such as e-mail or web searching, have little relation to the user's environment. The mobile user must continually assess what attentional resources he can commit to the interface and for how long before switching attention back to his primary task. Oulasvirta et al. specifically examine such situations (Oulasvirta et al. 2005) by fitting cameras to mobile phones and observing users attempting web search tasks while following predescribed routes. Subjects performed these tasks in a laboratory, in a subway car, riding a bus, waiting at a subway station, walking on a quiet street, riding an escalator, eating at a cafeteria and conversing, and navigating a busy street. Web pages required an average of 16.2 seconds to load and had considerable variance, requiring the user to attend the interface. The subjects shifted their attention from the phone interface more often depending on the task: 35% of page loadings in the laboratory versus 80% of the page loadings while walking a quiet street. The duration of continuous attention on the mobile device also varied depending on the physical environment: 8–16 seconds for the laboratory and cafe versus below 6 seconds for riding the escalator or navigating a busy street. Similarly, the number of attention switches depending on the demands of the environment.

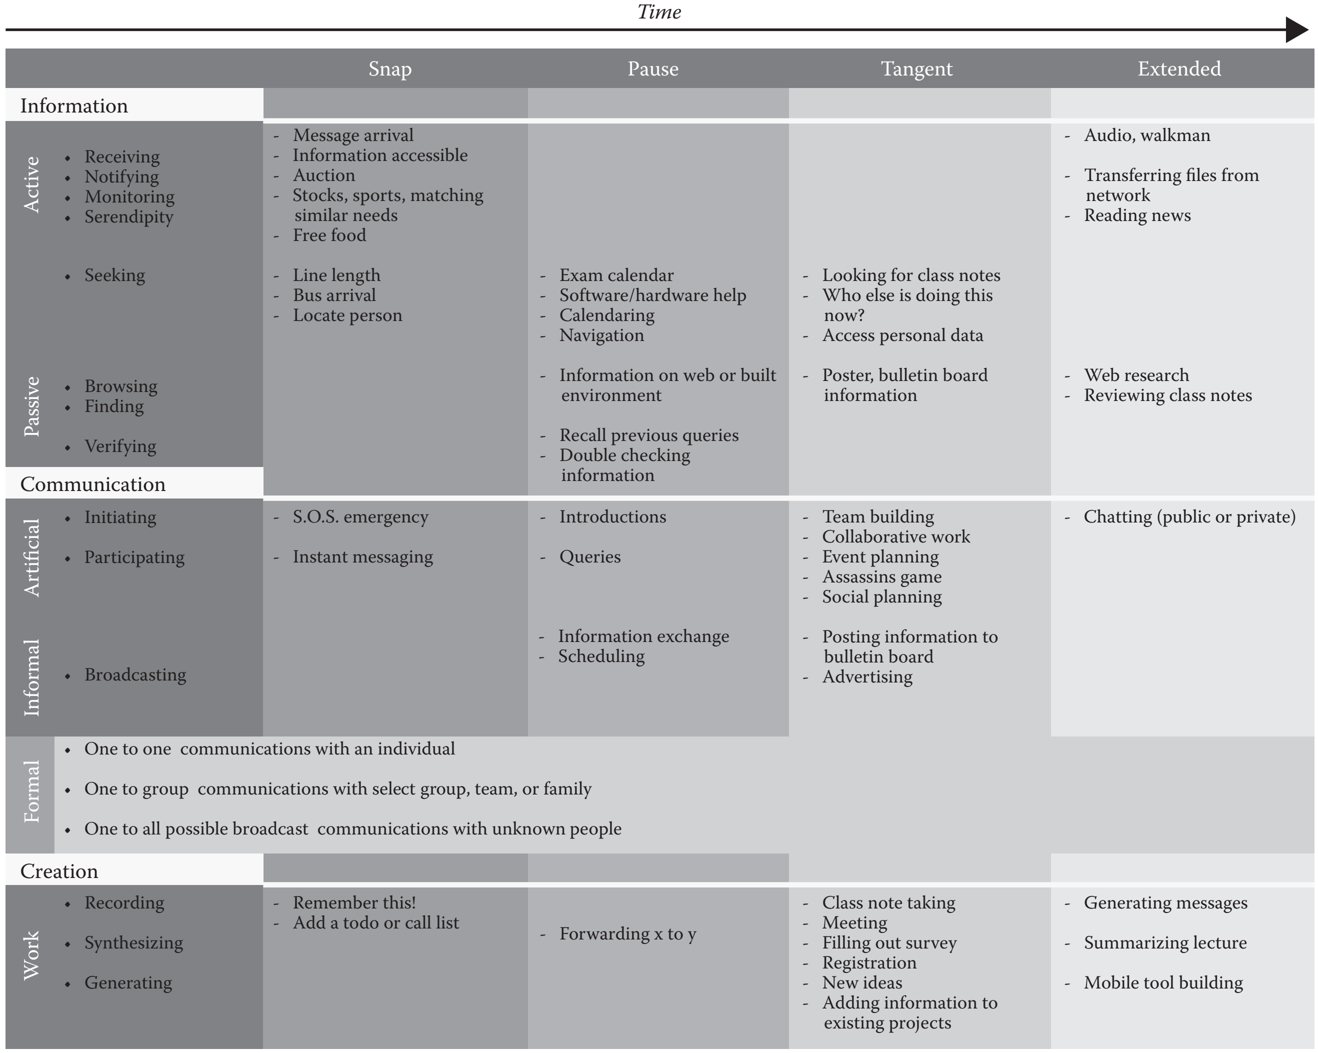
The authors note that even riding an escalator requires demands on attention (e.g., choosing a correct standing position, monitoring personal space for passersby, and determining when the end is in order to step off). Accordingly, they are working on a "Resource Competition Framework," based on the Multiple Resource Theory of attention (Wickens and Hollands 1999), to relate mobile task demands to the user's cognitive resources. This framework helps predict when the mobile user will need to adopt attentional strategies to cope with the demands of a mobile task. The authors report four such strategies that were observed in their study. (1) *Calibrating attention* refers to the process where the mobile user first attends to the environment and determines the amount of attention he needs to devote to the environment versus the interface. (2) *Brief sampling over long intervals* refers to the practice of only attending to the environment in occasional brief bursts to monitor for changes that may require a deviation from plan, such as reading while walking an empty street. (3) *Task finalization* refers to subjects' preference to finish, when sufficiently close, a task or subtask before switching attention back to the physical environment. (4) *Turntaking capture* occurs when the user is conversing with another person. Attending and responding to another person requires significant concentration, leading to minimal or no attention to the mobile interface.

The third author who has been using his wearable computer to take notes on his everyday life since 1993 has remarked on similar strategies in his interactions. Describing these attentional strategies and designing interfaces that leverage them will be important in future mobile interfaces. Much research has been performed on aircraft and automobile cockpit design to design interfaces that augment but do not interfere with the pilot's primary task of navigating the vehicle. However, only recently has it begun to be possible to instrument mobile users and examine interface use (and misuse) "in-the-field" for the mobile computer user. Now, theories of attention can be applied and tested to everyday life situations.

This newfound ability to monitor mobile workers may help us determine how *not* to design interfaces. In contrast to the VuMan 3 success described earlier, Ockerman's PhD thesis "Task Guidance and Procedure Context: Aiding Workers in Appropriate Procedure Following" warns that mobile interfaces, if not properly designed, may hinder the user's primary task (Ockerman 2000). Ockerman studied experienced pilots inspecting their small aircraft before flying. When a wearable computer was introduced as an aid to completing the aircraft's safety inspection checklist, the expert pilots touched the aircraft less (a way many pilots develop an intuition as to the aircraft's condition). In addition, the pilots relied too much on the wearable computer system, which was purposely designed to neglect certain safety steps. The pilots trusted the wearable computer checklist to be complete instead of relying on their own mental checklists. Ockerman shows how such interfaces might be improved by providing context for each step in the procedure. Another approach would be integrating the aircraft itself into the interface (e.g., use augmented reality to overlay graphics on the aircraft indicating where the pilot physically inspects the plane).

Most recently, the Defense Advanced Research Project Agency's Augmented Cognition project (Kollmorgen et al. 2005) aims to create mobile systems that monitor their user's attentional resources and records or delays incoming information to present it to the user in a more orderly and digestible time sequence. These systems exploit mobile electroencephalogram readings or functional near infrared imaging to monitor the user's brain activations and relate these results to the user's current state (Archinoetics). Such projects, if successful on a larger scale, could reveal much about the mental resources required for truly mobile computing (Archinoetics site).

The Attention Matrix, shown in Figure 12.4, (Anhalt et al. 2001) categorizes activities by the amount of attention they require. The activities are Information, Communication, and Creation. Individual activities are categorized by the amount



Time

		Snap	Pause	Tangent	Extended
Information					
Active	• Receiving • Notifying • Monitoring • Serendipity	- Message arrival - Information accessible - Auction - Stocks, sports, matching similar needs - Free food			- Audio, walkman - Transferring files from network - Reading news
	• Seeking	- Line length - Bus arrival - Locate person	- Exam calendar - Software/hardware help - Calendaring - Navigation	- Looking for class notes - Who else is doing this now? - Access personal data	
Passive	• Browsing • Finding		- Information on web or built environment	- Poster, bulletin board information	- Web research - Reviewing class notes
	• Verifying		- Recall previous queries - Double checking information		
Communication					
Artificial	• Initiating	- S.O.S. emergency	- Introductions	- Team building - Collaborative work - Event planning - Assassins game - Social planning	- Chatting (public or private)
	• Participating	- Instant messaging	- Queries		
Informal	• Broadcasting		- Information exchange - Scheduling	- Posting information to bulletin board - Advertising	
Formal	• One to one communications with an individual • One to group communications with select group, team, or family • One to all possible broadcast communications with unknown people				
Creation					
Work	• Recording • Synthesizing • Generating	- Remember this! - Add a todo or call list	- Forwarding x to y	- Class note taking - Meeting - Filling out survey - Registration - New ideas - Adding information to existing projects	- Generating messages - Summarizing lecture - Mobile tool building

FIGURE 12.4 Attention matrix.

of distraction they introduce in units of increasing time: (1) Snap, (2) Pause, (3) Tangent, and (4) Extended. The Snap duration is an activity that is usually completed in a few seconds, such as checking your watch for the time. The user should not have to interrupt his primary activity to perform this activity. The Pause action requires the user to stop current activity, switch to the new but related activity, and then return to the previous task within a few minutes. Pulling over to the side of the road and checking directions is an example of a pause. A Tangent action is a medium length task that is unrelated to the action that the user is engaged in. Receiving an unrelated phone call is an example of a tangent activity. An Extended action is when the user deliberately switches his task, beginning a wholly new long-term activity. For the car driver, stopping at a motel and resting for the night is an extended activity.

As distractions on the left of the matrix take less time from the user's primary activity, our intent is to move activities of the matrix toward the left side (Snap). Our goal is to evaluate how this process extends to a larger sample of applications.

12.6 MANIPULATION

12.6.1 VuMan 3 Dials Pointing

VuMan 3 added a novel manipulation interface suitable for use when physical attention is occupied. The VuMan 3 has a low-resolution display and, consequently, a purely textual interface. Figure 12.5 shows a sample screen from the user interface. The user navigates through a geographically organized hierarchy: top, bottom, front, rear; then left, right, and more detail. Eventually, at the node leafs, individual components are identified. There are over 600 of these components. Each component is indicated to be "serviceable" or "unserviceable." If it is serviceable, then no further information is given. If it is unserviceable, then one of a small list of reasons is the next screen.

The user can return up the hierarchy by choosing the category name in the upper right corner, or sequence to the next selection in an ordering of the components. Once a component is marked as serviceable or unserviceable, the next selection in the sequence is automatically displayed for the user. Furthermore, each component has a probability associated with it of being serviceable, and the cursor is positioned over the most likely response for that component.

FIGURE 12.5 VuMan 3 options screen.

The screen contained navigational information. Sometimes there is more on a logical screen than can fit on a physical screen. Screen navigation icons are on the left-hand side of the screen. The user can go to the previous physical screen or next physical screen that is a functional part of the logical screen. The user can always go back to the Main Menu. In Figure 12.6, the VuMan 3 information screen is shown, with different sections to inspect. The inspection is divided into sections, and different people can be inspecting different sections in parallel. The inspector would pick a section, highlight it by rotating the dial, and then select the highlighted item by pressing a button. The inspector would then receive a detailed set of instructions on what to do. In Figure 12.7, the inspector is instructed to check for damage and bare metal. The "smart cursor" anticipates that the inspector will be filling in the "status field" whose current value is "none." By clicking, a list of options is displayed, the first of which is "serviceable." With the marine LTI, the item is serviceable in 80% of the cases. By ordering the most probable selection first, the interface emulates a paper checklist where most of the items will be checked as "OK." The smart cursor then assumes the most likely step. There is no need to even move the dial—you merely need to click on the highlighted option. For example, in Figure 12.8 "serviceable" has been filled in and the box signifying the next activity is

"next." If all entries are "serviceable," one would simply tap the button multiple times. If an item is "unserviceable," the dial is turned and "unserviceable" is selected. Next, a list of reasons why that particular device was unserviceable would appear. The dial is rotated and one or more of the options are selected. Since more than one reason may be selected as to why it is unserviceable, "done" is selected to indicate completion. The selected items would appear in the "comment" field. When the checklist is completed, the data is uploaded to the logistics computer, which would then generate the job work orders.

Several lessons were derived from building the system. As part of the design cycle, a mouse (essentially a disk with buttons) was tested. However, the physical configuration of the device could be ambiguous. Was the left button in the proper position when the mouse's tail was toward the user or away from the user? Were the buttons supposed to be at the top? The dial removed this orientation ambiguity.

Another design lesson was to minimize cables. An earlier system had a cable connecting the battery, a cable for the mouse, and a cable for the display. These wires quickly became knotted. To avoid this problem, the VuMan 3 design used internal batteries, and the dial was built into the housing. The only remaining wire was the one to the display.

A third lesson was that wearable computers have a minimum footprint that is comfortable for your hand. While the keyboards of palmtop computers are getting smaller, evolution has not correspondingly shrunk our fingers. The thickness of the electronics will become thinner. Eventually, it will be as thick as a sheet of plastic or incorporated into clothing. However, there will be a minimal footprint for the interface. Furthermore, the interface—no matter where it is located on your body—is operated in the same way. This is a major feature of the dial. It can be worn on your hip or in the small of the back. In airplane manufacturing, where workers navigate small spaces, the hip defines the smallest diameter through which the person can enter. Here a shoulder holster is preferred for the wearable computer.

The marines' oversized coverall pockets were an advantage for the system. The soldiers could drop the computer into their coveralls and operate it through the cloth of the pocket. In terms of simplicity, as well as orientation independence, the dial integrated with the presentation of information on the screen. Everything on the screen could be considered to be on a circular list. In most cases, there are less than a dozen items on a screen that are selectable. This sparse screen is an advantage on a head-mounted display where the user may be reading while moving. The font must be large enough to read while the screen is bouncing. The dial should be an intuitive interface for web browsing. Probably, there are less than a half dozen items on a typical page to select, and it is rotated clockwise or counter clockwise. A button is then used to select the highlighted item. VuMan 3 had three types of buttons that all performed the same function. The buttons support left-hand and right-hand thumb-dominant as well as a central for finger-dominant users.

12.6.2 Mobile Keyboards

The VuMan 3 addressed the problem of menu selection in the mobile domain and effectively used a 1D dial to create a pointing device that can be used in many different mobile domains. However, for tasks like wireless messaging, more free-form text entry is needed. Although speech technology has made great strides in the last decade, speech recognition (SR) is very difficult in the mobile environment and often suffers from high error rates. In addition, speech is often not socially acceptable (in hospitals, meetings, classrooms, etc.). Keyboard interfaces still provide one of the most accurate and reliable methods of text entry.

Since 2000, wireless messaging has been creating billions of dollars of revenue for mobile phone service providers, and over 1 trillion messages are currently being typed per year. Until recently, many of these messages were created using the Multitap or T9 input method on phone keypads. Yet studies have shown that users average a slow 10–20 words per minute (wpm) using these common typing methods (for comparison, a highly skilled secretary on a desktop averages 70–90 wpm). Given the obvious desire for mobile text input, Human–Computer Interaction (HCI) researchers have begun reexamining keyboards. While keyboard entry has been well studied in the past, mobility suggests intriguing possibilities. For example, if an adequate method of typing can be combined with a sufficient display for the mobile market, computing may move "off-the-desktop" permanently.

Traditionally, text entry studies emphasize learnability, speed, and accuracy. However, a mobile user may not be able to devote all of his attention to the text entry process. For example, he may be taking notes on a conversation and wish to maintain eye contact with his conversational partner. Or, he may be in a meeting and may hide his keyboard under the desk to avoid distracting others with the keyboard's noise and the motion of his fingers. The user might also attempt to enter text while walking and need to attend his physical environment instead of looking at the screen. These conditions all describe "blind" typing where the user enters text with only occasional glances at the screen to ensure that the text has been entered correctly.

Lyons et al. and Clawson et al. (2005) have performed longitudinal studies on two keyboards, Handykey's Twiddler (Figure 12.9) and the mini-QWERTY "thumb" keyboard (Figure 12.10), to determine if they might achieve desktop

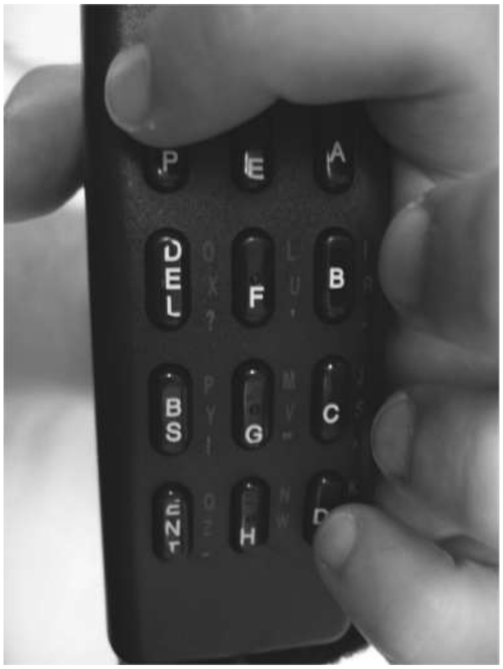

FIGURE 12.9 Handykey's Twiddler.

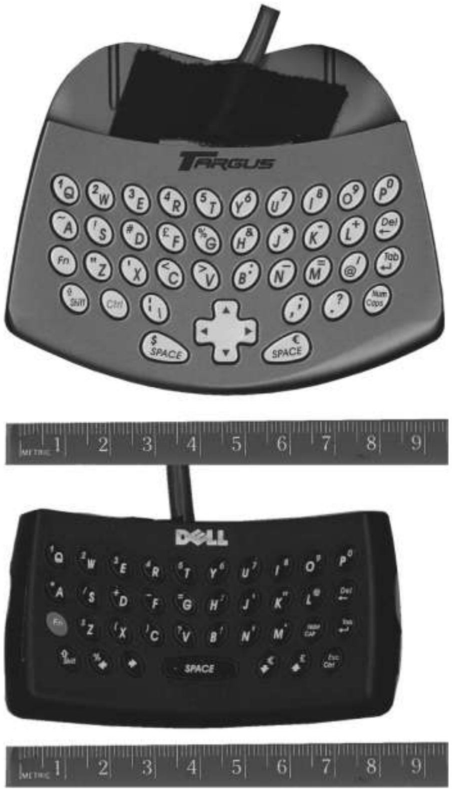

FIGURE 12.10 Mini-QWERTY thumb keyboard.

level text entry in the mobile domain. As the "average" desktop entry rate was considered to be 30 wpm, including hunt-and-peck typists, this benchmark was chosen as the minimum for speed. Traditionally, very high accuracy is desired for desktop typing. However, as a culture of informal e-mail and SMS messaging has developed, less accurate typing has become common. The community is debating how to reconcile speed and accuracy measures; however, error rates of approximately 5% per character are common in current mobile keyboard studies.

With the Twiddler, novices averaged 4 wpm during the first 20-minute session and averaged 47 wpm after 25 hours of practice (75 twenty-minute sessions). The fastest user averaged 67 wpm, which is approximately the speed of one of the authors who has been using the Twiddler for 12 years. While 25 hours of practice seems extreme, a normal high school typing class involves almost three times that training time to achieve a goal of 40 wpm.

Even so, mobile computer users may already have experience with desktop-QWERTY keyboards. Due to their familiarity with the key layout, these users might more readily adopt a mini-QWERTY keyboard for mobile use. Can a mini-QWERTY keyboard achieve desktop rates? The study performed by Clawson et al., examined the speed and accuracy of experienced desktop typists on two different mini-QWERTY designs. These subjects averaged 30 wpm during the first 20-minute session and increased to 60 wpm by the end of 400 minutes of practice!

While both of these studies easily achieved desktop typing rates and had error rates comparable to past studies, can these keyboards be used while mobile? While neither study tested keyboard use while the user was walking or riding in a car, both experimented with blind text entry (in that, in at least one condition, typists could not look at the keyboard nor the output of their typing). When there was a statistically significant difference between blind and normal typing conditions, experienced Twiddler typist slightly improved their speeds and decreased their error rates. However, experienced mini-QWERTY typists were significantly inhibited by the blind condition, with speeds of 46 wpm and approximately three times the error rate even after 100 minutes of practice. These results might be expected in that Twiddler users who are trained to type without visual feedback from the keyboard whereas the mini-QWERTY keyboard design assumes that the user can see the keyboard to help disambiguate the horizontal rows of small keys.

The results of these studies demonstrate that there are multiple ways that desktop typing rates can be achieved on a mobile device. The question remains, however, whether the benefits of typing quickly while "blind" or moving will be sufficient to cause users to learn a new text entry method. Other benefits might also affect the adoption of keyboards in the future. For example, a 12-button device like the Twiddler can be the size of a small mobile phone and still perform well, whereas 40-button mini-QWERTY keyboards may have already shrunk as much as possible for users' hands. Another factor may be adoption of mobile computing in developing countries. According to Techweb, almost 1 billon mobile phones were shipped in 2005. Many new mobile phone users will not have learned to type on a Roman alphabet keyboard and may be more concerned with quick learning than compatibility with desktop input skills.

12.7 SPEECH INTERFACES

12.7.1 Vocollect

Mobile keyboards are not suitable for applications in which hands-free control is necessary, such as warehouse applications. Pittsburgh-based Vocollect focuses on package manipulation—in particular, the warehouse-picking problem. In this scenario, a customer places an order consisting of several different items stored in a supplier's warehouse. The order transmits from the warehouse's computer to an employee's wearable computer (Figure 12.11). In turn, each item and its location are spoken to the employee through a pair of headphones. The employee can control how this list is announced through feedback via SR and can also report inventory errors as they occur. The employee accumulates the customer's order from the warehouse's shelves and ships it. This audio-only interface also frees the employee to manipulate packages with both hands, whereas a pen-based system would be considerably more awkward. As of December 2000, Vocollect had approximately 15,000 users and revenues between US$10 and US$25 million.

12.7.2 Navigator Wearable Computer with Speech Input

Boeing has been pioneering "augmented reality" using a head-mounted, see-through display. As the user looks at the aircraft, the next manufacturing step is superimposed on the appropriate portion of the aircraft. One of their first applications is fabrication of wire harnesses. Every aircraft is essentially unique. They may be from different airlines. Even if they are from the same airline, one might be configured for a long haul route and another for a short haul route. The airline may specify different configurations. For example, their galleys will be in different places, the wire harnesses would change, and so on. Wire harnesses are fabricated months before they are assembled into the aircraft. The assembly worker starts with a peg board measuring about 3 ft. high and 6 ft. long. Mounted on the board is a full-sized diagram of the final wire harness. Pegs provide support for the bundles of wire as they form. The worker selects a precut wire, reads its identification number, looks up the wire number on a paper list to find the starting coordinates of the wire, searches for the wire on the diagram, and threads the wire following the route on the diagram. With augmented reality, the worker selects a wire and reads the wire identification from the bar code. A head tracker provides the computer with information on where the worker is looking and superimposes the route for that particular wire on the board. Trial evaluations indicate a savings of 25% of the assembly effort primarily due to the elimination of cross-referencing the wire with paper lists.

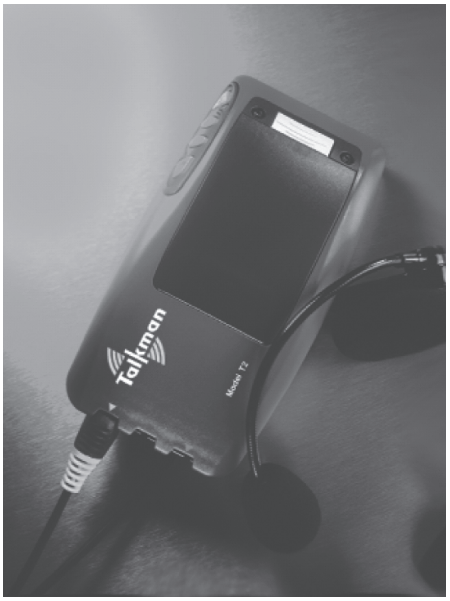

FIGURE 12.11 Vocollect's audio-based wearable computer.

The Navigator 2, circa 1995, is designed for a voice-controlled aircraft inspection application (Siewiorek, Smailagic, and Lee 1994; Smailagic and Siewiorek 1994; Smailagic and Siewiorek 1996). The SR system, with a secondary manually controlled cursor, offers complete control over the application in a hands-free manner, allowing the operator to perform an inspection with minimal interference from the wearable system. Entire or portions of aircraft manuals can be brought on-site as needed, using wireless communication. The results of inspection can be downloaded to a maintenance logistic computer.

Consider one portion of Navigator 2's application, three-dimensional inspections. The application was developed for McClellan Air Force Base in Sacramento, California and the KC-135 aerial refueling tankers. Every 5 years these aircraft are stripped down to bare metal. The inspectors use magnifying glasses and pocket knives to hunt for corrosion and cracks.

At start-up, as shown in Figure 12.12, the application prompts the user for either their choice of activating the SR system or not. The user then proceeds to the Main Menu. From this location, several options are available, including online documentation, assistance, and the inspection task (Figure 12.13). Once the user chooses to begin an inspection, information about the inspection is entered, an aircraft type to examine is selected, and the field of interest is narrowed from major features (Left Wing, Right Tail, etc.) (Figure 12.14) to more specific details (individual panes in the cockpit window glass) (Figure 12.15). A coordinate system is superimposed on the inspection region. The horizontal coordinates begin from the nose and the vertical coordinates are "water lines" derived as if the airplane was floating. The inspector records each imperfection in the skin at the corresponding location on the display. The area covered by each defect as well as the type of defect, such as corroded, cracked, or missing, are recorded. To maximize usability, each item or control may be selected simply by speaking its name. Figure 12.16 shows the Navigator 2 systems in use.

The user navigates to the display corresponding to the portion of the skin currently being inspected. This navigation is partially textual based on buttons (choose aircraft type to be inspected) and partially graphical based on side

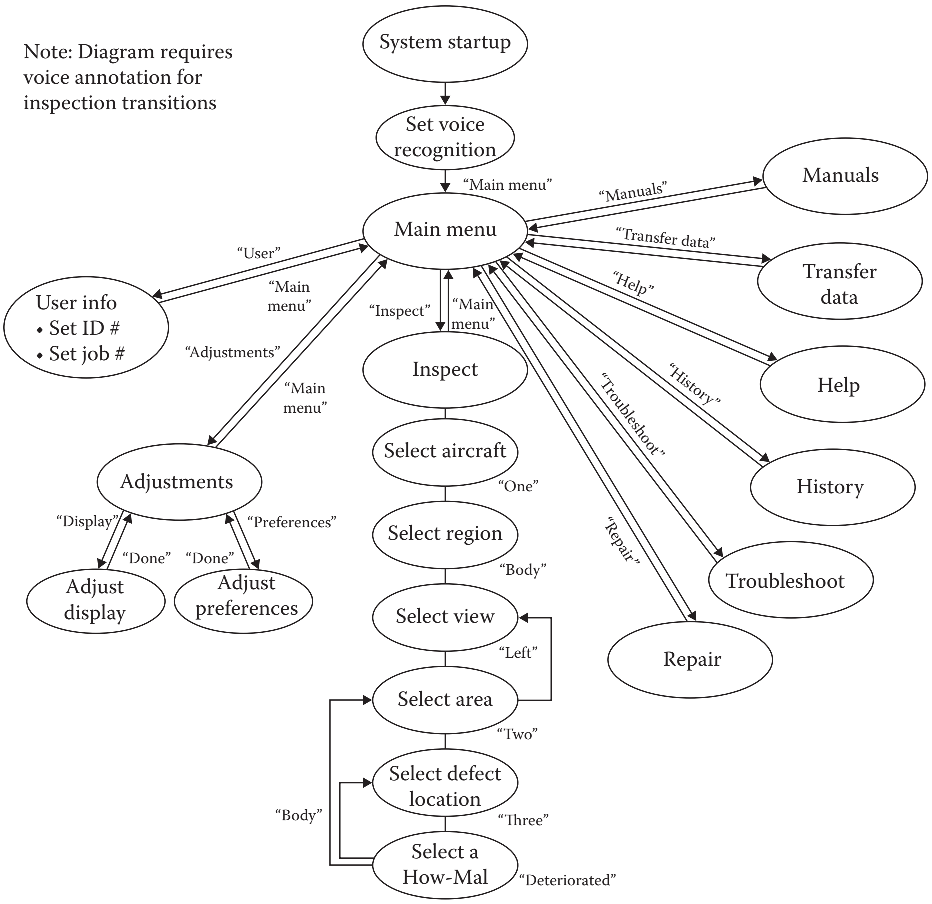

FIGURE 12.12 Navigator 2 state machine.

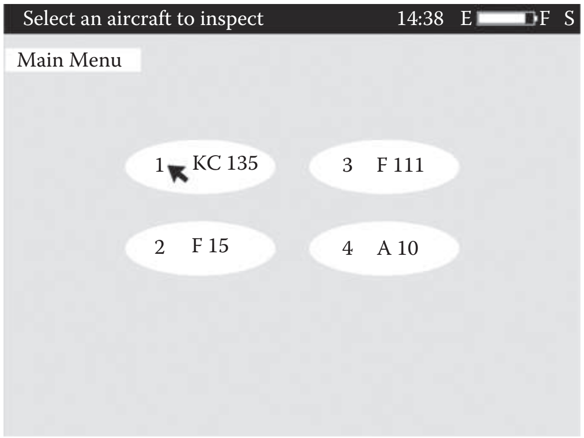

FIGURE 12.13 Navigator 2 main menu.

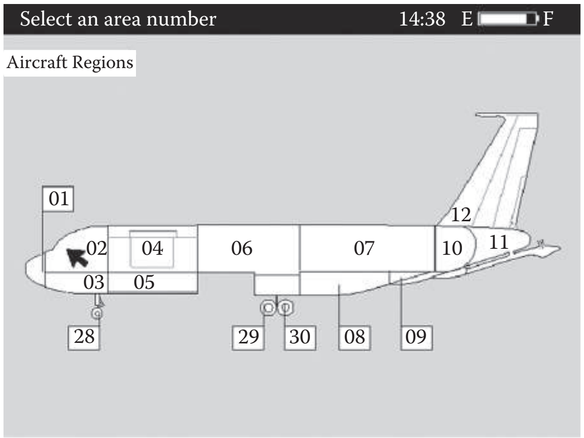

FIGURE 12.14 KC 135 inspection regions.

perspectives of the aircraft (choose area of aircraft currently being inspected). The navigation can be performed either through a joystick input device or through the use of speech input. The speech input is exactly the text that would be selected. The positioning of the imperfection is done solely through the joystick since speech is not well suited for the pointing necessary to indicate the position of the imperfection. As the cursor is moved by the joystick, the coordinates and the type of material represented by the cursor are displayed at the bottom of the screen. If a defect is at the current position, a click produces a list of reasons why that material would be defective such as corrosion, scratch, and so on. The defect type can be selected by the joystick or by speaking its name and the information would go into the database. The user can navigate to the main selection screen by selecting the "Main Menu" option on all of the screens. One level up in the hierarchy can also be achieved through a single selection.

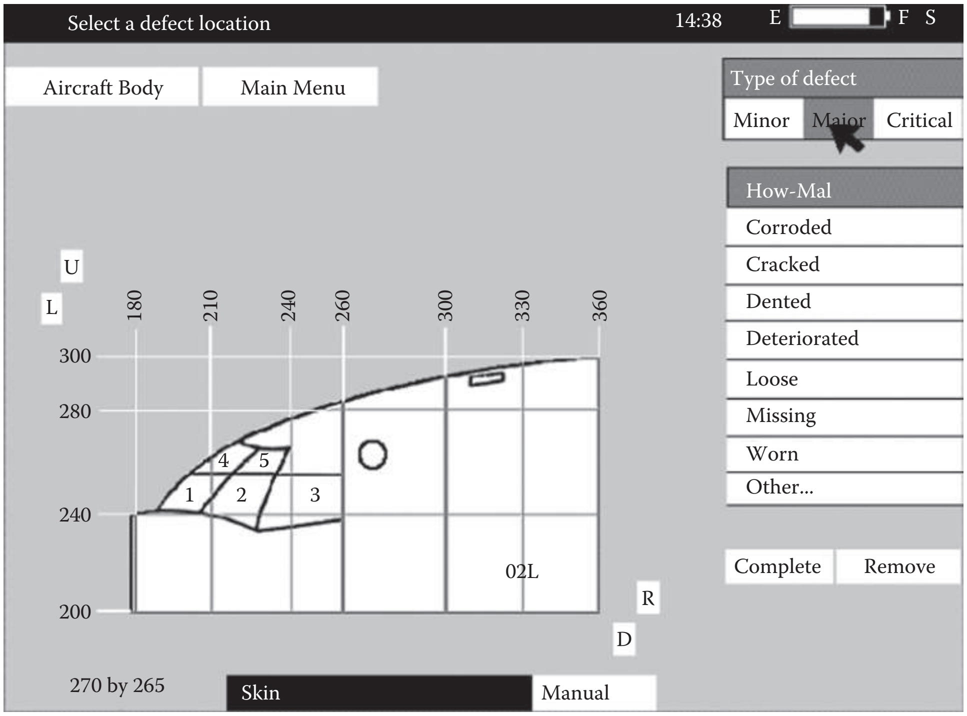

FIGURE 12.15 Locating and labeling a defect type.

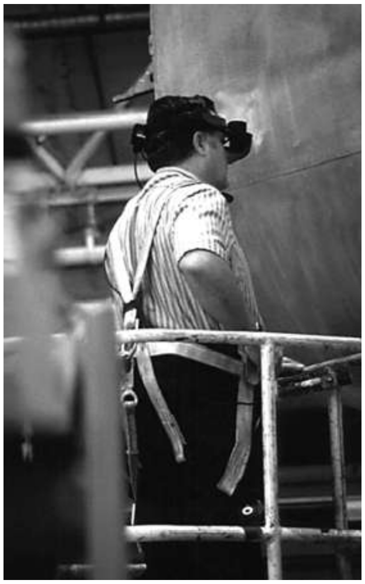

FIGURE 12.16 Inspector entering information into Navigator 2 system.

The relationship between the user interface design principles and the Navigator 2 user interface is as follows:

- Simplicity of function: The only functions available to the user are to enter skin imperfections for one of four aircrafts, to transfer data to another computer, to enter identification information both for the vehicle and for the inspector, and to see a screen that describes the Navigator 2 project.
- No textual input: The identification information required entering numbers. A special dialogue was developed to enable the entering of numeric information using the joystick as an input device. This was cumbersome for the users but only needed to be performed once per inspection.
- Controlled navigation: The interface was arranged as a hierarchy. The top level consisted of a menu that gave a choice of function. Once the inspection function and then the vehicle were chosen, the area of the skin inspected was navigated to via selecting an area of the aircraft to expand. Once an imperfection was indicated, the user had to select one of the allowable types of imperfections. At each stage, the user could go up one level of the hierarchy or return to the Main Menu.

One of the lessons learned with Navigator 2 is the power of forcing the use of a common vocabulary. Since the average age of the aircraft is 35 years, the type of defects encountered is a very stable set. Previously, one inspector would call a defect “gouged” whereas another inspector would call the same defect a “scratch.” What is the difference between a gouge and a scratch? How much material does it take? How much time does it take to repair? What skill of labor is needed? The logistics problem is much more difficult without a standardized vocabulary. Thus, there is a serendipitous advantage in injecting more technology.

A second lesson is that in some cases the SR front end mistakenly produces the wrong output. SR systems typically have an error rate of 2%–10%. The unexpected output may cause the application to produce the wrong result. In one of Navigator 2’s early demonstrations, the user was attempting to exit the application. The SR system thought a number was spoken. At that point, the application was expecting a second number, but there was no match since the user was saying "exit," "quit," "bye," and so on. The system appeared to be frozen when in actuality there was a mismatch between what the application software was expecting and what the user thought the application state was. The solution was to give the user more feedback on the state of the application by additional on-screen clues. Also, a novel application input test generator was developed that took a description of the interface screens and created a list of all possible legal exits from each screen.

A third lesson learned was the criticality of response time. When SR was done in software on Navigator (circa 1995), it was 12 times real time, which became very frustrating. People are less patient when they are on the move than when they are at a desktop. People at a desk are willing to wait 3 minutes for the operating system to boot up, but when you are on the move, expectations are for instant response like that of portable tools such as a flashlight. For example, some airplanes have a digital computer to control the passengers' overhead lights. It is disconcerting that when the button is pushed, it may take 2 or 3 seconds before the light turns on. Even a couple of second delay in a handheld device is disruptive. Users typically continue to push buttons until there is a response. The extra inputs cause disconnect between the software and the user. The software receives a stream of inputs, but the user sees outputs that are related to inputs given a long time before the screen appears. The situation is similar to listening to yourself talk when there is a second or two delay in the sound played back. The user easily becomes very confused.

The field evaluation indicated that the inspection is composed of three phases. The inspectors would spend the same amount of time maneuvering their cherry picker to access a region of the airplane, visually inspecting and feeling the airplane's skin, and recording the defect's type and location. Navigator 2 reduced the paperwork time by half resulting in an overall time savings of about 18%. Training time to familiarize inspectors with the use of Navigator 2 was about 5 minutes after which they would proceed with actual inspections. A major goal of field evaluations is that users perform productive work. They do not want to redo something that was already done once.

The typical inspection requires about 36 hours discovering approximately 100 defects. Today, the inspector takes notes on a clipboard. Upon completion, the inspector fills out forms on a computer. Each defect takes 2–3 minutes to enter. The data entry is thus an additional 3- to 4-hour task. Navigator 2 transmits the results of the inspection by radio in less than 2 minutes.

In summary, evaluations of inspectors before and after the introduction of Navigator 2 indicated a 50% reduction in the time to record inspection information (for an overall reduction of 18% in inspection time) and almost two orders of magnitude reduction in time to enter inspection information into the logistics computer (from over 3 hours to 2 minutes). In addition, Navigator 2 weighs 2 lb. compared with the cart the inspectors currently use with 25 lb. of manuals.

12.8 SPEECH TRANSLATION

The Speech Recognition/Language Translation (SR/LT) application consists of three phases: (1) speech to text language recognition, (2) text to text LT, and (3) text to speech synthesis. The application running on Tactical Information Assistant-Prototype (TIA-P), circa 1996, is the Dragon Multilingual Interview System (MIS), jointly developed by Dragon Systems and the Naval Aerospace and Operational Medical Institute (NAOMI). It is a keyword-triggered multilingual playback system, which listens to a spoken phrase in English, proceeds through a SR front end, plays back the recognized phrase in English, and after some delay (~8–10 seconds) synthesizes the phrase in a foreign language (Croatian). The other, local person can answer with Yes, No, and some pointing gestures. The Dragon MIS has about 45,000 active phrases in the following domains: medical examination, mine fields, road checkpoints, and interrogation. Therefore, a key characteristic of this application is that it deals with a fixed set of phrases and includes one-way communication. A similar system is used in Iraq as a briefing aid to interrogate former Iraqi intelligence officials and to speak with civilians about information relevant to locating individuals. This shows the viability of the approach.

TIA-P is a commercially available system, developed by CMU, incorporating a 133-MHz 586 processor, 32-MB DRAM, 2-GB IDE Disk, full-duplex sound chip, and spread spectrum radio (2 Mbps, 2.4 GHz) in a ruggedized, handheld, pen-based system designed to support speech translation applications. TIA-P is shown in Figure 12.17.

Dragon loads into memory and stays memory resident. The translation uses uncompressed ~20 KB of .WAV files per phrase. There are two channels of output: the first plays in English and the second in Croatian. A stereo signal can be split and one channel directed to an earphone, and the second to a speaker. This is done in hardware attached to the external speaker. An Andrea noise canceling microphone is used with an on-off switch.

Speech translation for one language (Croatian) requires a total of 60-MB disk space. The SR requires an additional 20–30 MB of disk space.

TIA-P has been tested with the Dragon speech translation system in several foreign countries: Bosnia (Figure 12.18), Korea, and Guantanamo Bay, Cuba. TIA-P has also been used in human intelligence data collection and experimentation with the use of electronic maintenance manuals for F-16 maintenance.

The following lessons were learned during the TIA-P field tests: wires should be kept to a minimum; handheld display is convenient for checking the translated text; standard external electrical power should be available for use internationally; battery lifetime should be extended; ruggedness is important.

The smart modules (circa 1997) are a family of wearable computers dedicated to the speech processing application (Smailagic, Siewiorek, and Reilly 2001). A smart module provides a service almost instantaneously and is configurable

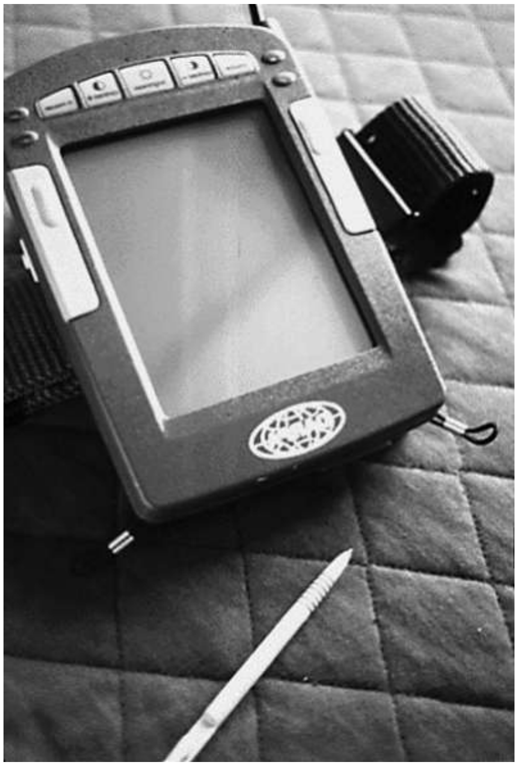

FIGURE 12.17 Tactical Information Assistant-Prototype wearable computer.

FIGURE 12.18 U.S. soldier in Balkans using Tactical Information Assistant-Prototype.

for different applications. The design goals also included: reduce latency, remove context swaps, and minimize weight, volume, and power consumption (Reilly 1998; Martin 1999; Smailagic 1997). The functional prototype consists of two functionally specialized modules, performing LT and SR. The first module incorporates speech to text language recognition and text to speech synthesis. The second module performs text to text LT. The LT module runs the PANLITE LT software (Frederking and Brown 1996), and the SR module runs CMU's Sphinx II continuous, speaker-independent SR software (Ravishankar 1996; Li et al. 1989) and Phonebox Speech Synthesis software.

Figure 12.19 depicts the structure of the speech translator from English to a foreign language and vice versa. The speech is input into the system through the SR subsystem. A user wears a microphone as an input device, and background noise is eliminated using filtering procedures. A language model, generated from a variety of audio recordings and data, provides guidance for the SR system by acting as a knowledge source about the language properties. The LT engine uses an example-based machine translation (EBMT) system, which takes individual sentence phrases and compares them to a corpus of examples it has in memory to find phases it knows how to translate. A lexical machine translation (glossary) translates any unknown word that may be left. The EBMT engine translates individual "chunks" of the sentence using the source language model and then combines them with a model of the target language to ensure correct syntax. When reading from the EBMT corpus, the system makes several random-access reads while searching for the appropriate phrase. Since random reads are done multiple times, instead of loading large, continuous chunks of the corpus into memory, the disk latency times will be far more important than the disk bandwidth. The speech generation subsystem performs text to speech conversion at the output stage. To make sure that misrecognized words are corrected, a Clarification Dialog takes place on-screen. It includes the option to speak the word again or to write it in. As indicated in Figure 12.19, an alternative input modality could be the text from the Optical Character Recognition subsystem (such as scanned documents in a foreign language), which is fed into the LT subsystem.

User-interface design went through several iterations based on feedback during field tests. The emphasis was on getting completely correct two-way speech translation, and having an easy to use, straightforward interface for the clarification dialogue.

The SR code was profiled and tuned. Profiling was performed to identify "hot spots" for hardware and software acceleration and to reduce the required computational and storage resources. A six times speedup was achieved over the original desktop PC system implementation of LT, and five times smaller memory requirements (Christakos 1998). Reducing operating system swapping and code optimization made a major impact. Input to the module is audio and output is ASCII text. The SR module is augmented with

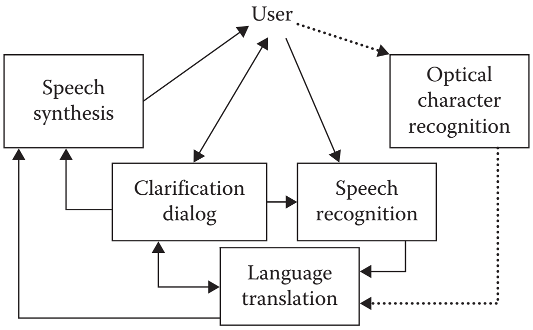

FIGURE 12.19 Speech translator system structure.

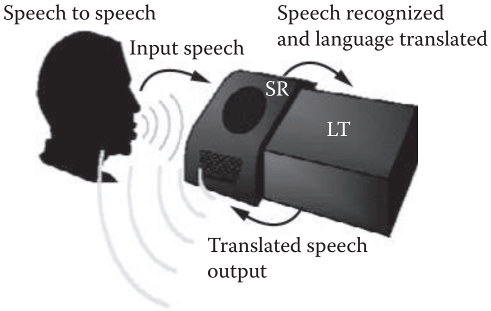

FIGURE 12.20 Speech recognizer (SR) and language translator (LT) smart module.

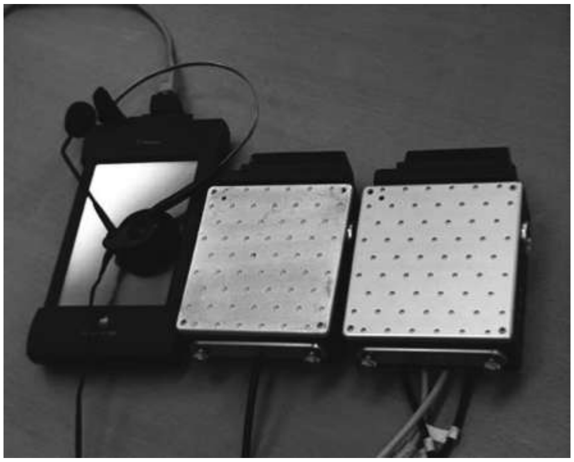

FIGURE 12.21 Speech translator smart module functional prototype.

speech synthesis. Figure 12.20 illustrates a combination of the LT module, and SR module, forming a complete standalone audio-based interactive dialogue system for speech translation.

Target languages included Serbo-Croatian, Korean, Creole French, and Arabic. Average LT performance was 1 second per sentence.

The key factors that determine how many processes can be run on a module are memory, storage space, and available CPU cycles. To minimize latency, the entirety of an application's working dataset should be able to stay memory resident.

Figure 12.21 depicts the functional prototype of the speech translator smart module, with one module performing LT, and another one SR and synthesis.

12.9 WEARABLE TACTILE DISPLAYS

TACTILE interfaces have been used successfully in wearable computing in many applications, ranging from early work on sensory prostheses and navigation aids (Collins, Scadden, and Alden 1977; Bach-y-rita and Kercelz 2003) to recent developments in learning manual skills (Huang et al. 2010) and rehabilitation (Markow et al. 2010; Dimitrijevic, Soroker, and Pollo 1996). Most tactile displays are based on mechanical actuators or electrical stimulation of the skin. Examples of mechanical actuators include vibrators constructed from masses mounted off-center on a spinning motor shaft, solenoids, piezoelectric actuators, and pin arrays. Generally, off-center mass vibrators are used for less precise tasks, such as presenting an alert, due to their longer start and stop times (in the range of 100 ms). Electrical stimulation systems use surface electrodes to create a vibration-like sensation without the use of moving parts. However, depending on the water content of the skin, location, voltage, current, electrical waveform, and electrode size, the perception may range from a tingle, itch, or buzz to a sharp or burning pain (Kaczmarek et al. 1991). While electrical stimulation has many potential benefits, including design simplicity, display resolution, negligible latency, and adjustability of sensation, the changing moisture level of human skin and inconsistent contact during movement makes these systems difficult to use in practice (Lee 2010).

With both electrical and mechanical methods of stimulation, a tactile display interface designer needs to consider where on the body the display will be placed due to the highly varying sensitivity of different areas (Guyton 1991). High-resolution and fidelity displays can be used on the tongue, lips, and fingers (Bach-y-rita and Kercelz 2003), but the wrists (Lee 2010), legs, and back can be surprisingly insensitive. In addition, a tactile display may be masked while a user is in motion due to the self-stimulation caused as clothing moves over the body.

One of the most common uses of a mobile tactile system is to provide better feedback for a graphical user interface (GUI). HCI researchers have shown that tactile feedback can increase users' accuracy when pressing virtual buttons rendered on a touch screen (Hoggan et al. 2008), as is common on many modern mobile phones. Alerts are another common use of mobile tactile displays. A simple example is the "silent," vibration mode on most mobile phones, where the phone vibrates to indicate an incoming call. (Lee and Starner 2010) have shown that a wrist-based, three-vibrator system could be used to communicate richer alert information to the user, such as caller ID. Several projects have explored how best to place actuators on the forearm and determined which features of tactile patterns convey information most efficiently (Lee and Starner 2010; Brown, Brewster, and Purchase 2006; Chen et al. 2008; Borst and Baiyya 2009). The assumption in many of these projects is that tactile alerts may be less distracting than visual or auditory alerts during critical tasks such as driving. This assumption is based on evidence from experimental psychology that users can better divide their attention across modalities as opposed to in the same modality (Wickens and Hollands 1999). Indeed, Lee found that her tactile system is less distracting when the user is performing a visually intensive task than the current practice of retrieving and visually checking the screen of a mobile phone (Lee and Starner 2010). Similarly, soldiers have found tactile alert systems useful to communicate commands covertly and with little distraction while in the field (Gilson, Redden, and Elliot 2007).

Wearable tactile displays have been used for many years as sensory prosthetics or to augment the user's natural sensors.

For example, much work has been performed creating tactile displays that help people who are blind navigate an environment (Collins, Scadden, and Alden 1977). Similarly, directional tactile systems have been used by soldiers for improving situational awareness while clearing buildings (Lindeman et al. 2005). Bach-y-rita's work in the area of sensory prosthetics is of particular interest, as his displays often involve electrical stimulation of the tongue or forehead and have been used for sensory substitution for sight, vestibular balance, and tactile sensation from other parts of the body (Bach-y-rita and Kercelz 2003).

"Passive Haptic Learning" is a recent use of mobile tactile displays. In a series of experiments described by (Huang et al. 2010), subjects learn simple piano melodies while attending other tasks. Participants were equipped with the Mobile Music Touch system; a mobile phone-based music player and a fingerless glove fitted with small vibrators inserted above the thumb and each finger (see Figure 12.22). The melody to be learned is played repeatedly through earphones and, as each note is played, the finger that would be used to play the respective key on the piano (if the user was at a piano and not mobile) is stimulated. Even though participants were required to focus their attention on a distractor task, such as a reading comprehension exam, they still learned the note sequence. A control group who heard the audio repeatedly but did not receive tactile stimulation performed significantly worse. These experiments suggest that passive training for manual tasks might be possible with wearable tactile displays.

Building on the earlier work, Markow et al. (2010) report preliminary results where practice with the Mobile Music Touch system may assist in hand dexterity and sensation rehabilitation in participants with quadriplegia due to partial spinal cord injury. In more mature work, Dimitrijevic et al. (1996) describe a series of experiments using a "Mesh Glove" that uses electrostimulation, sometimes applied below conscious sensation, on the hand to help stroke patients recover arm mobility without active participation. While the Mesh Glove is not designed to be mobile necessarily, the two systems suggest that wearable tactile displays might be worn during the user's everyday life to aid in rehabilitation.

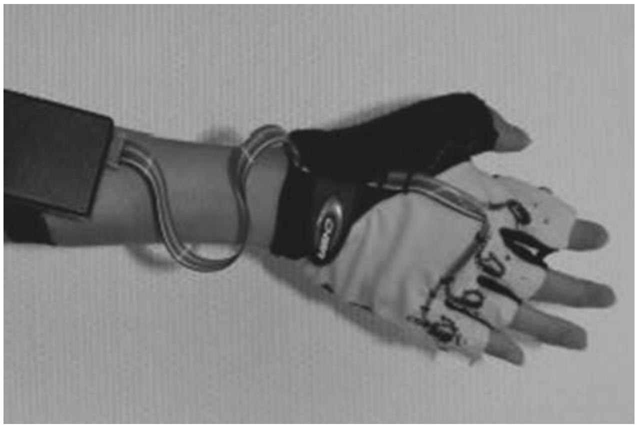

FIGURE 12.22 The Mobile Music Touch glove allows users to learn note sequences while performing other tasks.

12.10 PERFORMANCE EVALUATION

Figure 12.23 illustrates the response time for SR applications running on TIA-P and SR smart module. As SR is using a lightweight operating system (Linux) versus Windows 95 on TIA-P and the SR code is more customized, it has a shorter response time. An efficient mapping of the SR application onto the SR smart module architecture provided a response time very close to real time. To ensure system responsiveness, it was important to provide feedback to the person in near real time.

The lessons learned from tests and demonstrations include: manual intervention process to correct misrecognized words incurs some delay; swapping can diminish the performance of the LT module; the size of display can be as small as a deck of cards.

The required system resources for speech translator software are several times smaller than for the laptop/workstation version, as shown in Table 12.2.

12.11 DUAL PURPOSE SPEECH

In industry, most SR on mobile computers concentrates on the tasks of form filling or simple interface commands and navigation. One reason is that speech interfaces are often socially interruptive when other people are nearby. Speech translation, as with the TIA system above, is a different class of interface. The computer is an essential enabler of the conversation. Lyons et al. (Lyons, Starner, and Plaisted 2004) introduce a different type of conversation enabler in their Dual Purpose Speech work.

Dual Purpose Speech is easiest to discuss using a scenario. Tracy, a wearable user equipped with a head-up display and a Twidder keyboard, is in conversation with a recently introduced colleague. Pressing a button on the keyboard, the

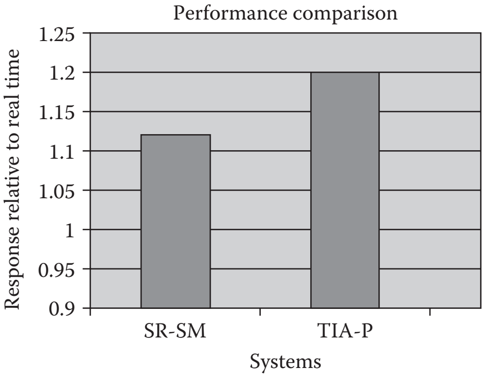

FIGURE 12.23 Response times (lower is better).

TABLE 12.2
Comparison of Required System Resources

	Laptop/ Workstation	Functional Module SR/LT	Optimized Module SR/LT
Memory size	195 MB	53 MB	41 MB
Disk space	1 GB	350 MB	200 MB

wearable user enables SR and says, "Bob, what is your phone number so that I have it for later?"

The wearable recognizes that its user wants to record a phone number and starts the user's contact list application. It attempts to recognize the name spoken and enters that into the application. However, it also saves the speech so that the user can correct the text later if there is an error.

Bob responds "Area code 404."
"404," repeats Tracy.
"555-1212," completes Bob.
"555-1212," continues Tracy who presses another button on her keyboard indicating the interaction is over, "Ok, I have it!"

On Tracy's head-up display a new contact has been made for "Bob (404) 555-1212." When Tracy finishes her conversation, she clicks an "accept" button on the application because she has recognized the information correctly. Tracy could also edit the information or play back the audio recorded during the interaction with Bob. Note that Tracy verbally repeated the information that Bob provided—a good conversational practice. Tracy both confirmed that she understood the information and provided Bob with an opportunity to correct her if necessary. However, this practice is also good from a privacy standpoint. Tracy wears a noise-canceling microphone that is thresholded to record only her own voice and not that of her conversational partners. In this way, Tracy respects the privacy of her colleagues.

Lyons et al. have designed Dual Purpose Speech applications for scheduling appointments, providing reminders for the user, and communicating important information to close colleagues. However, the key point of this research from the perspective of this section is that these applications allow the user to manipulate information on their wearables as part of the process of communicating (thus, the "dual purpose" name). The users may actively format their speech so the system can better understand them, and they may have to correct the system afterwards. However, the interface is manipulated and the information is entered as part of a social process.

This style of interface provides a contrast to the traditional desktop computer where the user's attention is assumed to be dedicated to the interface. Other wearable computing related fields also attempt to create interfaces that are driven by the user's interactions with the environment. For example, Feiner's early augmented reality systems attempted to display appropriate repair instructions based on the user's actions during the repair process (Feiner, MacIntyre, and Seligmann 1993). Such awareness of the user's context and goals may allow wearable computers to be utilized where a user's lack of attentional or physical resources would normally preclude traditional desktop applications.

12.12 PERCEPTION

Just as dexterity is impaired when a user is on-the-go, the user's ability to perceive a wearable's interface is lessened. The vibration and visual interference from a moving background interferes with visual tasks. Background noise and the noise from the body itself affect hearing. The moving of clothes over the body and the coupling of mechanical shock through the body can lessen the user's ability to perceive tactile displays. Sears et al. describe these detriments to mobile interaction caused by environmental and situational factors as "Situationally-Induced Impairments and Disabilities" (Sears et al. 2003). These researchers and others are developing procedures to test human performance in mobile computing tasks in context (in this case, walking a path) (Barnard et al. 2005; Barnard et al. in press). Such research is sorely needed as not enough is known about how to adequately simulate mobile computing scenarios in testing. For example, in Barnard et al.'s work on performing reading comprehension tasks on personal digital assistants while walking, lighting levels affected workload measures more when walking a path than when walking on a treadmill. The community needs to develop understanding about the interactions between mobility, attention, and perception in common mobile computing scenarios in order to adequately develop testing environments for mobile interfaces.

In the past, such work focused on cockpits, both for aviation and automobiles (Wickens and Hollands 1999; Melzer and Moffitt 1997; Velger 1998). However, the U.S. military's Land Warrior project has highlighted the need for such research for dismounted users who are on-the-go (Blackwood 1997). Some researchers have begun exploring mobile output devices for very specific tasks. For example, Krum (Krum 2004) describes experiments with a head-up display that focus on determining how to render overhead views of an area to encourage learning of the layout of the surrounding environment while the user is navigating to a goal on foot. As mobile augmented reality is becoming practical from a technical standpoint, researchers have begun to address perceptual issues. While not a mobile experiment, Laramee and Ware (2002) have investigated head-mounted displays to determine the relative effects of rivalry and visual interference between binocular and monocular displays with varying levels of transparency. As the market determines which mobile contexts are most important for users, experiments such as these will help determine how to design interfaces to least interfere with the user's primary tasks while providing the most value in terms of augmentation.

12.13 RESEARCH DIRECTIONS

The evolution of computing has shown that it takes several years to develop a user interface style that often emerges quite a while after the technology threshold has been passed. The thresholds represent the time when microprocessors have the capability of supporting the indicated form of interface. Figure 12.24 depicts the increase in microprocessor performance (measured in millions of instructions per second, or MIPS) as a function of time. In the early 1960s, Gordon Moore of Intel made the observation/prediction that the capacity of semiconductor chips was doubling every year. Similar trends have been noted for microprocessor speed, magnetic disk storage

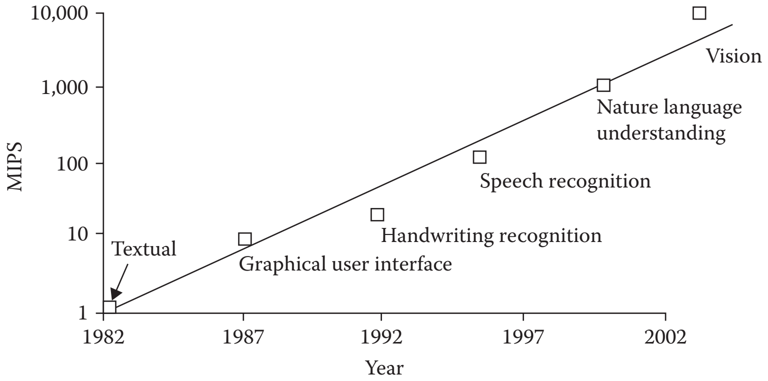

FIGURE 12.24 Minimum performance requirements for various user interaction modalities.

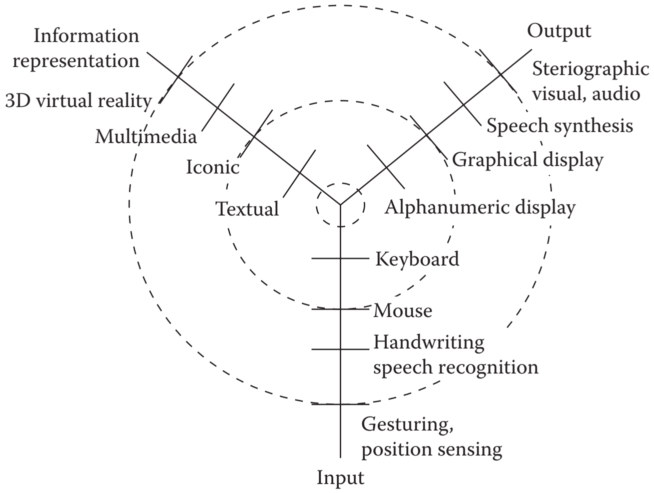

FIGURE 12.25 Kiviat graph for wearable computer use modalities.

capacity, and network bandwidth. The points depicted in Figure 12.24 are the performance thresholds necessary for each of the user interface types. Thus a textual interface requires 1 MIPS, a GUI 10 MIPS, a handwriting interface 30 MIPS, a SR interface 100 MIPS, natural language understanding 1,000 MIPS, and vision understanding, 10,000 MIPS.

Because ease of use is so closely associated with human reaction, it is much more difficult to quantify. There are at least three basic functions related to ease of use: (1) input, (2) output, and (3) information representation.

Figure 12.25 summarizes several points for each of these basic functions. Note that unlike the continuous variables for capacity and performance, the ease of use metrics is discrete.

Just as the performance of microprocessors has increased over time, as shown in Figure 12.24, the characteristics of the user interface shown in Figure 12.25 are also moving out with time. For example, the keyboard with an alpha/numeric display using textual information is representative of timesharing systems of the early 1970s. The keyboard and mouse, graphical output, and iconic desktop are representative of personal computers of the early 1980s. The addition of handwriting recognition input, speech synthesis output, and multimedia information began emerging in the early 1990s. It takes approximately one decade to broadly disseminate new input, output, and informational representations. In the 2000 decade, SR, position sensing, and eye tracking became common inputs. Heads-up projection displays should allow superposition of information onto the user's environment.

12.14 CONTEXT AWARENESS

The next step in the evolution of wearable computers is context awareness. Context-aware computing is aware of a user's state and surroundings and the mobile computer modifies its behavior based on this information. A user's context can be quite rich, consisting of attributes such as physical location, physiological state (such as body temperature, heart rate, and skin resistance), emotional state (such as angry, distraught, or calm), personal history, daily behavioral patterns, and so on. If a human assistant were given such context, he or she would make decisions in a proactive fashion, anticipating user needs. In making these decisions, the assistant would typically not disturb the user at inopportune moments except in an emergency. The goal is to enable mobile computers to play an analogous role, exploiting context information to significantly reduce demands on human attention. Context-aware intelligent agents can deliver relevant information when a user needs that information. These data make possible many exciting new applications, such as augmented reality, context-aware collaboration, wearable assisted living, augmented manufacturing, and maintenance.

12.14.1 Example System: Virtual Coach

The Seating Coach (or Power Wheelchair Virtual Coach) is an intelligent system that can guide power wheelchair users in achieving clinician established goals for body positioning. It was developed at Carnegie Mellon, with the University of Pittsburgh Center for Assistive Technology as the project client. The Seating Coach provides capabilities such as interacting with the user in a manner appropriate to their capability, inferring user capabilities from the data, indicating user compliance, and creating reminders to do past due activities. The Seating Coach sensing and computational infrastructure determines if a user employs auxiliary seating functions according to the physical therapist's prescriptions and coaches him/her to use them in a proper and timely fashion. The Seating Coach can help power wheelchair users to reduce the risk of chronic sores by comparing auxiliary seating function use against a prescription of positions and their durations as established by a physical therapist. It can aid clinicians in tracking results from training and reinforces proper technique to reduce the incidence of injuries caused by improper power wheelchair use.

A power wheelchair allows the user to recline, tilt, elevate the seat, and change leg-rest elevation of the chair. Tilt involves the same change in angle of backrest, seat and leg-rest. Recline changes the backrest angle only and leg-rest elevation changes only the leg-rest angle. The seat elevation only changes the elevation from the ground.

The Seating Coach records sensor data on user position and usage patterns. An array of pressure sensors is distributed over the back rest and seat cushion providing the pressure information to the virtual coach, as shown in Figure 12.26. Three tilt sensors determine the tilt angle of the back rest, seat recline, and leg rest elevation, as illustrated in Figure 12.27. Tilt, recline, and leg rest elevation are monitored for any improper sequences in using seat functions, such as recline without tilt, leg rest elevation without recline, and recline or tilt angles that are too large, as well as any inappropriate use of seat functions during driving. Infrared sensors are used to detect obstacles behind the chair and determine the height of the seat. Pressure sensors are monitored for weight distribution inferring body positions.

The data analysis software extracts underlying user patterns. A clinician-friendly interface allows therapists to prescribe physical activities, rules for proper use of the wheelchair, as well as parameters for user compliance goals. We created a prescription format which is easy to use and expressive enough to cover a range of subjects and conditions. The prescription encompasses all the power seat functions (PSFs) and sets limits for the user. The prescription is specified using the following information: activity type, parameter, duration of the activity, and time gap after which to repeat the activity, and alert after specified number of rule violations (Table 12.3).

After entering a usage prescription, the clinician can periodically monitor the wheelchair user's compliance to those recommendations. Reminders are generated to prompt the user to comply while alerts indicate noncompliance and are sent to the user, as shown in Figure 12.28.

In addition, a Wizard of Oz experiment was conducted where users made selections from a variety of feedback modalities and preferences to create a user interface (Liu et al. 2010). Nine PSF users and six clinicians were recruited for this study. The subjects reviewed modalities with various properties using a computer demonstration program with supplemental devices. Their preferences and suggestions were collected using a questionnaire and interviews. An animation of PSF usage tasks was preferred because it conveyed

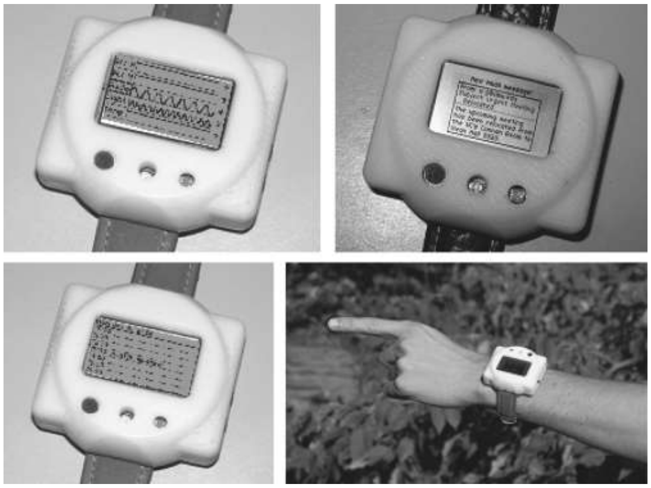

FIGURE 12.29 eWatch—a proactive assistant.

essential information. The subjects rank ordered the interaction options as a function of situation. For example, 40% of the subjects selected vibration for the reminding theme in the noisy restaurant scenario, and 46.7% selected speech for the reminding theme in the home scenario. As another example, ranking of vibration location on the seat had armrest ranked highest (60%), and headrest as lowest (6.7%). These studies will inform user interaction designs for virtual coaches.

12.14.2 Example: eWatch, a Proactive Assistant

Our research on context-aware computing employs unsupervised machine learning techniques to combine real-time data from multiple sensors into a model of behavior that is individualized to the user. The eWatch is a wearable sensing, notification, and computing platform built into a wrist watch form factor making it highly available, instantly viewable, ideally located for sensors, and unobtrusive to users (Smailagic and Siewiorek 2005). Bluetooth communication provides a wireless link to a cellular phone or stationary computer. eWatch senses light, motion, audio, and temperature and provides visual, audio, and tactile notification. The system provides ample processing capabilities with multiple day battery life enabling realistic user studies. Figure 12.29 shows a few representative eWatch screenshots: sensor waveforms, calendar, and messages. Figure 12.30 illustrates sensors and main hardware components on eWatch. We developed a wearable computing platform with power-aware hardware and software architectures, and showed how online nearest neighbor classification can identify and recognize a set of frequently visited locations.

Knowing about the user's location is an important aspect of a context-aware system. Using eWatch we developed a system that identifies previously visited locations. Our method uses information from the audio and light sensor to learn and distinguish different environments. We recorded and analyzed the audio environment and the light conditions at several different locations. Experiments showed that locations have unique background noises such as car traffic, talking, noise of computers, air conditioning and television. The light sensor sampling at a high frequency can also provide additional information beyond the brightness of the location. We observed that the frequency characteristics of light conditions tend to remain constant in most locations. For our study, audio data was recorded with the built-in microphone at a sample rate of 8 kHz and the light sensor at a frequency of 2048 Hz. At every location five consecutive recordings of audio and light were taken, separated by 10-second pauses. For every recording we sampled the microphone for 4 seconds (32,000 samples) and the light sensor for 0.5 seconds (1024 samples). The recorded data was then compressed and stored into flash memory. Locations frequently visited by the user were recorded; the rooms of the user's apartment (living room, kitchen, bedroom, bathroom), their office, the lab, different street locations on the way to university, the interior of a bus, and several restaurants and supermarket. Each location was visited multiple times on different days. In total, we collected 600 recordings at 18 different locations.

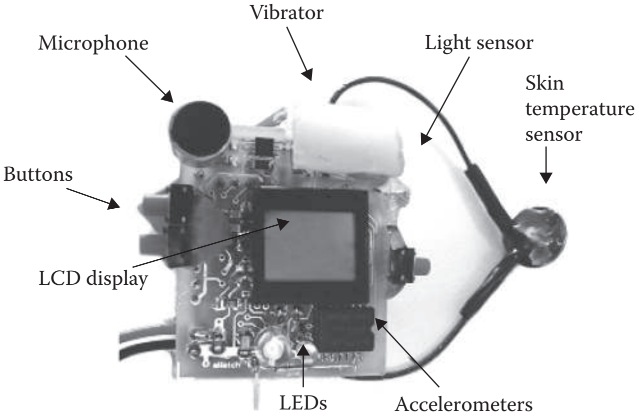

FIGURE 12.30 The eWatch hardware.

We estimated the power spectral density of the recorded sensor data using Welch's method. A 128-point fast Fourier transform was calculated for a sliding window over the complete recording and averaged over frequency domain coefficients for all windows.

The result is a smoothed estimation of the power spectral density. To reduce the number of feature components, the Principal Component Analysis was used. The dimensionality of the feature vector was reduced to its first five principal components. To visualize the feature space, Figure 12.31 shows the first three components of the feature vectors after a Linear Discriminant Analysis transformation.

The nearest neighbor method with a five-fold cross-validation was used for classification. Three different feature sets were evaluated: features from the light sensor only, microphone only, and both sensors combined. As expected, the combination of both sensors gave the best results in identifying the location. The classification with the light sensor alone gave an overall result of 84.9% correctly classified samples. The classifier confused the *lab* and *office* location and also the *bus* with the *street*. This occurred because both location pairs can have similar light conditions. Using only the audio sensor the overall recognition accuracy was 87.4%. The *office* and *apartment* location were confused in this case. Both sensors combined gave the best result of 91.4%. Locations that could not be distinguished well with only one sensor were classified more accurately with both sensors combined.

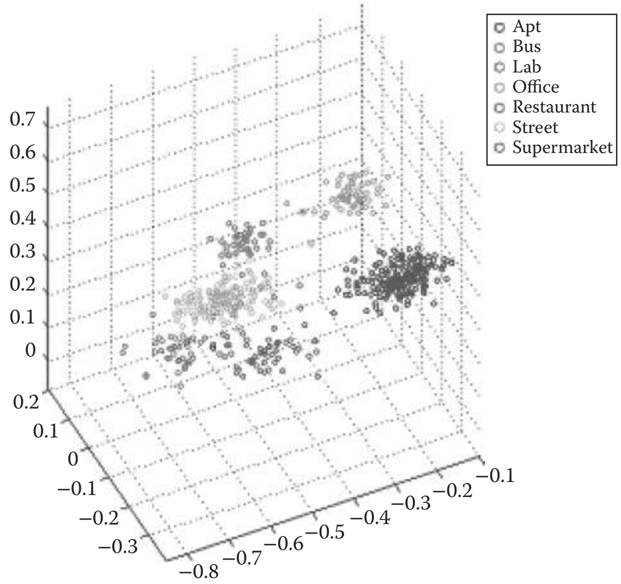

FIGURE 12.31 Learning context: audio and light sensor clustering.

12.15 WEARABLE COGNITIVE AUGMENTATION

An important goal of our research is to determine the cognitive state of a user—especially the user's cognitive load—from external observations. Knowing the user's cognitive state would enable development of proactive cognitive assistants that anticipate user needs much like a human assistant does.

What makes this attempt possible is an unprecedented advance in measuring and understanding brain activity during complex cognition using functional magnetic resonance imaging (fMRI) (Figure 12.32). The brain activity measured with fMRI is only one step removed from the neural activity itself. fMRI provides a measure of the oxygenated hemoglobin in the capillary beds in which the neural activity is occurring. Routinely used protocols in neurocognitive research on advanced MRI scanners sample the entire cortex approximately once per second. It is feasible to pursue a research plan to recognize some of the brain/cognitive states that should be amenable to improvement, and then develop an intelligent tutoring system that uses the fMRI-measured brain activation to guide the tutoring, to infer current mental states, and to rapidly guide the learner to desired mental states.

There is also a maximum on the total activation across cortical areas. Such a system-wide capacity constraint might be expected to operate when subjects co-perform two tasks that draw on nonoverlapping brain areas. The requirement of nonoverlap assures that any constraint on performance is not due just to competition for the same neural mechanisms.

In a study that found evidence for such a constraint, the two tasks were auditory sentence comprehension and mental rotation (Just et al. 2001). If there were no system-wide

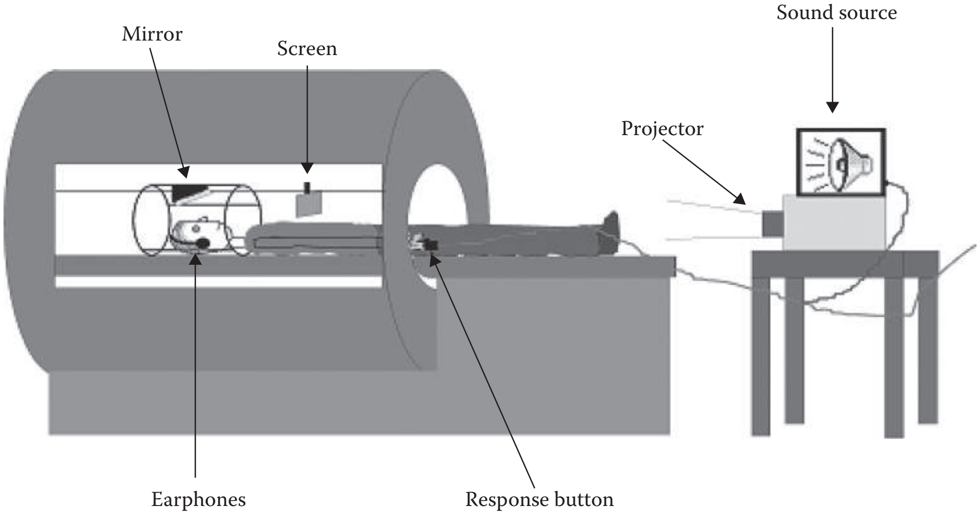

FIGURE 12.32 Functional magnetic resonance imaging experiment configuration.

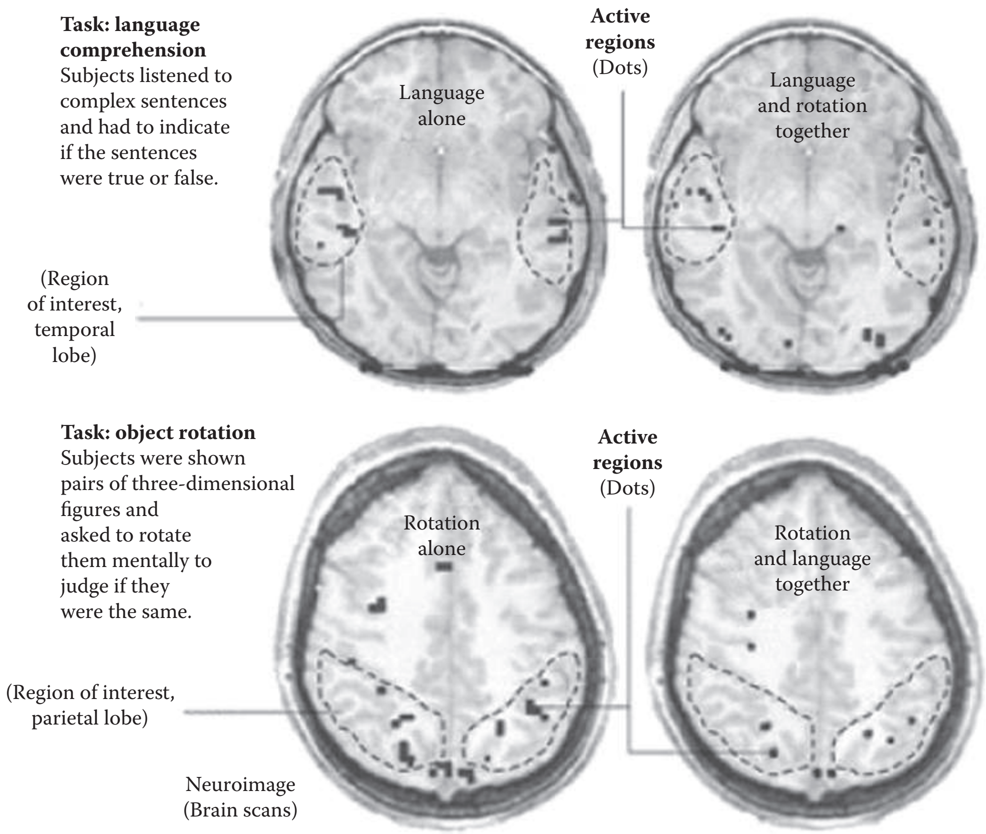

Task: language comprehension
Subjects listened to complex sentences and had to indicate if the sentences were true or false.
Language alone

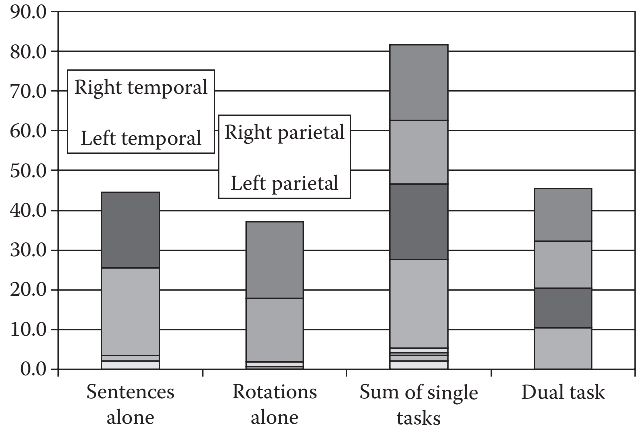

FIGURE 12.34 Activation volume in dual task comparing to single task.

capacity constraint, one would expect that because the two tasks draw on different neural substrates (language and spatial-related areas respectively), the activation in the dual task would simply be the union of the activations in each of the two single tasks. However, the activation in the dual task was far less than the union of the two single tasks. The activation associated with each individual task decreased by 30%–50% in the dual task condition, as shown in the representative brain slices of individual subjects (Figure 12.33), and in the graph presenting the group data results (Figure 12.34). The decrease in the dual task condition applied to 17 of the 18 subjects. Thus there appears to be a detectable upperbound on the total amount of activation that can be sustained in a set of cortical areas. (This study was widely applied to the question of what happens in the brain during driving and using a cell phone simultaneously.)

12.16 CONCLUSION AND FUTURE CHALLENGES

Wearable computers are an attractive way to deliver a ubiquitous computing system’s interface to a user, especially in non-office-building environments. The biggest challenges in this area deal with fitting the computer to the human in terms of interface, cognitive model, contextual awareness, and adaptation to tasks being performed. These challenges include the following:

- User interface models: What is the appropriate set of metaphors for providing mobile access to information (i.e., what is the next “desktop” or “spreadsheet”)? These metaphors typically take over a decade to develop (i.e., the desktop metaphor started in early 1970s at Xerox PARC (Palo Alto Research Center Incorporated) and required over a decade before it was widely available to consumers). Extensive experimentation working with end-user applications will be required. Furthermore, there may be a set of metaphors each tailored to a specific application or a specific information type.

- Input/output modalities: While several modalities mimicking the input/output capabilities of the human brain have been the subject of computer science research for decades, the accuracy and ease of use (i.e., many current modalities require extensive training periods) are not yet acceptable. Inaccuracies produce user frustrations. In addition, most of these modalities require extensive computing resources which will not be available in low-weight, low-energy wearable computers. There is room for new, easy-to-use input devices such as the dial developed at Carnegie Mellon University for list-oriented applications.
- Quick interface evaluation methodology: Current approaches to evaluate a human computer interface requires elaborate procedures and with scores of subjects. Such an evaluation may take months and is not appropriate for use during interface design. These evaluation techniques should especially focus on decreasing human errors and frustration.
- Matched capability with applications: The current thought is that technology should provide the highest performance capability. However, this capability is often unnecessary to complete an application and enhancements such as full-color graphics require substantial resources and may actually decrease ease of use by generating information overload for the user. Interface design and evaluation should focus on the most effective means for information access and resist the temptation to provide extra capabilities simply because they are available.
- Context-aware applications: How do we develop social and cognitive models of applications? How do we integrate input from multiple sensors and map them into user social and cognitive states? How do we anticipate user needs? How do we interact with the user? These, plus many other questions, have to be addressed before context-aware computing becomes possible. Some initial results have been reported in (Krause, Smailagic, and Siewiorek 2006).

13 Design of Fixed, Portable, and Mobile Information Devices

Michael J. Smith and Pascale Carayon

CONTENTS

13.1 INTRODUCTION

In this second revision of our chapter, we discuss fixed computer workstations and mobile use of information technology (IT), which we have termed "portable information devices" (PIDs). These portable technologies are now in use in almost every venue and human activity, and the nature of their characteristics and activities of use do not lend them to traditional fixed workstation considerations. This introduces a host of potential ergonomic concerns related to the design of work areas (and activities) where PIDs and other forms of computing are used. There have been decades of research and applications that have defined important considerations in the ergonomic design of fixed computer work areas (Grandjean 1987; ANSI/HFES 100-1988; Smith and Cohen 1997; Smith, Carayon, and Cohen 2003, 2008; BSR/HFES-100 2005; ANSI/HFES-100 2007; OSHA 2008; WorkSafeBC 2009). However, much less has been done to define the design of work areas for PIDs and mobile computing. In this chapter, we propose some ideas and considerations for dealing with ergonomic concerns for these mobile technologies in addition to updating information on fixed computer workstation applications.

Ergonomics is the science of fitting the environment and activities to capabilities, dimensions, and needs of people to enhance their performance, safety, and health. Ergonomic knowledge and principles are applied to adapt activities and environmental conditions to the physical, psychological, and social nature of the person and groups. Computer workstation design is more than just making the computer interfaces easier to use, or making furniture adjustable in various dimensions. It also involves integrating design considerations with the work environment, task requirements, and psychosocial aspects of work and job design. Critical considerations for good ergonomic practice are as follows:

- To reduce biomechanical loading on the back and joints to the lowest practical forces
- To keep repetition of body parts as low as practical
- To keep the back, neck, and joints in good postures
- To reduce the amount of time of static postures
- To reduce the duration and extent of highly repetitive motions or high forces
- To resign environmental conditions so that people can easily see and hear
- To provide frequent rest breaks from activities for resting and recovery
- To provide healthy psychosocial working conditions

A fundamental perspective discussed in this chapter is that the work area (workstation) design influences employees' comfort, health, motivation, and performance. We will examine basic ergonomic considerations (principles, practices, concerns) that can be used to develop guidance for the design of work areas (workstations) for the use of computing and related IT products such as PIDs. Some of today's technologies have the capability to directly interact with one another, sometimes without human intervention, whereas older technologies require human action. The wide myriad of computer technologies, environments of use, interaction schemes, and activities of use make specific guidance for PIDs complex and difficult. However, we will provide general guidance that has the possibility to reduce musculoskeletal stress and to enhance employees' physical comfort.

The relationship between the user and technology is a system in which the constraints of one component can affect the performance of the other. Various aspects of the work system such as the task requirements, the work demands, the environment, and the workstation influence how effectively and comfortably the technology can be used by the user (Smith and Sainfort 1989; Smith and Carayon 1995; Carayon and Smith 2000). One of the consequences of this is that the design of the workspace limits the nature and effectiveness of the interaction between the user and the technology. For instance, inadequate space for carrying out physical activities can lead to constrained postures, which together with long-lasting static loading may produce discomfort in the muscles and joints. This leads to symptoms of tiredness, muscle aches, and muscle and joint pain. In addition, heavy workload, chronic high repetition, and other biomechanical strains can cause similar problems. The adverse postural, repetition, and workload exposures can lead to reduced performance and productivity, and in the long run, they may also affect employees' well-being and health.

Today, people carry their computing and communications on their person and engage in activities in many diverse work areas without a workstation. There is a potential for serious ergonomics risks from the new modes of using new technologies.

13.2 HISTORICAL AND RECENT ERGONOMIC PERSPECTIVES ON COMPUTER WORKSTATIONS

Forty-five years ago, a person would interact with several different types of information sources and technologies when engaging in activities. Computer terminals that were connected to mainframe computers were just coming into common use in government, insurance, and banking industries. An employee might look at hard-copy documents, take notes with a pen and a paper, use a fixed location telephone, talk face-to-face with colleagues, type on a typewriter, and use a fixed computer terminal. The diversity of activities led people to actively move around during the day. Then, 35 years ago, many employees started to spend most of their workday in sedentary work, that is, sitting in front of a computer terminal. This type of human–machine system led to restricted physical movement, and much greater mental attention of the employees was directed toward the computer monitor. Over time, the terminals that were connected to mainframe computers were replaced by PCs connected to a network of computers. Later, laptop computers and easily portable IT devices were increasingly used.

Today, millions of employees still work primarily at fixed workstations on PCs. But there has also been a substantial shift to the use of laptop computers and PIDs, which seems to be the trend for the future. Today, we have a variety of circumstances in multidimensional environments where people operate from fixed workstations part of the time, laptops part of the time, and mobile connections to the Internet at other times. In many instances, people are again on the move and not completely in fixed, sedentary situations. Although this moving around is better for the muscles and joints than constant sedentary sitting, it has introduced new ergonomics challenges. The interaction with technology while moving can create awkward postures and loads that can produce strain on the body. Hence, we have a whole new set of ergonomic concerns and benefits due to the dynamics that new technologies have afforded.

Since the initial work looking at health issues of computerized work by Hultgren and Knave (1973), Ostberg (1975), Gunnarsson and Ostberg (1977), Cakir, Hart, and Stewart (1979), Grandjean (1979, 1980), and Smith et al. (1980, 1981), there have been thousands of research studies from every corner of the globe examining the working conditions of computer users and their health and productivity issues. There have been several international conferences devoted to these issues starting in 1980, and these conferences have continued on a regular basis to the present. Suffice it to say that interest in human factors and ergonomics, usability and human–computer interaction issues of new IT will be of interest for decades to come.

The findings from research on health of computer users have generally indicated that poor ergonomic conditions are associated with visual discomfort, musculoskeletal discomfort and pain, and psychological distress. Research indicates that long-term adverse ergonomic conditions lead to chronic employee aches and pains in the upper extremities and back, and may involve not only muscles but also other soft tissues, such as tendons and nerves. Across many types of jobs, long-lasting, adverse ergonomic conditions have been shown to lead to a deterioration of joints, ligaments, tendons, and nerves (Hagberg et al. 1995; Bernard 1997; Carayon, Smith, and Haims 1999). Reviews of field studies for fixed computer workstations (Grandjean 1979, 1980, 1987; NAS 1983; Bergqvist 1984; Smith 1984, 1987, 1997) have shown that poor ergonomics and working conditions for computer users are related to visual, musculoskeletal, and psychological discomfort and health disorders.

Findings from recent research on computer users are similar to that from research in the 1970s and 1980s that indicated employees who work extensively with computers experience upper extremity musculoskeletal discomfort and health complaints.

Robertson, Huang, and Larson (2009) conducted a survey of 1259 computer users at a large manufacturing company in the United States. In their study, 48% reported eye strain, 45% headaches, 43% neck pain, 40% shoulder pain, 36% wrist pain, and 35% low back pain. Significant associations were found between all visual and body part discomfort symptoms and the number of hours working at computers. About one-half of the computer users made appropriate changes to their workstations or work habits to address their visual and musculoskeletal discomfort. Computer users who made positive changes reported less discomfort.

Eltayeb et al. (2007, 2009) conducted a prospective cohort study over a 2-year period examining upper extremity health complaints among 264 computer users at the Dutch national social security office. They examined workstation considerations, employees' work postures, job demands, and psychosocial work characteristics. The first year prevalence of musculoskeletal symptoms was 33% for the neck, 31% for the shoulders, 11% for the hand, 12% for the upper arms, 6% for the elbows, and 7% for the lower arms/wrist. The results were consistent over the 2-year period, but there was an increase in arm/hand prevalence to 21% by the end of the second year. Four main predictors were identified for neck and shoulder complaints: (1) irregular head and body postures, (2) task difficulty (job demands), (3) number of hours per day working on the computer, and (4) a history of musculoskeletal complaints. Two main predictors were identified for forearm/hand complaints: (1) job time pressures (job demands) and (2) a history of musculoskeletal complaints.

Eltayeb et al. (2008) conducted a second study of computer users in a mobile telecommunications company and three banks in Sudan to compare the prevalence of musculoskeletal complaints with those they found in the Netherlands. They surveyed 282 employees and received 250 responses. The 1-year prevalence for musculoskeletal symptoms of the neck was 64% and for the shoulder 41%.

Gerr et al. (2002) conducted a prospective study of computer users who were newly hired for jobs requiring at least 15 hours of computer use per week. They followed 642 of these computer users for 3 years. They evaluated workstation characteristics and medical and psychosocial risk factors. The 1-year incidence for neck/shoulder musculoskeletal symptoms was 58%, and the incidence of neck/shoulder musculoskeletal disorders was 35%. The 1-year incidence for hand/arm musculoskeletal symptoms was 39%, and the incidence of hand/arm musculoskeletal disorders was 21%. Overall, more than 50% of computer users reported musculoskeletal symptoms during the first year after starting the job. Predictors for neck/shoulder problems were gender, age, ethnicity, and prior history of neck/shoulder pain. Predictors for hand/arm musculoskeletal problems were gender, prior history of hand/arm pain, prior computer use, and having children at home. The postures of the elbows, the head tilt, and the presence of arms rests influenced the prevalence of neck/shoulder problems, whereas wrist radial deviation when using a mouse, keyboard location and height, and key activation force influenced the prevalence of hand/arm problems. The number of hours of keying per week was associated with a greater risk of hand/arm musculoskeletal symptoms or disorders (Marcus et al. 2002).

13.3 DESIGN OF FIXED WORKSTATIONS

Workstation design is a major element in ergonomic strategies for improving user comfort and particularly for reducing musculoskeletal problems. Often the task requirements will have a role in defining the layout and dimensional characteristics of the workstation. The relative importance of the screen, input devices, and hard copy (e.g., source documents) depends primarily on the task, and this can influence the design considerations necessary to improve operators' performance, comfort, and health. Many studies have examined fixed computer workstation design issues and generally have found that the quality of the fit between the user and the interactive devices being used has a substantial role in the user's musculoskeletal comfort and musculoskeletal pain (Smith, Carayon, and Cohen 2003, 2008). For instance, Cohen et al. (1995) identified the following working conditions that influenced work postures and led to undue loads on the musculoskeletal system:

- Static postures of the trunk, neck, and arms
- Awkward twisting and reaching motions
- Poor lighting and glare
- Placement of the keyboard on uneven working surfaces
- Insufficient work surface space
- Insufficient knee and toe space
- The inability for the chair armrests to fit under the working surfaces
- Chairs with poor back and shoulder support, inadequate padding in the backrest and seat pan, arm rests that did not fit under working surfaces, and a lack of appropriate seat pan height adjustment

Derjani-Bayeh and Smith (1999) and Smith and Derjani-Bayeh (2003) conducted a prospective intervention study to examine the benefits of ergonomic redesign for computer users at fixed workstations. The study took place in a consumer products call center where shoppers could order products from a catalog using a telephone or an Internet site. There were three ergonomic interventions studied. In the first condition, ergonomics experts modified current workstation configurations to maximize their fit with the incumbent. In the second condition, new workstation accessories (keyboard tray, monitor holder, document holder, wrist rest, foot rest, and/or task lighting) were added as needed to improve the employees' fit with their workstations and general environment. In the third condition, the same factors in the second condition were added but in addition a new chair with multiple adjustments was also added.

A total of 80 volunteer subjects participated in the study. They were drawn from a larger pool of volunteers. The participants for the third condition were randomly selected from the larger pool, and then subjects for conditions 1 and 2 were matched to these selections based on the type of job, age, gender, and length of experience with the company. Baseline measurements of self-reported health status were collected using a questionnaire survey. Follow-up measurements were taken directly after implementation of the ergonomic improvements and then 12 months later. In addition, productivity measurements were obtained for each participant and a control group of about 375 employees in the same departments. The results indicated that subjects working under conditions 2 and 3 showed reductions in the extent and intensity of musculoskeletal health complaints, but not the subjects in condition 1. However, the subjects in condition 1 showed greater average improvement in productivity than those in conditions 2 and 3 and to the control group receiving no treatment. Of importance to designers was the finding that not all subjects showed improved productivity with the ergonomic improvements. In fact, about one-half of the subjects showed reduced productivity with the ergonomic improvements, even though the overall average for the ergonomic improvements showed a positive effect.

Gerr et al. (2002, 2005) and Marcus et al. (2002) prospectively examined the influences of computer use on workers' musculoskeletal and psychosocial health. They carried out ergonomics interventions to determine whether improvements in workstation design and employee postures could reduce musculoskeletal symptoms and disorders (Gerr et al. 2005). They conducted a randomized controlled trial of two different interventions among 376 computer users who used keyboards at least 15 hours per week and compared the subjects not receiving an intervention. They examined the incidence of neck/shoulder and hand/arm symptoms after implementation of the interventions for the intervention groups and control subjects. The two interventions consisted of adjusting each computer user's workstation for a better fit or training computer users to assume proper postures. The findings indicated that there were no significant differences among the two intervention groups and/or the comparison group. However, the findings also showed that the intervention groups complied with all components of the interventions for 24%–38% of the participants due to the inflexibility of workstation configurations. Thus, the majority of the employees in the intervention groups were able to achieve good ergonomic conditions.

Robertson (2007) investigated the effects of office ergonomic interventions on musculoskeletal health and group performance among knowledge workers at a corporate office in the United States. A new flexible office work environment was created for about 750 employees in an office building housing about 1750 employees. About 500 employees who were engaged in identical work but remained in traditional office workspaces in other parts of the building served as controls. The ergonomics interventions consisted of (1) a new flexible office space with adjustable workstations and flexible facility layout and (2) the new workstations plus office ergonomics training regarding the use of the new space and workstations. A total of 642 workers participated in the data collection, and 68% completed three rounds of data. Baseline musculoskeletal symptoms were taken with a follow-up at 3 and 6 months.

The flexible/adjustable workstation intervention group showed a 14% reduction in musculoskeletal symptoms from baseline to the 3-month measurements. But from the 3-month measurement to the 6-month measurement, there was a 19% increase in musculoskeletal symptoms. The flexible/adjustable workstation plus training intervention group showed a 48% reduction in musculoskeletal symptoms from baseline to the 3-month measurement, with a further reduction of 23% from the 3-month measurement to the 6-month measurement. There was no change in musculoskeletal symptoms for the control group over the 6-month measurement period. The flexible/adjustable workstation intervention group had an approximately 6% improvement in process time during the course of the experiment, whereas the workstation plus training intervention had an approximately 11% improvement and the control group had less than 1% improvement.

13.4 GUIDANCE FOR FIXED COMPUTER WORKSTATIONS

There are many online and hard-copy resources that provide specific guidance for computer users in setting up and using fixed computer workstations and work areas (ANSI/HFES-100 2007; BSR/HFES-100 2005; OSHA 2008; WorkSafeBC 2009; Smith, Carayon, and Cohen 2003, 2008). The guidance provided by these resources is generally consistent, and most provide specific information about each component of the workstation. We present below some general guidance for the design of fixed computer workstations and work areas without specific dimensions that are available in the aforementioned resources.

The recommended size of the work surface is dependent upon the task(s), documents, and technologies being used. The primary working surface (e.g., those supporting the keyboard, mouse, display(s), and documents) should be able to meet the following requirements:

- Allow the display screens to be moved forward or backward for a comfortable viewing distance for different employees with differing visual capabilities; provide means for adjusting the screen height to attain proper head/neck and back postures.
- Allow a detachable keyboard and a detachable mouse (or other pointing device) to be placed in several locations on the working surface to provide easy access and use. When using a laptop computer at a permanent fixed workstation, use a docking station to meet these requirements.
- Allow source documents to be positioned for easy viewing and proper musculoskeletal alignment of the upper extremities and the back when viewing the documents.
- Additional working surfaces (e.g., secondary working surfaces) may be necessary to store, lay out, read, write on, or manipulate documents, materials, or technologies (input devices, displays, computers, PIDs). These should provide easy access to materials and equipment on the surfaces, and comfortable postural shifts between the primary and secondary surfaces.
- Provide adequate knee and legroom for repositioning movements while working at primary and secondary surfaces.

- The tabletop should be as thin as possible for better thigh and knee clearance.
- Establish a comfortable table height that provides the necessary thigh/knee clearance, and allows input devices (keyboard, mouse) to be at comfortable heights. Adjustable tables provide the opportunity to better fit the users.
- Use keyboard trays for fixed height tables to enable better trunk and upper extremity postures when using the keyboard and mouse/trackball.
- Provide an adjustable height chair with swivel/tilt capabilities, adequate seat, and back padding and lumbar support.

Sometimes computer workstations are configured with multiple working surfaces so that several pieces of equipment and source materials can be easily accessible to the user. The setup should be arranged to allow for easy movement from one surface to another. Proper clearances under each working surface should be maintained, as well as a comfortable height to promote good posture of the back, neck/head, and upper extremities.

For all workstations, it is important to provide unobstructed room under the working surface(s) for the feet and legs so that users can easily shift their posture. Regular postural changes and body movement are important for reducing musculoskeletal fatigue and discomfort. Knee space height and width and toe depth are the three key factors for the design of clearance space under the working surfaces. Recommendations for clearance dimensions are provided in the ANSI/HFS-100, 2007 standard.

Table height has been shown to be an important contributor to musculoskeletal problems in computer users. Normal desk height of 30 in. (76 cm/30") is often too high for keyboard and mouse use by most people. It is desirable for the keyboard and mouse/trackball height to vary with the seated height of the user. A height adjustable keyboard/mouse/trackball tray provides this ability with a fixed height workstation. Height adjustable table surfaces can also achieve this, and adjustable multisurface tables encourage good posture by allowing the keyboard, mouse, trackball, and displays to be independently adjusted to appropriate keying, pointing, and viewing heights for each user and each task.

Tables that cannot be adjusted can be a problem when they are used by multiple users of differing sizes. When adjustable tables are used, the ease of making the adjustments is essential to encourage users to take the time to make the appropriate adjustments. Users should be instructed on how to adjust the workstation to be comfortable (Robertson 2007).

Adjustable tables allow vertical adjustments of the keyboard (and mouse) and displays. Some allow for the independent adjustment of the keyboard and display. Specifications for seated working surfaces' heights vary with whether the table is adjustable or at one fixed height and with a single working surface or multiple working surfaces (see ANSI/HFES 100-2007). For standing only workstations and for sit/stand workstations, the ANSI/HFES 100-2007 standard provides recommendations for the table surface height adjustment range.

13.5 DESIGN OF WORKSTATIONS FOR USE WITH LAPTOP COMPUTERS

Let us start with the laptop as a prime example of the influence of portability and efficiency, and then we will move on to other portable IT devices. A decade ago, the Human–Computer Interaction Committee of the International Ergonomics Association (IEA) produced a guideline for the use of laptop computers to improve ergonomic conditions (Saito et al. 2000). This was prompted by the ever-increasing sales of laptops and the replacement of fixed PCs by portable laptops on fixed working surfaces.

The primary advantage of the laptop is easy portability so the user can take the computer anywhere to do work. She or he can use it at the office, and then take it home to finish work, or take it with her or him to make a presentation at a meeting. The convenience and effectiveness of easy, lightweight portability are very high. In addition, all of the files are with the laptop, so nothing is mistakenly left behind at the office (or home). However, the comfort and health factors can be very low if the person uses the laptop in all manner of environments, workstations, and tasks that diminish the consistent application of good ergonomic principles. An important feature of the IEA laptop guideline (Saito et al. 2000) is to encourage situations of use that mirror the best practices of ergonomic conditions for fixed computer workstations. The best solution is to use a docking station for the laptop set up at a workstation that follows the guidance established for fixed workstations.

The following material in italic print has been extracted directly (with some minor editing) from the Saito et al. article "Ergonomic Guidelines for Using Notebook Personal Computers," which appeared in *Industrial Health*, volume 38, 2000, pp. 421–434.

> *Work Environment and Workstation Layout, "Create an environment that fits your work"*
>
> 1. *Use your laptop in a proper environment (lighting, temperature, noise, and so on). In particular, make sure the work area is neither too bright nor too dark.*
> 2. *Allocate enough space on your desk when placing a laptop.*
>
> *Chair and Desk, "Adjust chair height to match your physique"*
>
> 1. *Adjust your chair height based on the height of the keyboard, such that your forearm is parallel to the surface of the keyboard.*
> 2. *If your feet do not lie flat on the floor, provide a footrest.*
> 3. *Provide enough space underneath the desk.*
>
> *Keyboard, "Set the keyboard to a desirable angle, and use a palm rest if necessary"*

1. *Adjust the angle of the keyboard based on your posture and preferences.*
2. *Make sure there is space in front of the keyboard for you to comfortably rest your wrists (this space can be on the desktop surface itself if the keyboard is thin).*
3. *If the keyboard seems difficult to use, use an external keyboard.*

Working Posture, "Avoid unnatural postures, and change your posture occasionally"

1. *Avoid staying in postures where you are bent too far forward or backward, or twisted, for an extended duration.*
2. *Laptop users tend to view the display from too close, so make sure you maintain a distance of at least 40–50 cm between the display and your eyes.*
3. *Alternate near vision with far vision (i.e. observe object located at least 6 m far) as frequent as possible.*
4. *Make sure your wrists are not at an unnatural angle.*

Non-keyboard Input Devices, "Use a mouse as your pointing device if at all possible"

1. *If a mouse can be connected to your laptop, then do so as often as possible. Use a mouse pad whenever you use a mouse.*
2. *When you cannot connect a mouse, make sure you understand the built-in pointing device, and use the pointing device appropriately.*

These laptop guidelines provided by Saito et al. (2000) are useful when the laptop is used as a fixed PC at a docking station or at a desk (worktable). However, they do not provide as much help in the situations where there is no fixed workstation. We will describe some situations below where this can occur.

Imagine yourself sitting at the airport and your flight has been delayed for 2 hours. You have your laptop with you so you decide to get some work done while you wait. You could rent a cubicle or kiosk at the airport that would provide you with a high-speed Internet connection, a stationary telephone, a working surface (desk or table), a height adjustable chair, and some privacy (noise control, personal space). The characteristics of these work areas do not often conform to the best principles of ergonomic design. It is likely that the cubicle will provide some improvement over sitting with the laptop on your lap, but the characteristics may not meet the recommendations presented in this chapter. Such situations are acceptable for short exposures of up to 60 minutes, but longer exposures may lead to musculoskeletal discomfort, pain, and injury (if chronic). Now imagine that you have been told to stay in the boarding area because it is possible that the departure may be sooner than 2 hours. You get out your laptop, connect it to your cell phone, and place them on your lap. (That is why they are called laptops). You are sitting in a nonadjustable chair with poor back support.

This scenario is all too common. You can walk through O'Hare International Airport on any given day and see hundreds of people sitting at their boarding gates working on their laptops that are sitting on their laps. Now imagine a palm-held device that allows you to access your e-mail or to connect to the Internet. This device can be operated while you are standing in a line at the airport to check in, or sitting at the boarding gate like the laptop users. You can stand or sit punching at miniature buttons (sometimes with a stylus because they are so small) and interact with the interconnected world. Again, this scene is all too familiar in almost any venue (airport, restaurant, street, office).

In situations where there is not a fixed workstation, the device is typically positioned wherever is convenient. Very often such positioning creates bad postures for legs, back, shoulders, arms, wrists/hands, or neck. In addition, the smaller dimensions of the manual input devices (touch pad, buttons, keyboard, joy stick, roller ball) make motions much more difficult, and these often produce constrained postures and/or the use of too much force to operate the device. If the devices are used continuously for a prolonged period (such as 1 hour or more), muscle tension builds up, and discomfort in joints, muscles, ligaments, tendons, and nerves can occur. Some devices use voice/audio interfaces and can be used when you are walking (or even running). These might be headsets with earplugs and a microphone. These devices put additional load on the neck, and the voice/audio interfaces can strain the voice or the ears. These are "new" strains that we know very little about in terms of discomfort, health effects, and psychosocial effects. However, it is intuitive that frequent use of these interfaces will lead to strain and potential adverse consequences.

To reduce the undesirable effects of the poor workstation characteristics that lead to the discomfort, the following recommendations are given:

- If you are using a laptop on your lap, find a work area where you can put the laptop on a table (rather than on your lap). Then arrange the work area as closely as possible with the recommendations presented in the IEA laptop guidelines (Saito et al. 2000).
- If you are using a handheld PID, you should position yourself so that your back is supported. It is preferable to use the device sitting down. Of course, if you are using the PID as you are walking then this is not possible. If the PID has a voice interface, then use an earpiece and a microphone so that you do not have to hold it with your hand. But be sure not to overuse the device such that your voice and hearing are strained. Take frequent breaks from use to provide recovery for your voice and ears.
- Never work in poor postural conditions for more than 30 minutes continuously. Take at least a 5-minute break (preferably 10 minutes) away from the laptop/PID use, put the device down (away), get up and stretch for 1 minute or more, and then walk for 2–3 minutes (unless you are already walking in which case you should sit down for 5 minutes). If you are using a handheld PID in a standing position,

then during your break put it away, do 1 minute of stretching, and then sit down for 4 minutes. That may mean sitting on the floor, but preferably you will sit where you can support your back (against a wall, or a seat back).

- Buy equipment that provides the best possible input interfaces and displays (screens, headphones, typing pads). Since these devices are small, the perceptual-motor requirements for their use are much more difficult (sensory requirements, motion patterns, skill requirements, postural demands, and force demands). Therefore, screens should provide easily readable characters (large, understandable), and input buttons should be easy to operate (large, properly spaced, easily accessible, low force).
- Only use these devices when you do not have access to fixed workstations that have better ergonomic characteristics. Do not use these devices continuously for more than 30 minutes.

13.6 PORTABLE INFORMATION DEVICES, SMARTPHONES, AND CARRY-ALONG AND WEARABLE INFORMATION TECHNOLOGY

We have already discussed some ergonomic issues of using PIDs. We can foresee an even greater potential for ergonomic concerns with the use of PIDs than with laptop computers. PIDs are made to be as small and light as possible for portability and convenience of carrying. This is good as the lower weight produces smaller loads of the body. But small-sized devices are more difficult to manipulate with the hands and to observe displays with the eyes. This has led many designers to emphasize verbal/auditory and haptic interfaces that do not require substantial manipulation by the hands or good vision (Hirose and Hirota 2005; HCII 2005). In fact, several new PIDs have the capability to communicate with other IT devices without human intervention (HCII 2005, 2007, 2009, 2011).

Now let us explore some current applications of PIDs and some possible future applications to see where ergonomic and workstation issues might emerge. There are millions and millions of cell phones in use worldwide, and cell phones are a good representative of the PID. There is virtually nowhere in the world where cell phone cannot be used (with a few exceptions), and there is virtually no one (with adequate finances) who cannot access a cell phone and connect with the world. Cell phones can have many capabilities including telephoning, e-mailing, texting, auditory streaming, Internet surfing, walkie-talkie communicating, photographing, video camera picturing and recording, and television/cable/satellite broadcast receiving. Even with all of these built-in features, the size of cell phones is shrinking. As cell phones shrink, the manual hand interfaces are getting smaller, as are the visual displays. With their small size, cell phones can be carried easily and can be used when a person is walking, sitting, running, lying down, or hanging upside down. So what are the ergonomic concerns with their use, and in particular, the workstation design issues?

Small manual interfaces and displays make the accurate and comfortable application of perceptual-motor skills difficult (Albers and Kim 2002; Haggerty and Tarasewich 2005; Myers and Wobbrock 2005; Hinckley 2008). A cell phone can be held in one hand (this hand becomes the workstation) and then be manipulated with the other hand. In some instances, the hand holding the cell phone is also used to manipulate the manual interface. Either of these situations leads to workstation conditions where the users cannot apply their highest level of perceptual-motor skills. For example, they cannot use both hands for inputting into the interface, or the device is held at an awkward angle for manual inputting, or the posture of the trunk is unstable, which limits the capacity to effectively use the hands.

Due to this, a preferred form of input to control the action of the PID is speech (Lai, Karat, and Yankelovich 2008), whereas the displays are typically a combination of visual and auditory information. These interfaces may lead to ergonomic problems of overuse of the voice, increased duration of mental concentration, increased eye strain and visual discomfort, and increased error rates of the communication with the devices. There is no body of research data to tell us if these problems are or will become prevalent among PID users, or whether there will be long-term effects on comfort, health, and performance. For now, we can only conjecture about the possibilities for problems. But it is clear that many people are using PIDs and other computer-based technologies many hours per day, and this increased extent of use will likely lead to discomfort and some health effects for voice, ears, upper extremities, and mental stress.

Now let us think about the workstation issues with PIDs using cell phone as an example. We will go back to the airport example, and I will use my cell phone to communicate with my office. At this time, I am standing in a long line at the airline check-in counter. My cell phone has voice activation and control capability. I ask my cell phone for my e-mail service provider and up come my e-mails on the display screen. I am using my thumb to scroll through the e-mails one at a time. I hold the cell phone close to my face to enhance my ability to read the display screen. I shuffle forward as the line moves toward the airline counter (automated check-in station). I am standing, and I have no postural support for my back, buttocks, and legs. It is true that I would be standing in the line feeling the postural strain even if I were not using my cell phone. But my cell phone use adds extra postural loading since I am manually (or vocally) manipulating the interface to operate the e-mail processing. The small visual display may create eyestrain, and if I talk on the cell phone for too long it may create voice strain.

One way to reduce the load would be if I had a workstation where I could sit and support my back, buttocks, and legs, even be able to rest my arms and elbows as I manually manipulate the interface. I could use a vocal/auditory interface with a head-mounted earplug and microphone (headset) and thus eliminate the manual input and visual display viewing. The headset is a workstation improvement that reduces the manual manipulation and some of the postural loading on the upper extremities and back. But the headset adds some weight to the head, and this increases loading on the neck, shoulders, and back. One difficulty with using an auditory interface is the high ambient noise in the airport lounge that interferes with and masks the cell phone's auditory signals. To reduce this auditory interference, a helmet with acoustical privacy could serve as a workstation improvement. However, a helmet adds substantial weight to the head, which puts increased loading on the neck, shoulders, and back.

A major workstation improvement for users waiting in a line, which would reduce the postural loading when using a cell phone, is to provide chairs so a user can sit down. A chair provides postural support for the back, buttocks, and legs. A chair on casters/wheels that can be scooted along as the line moves forward could be beneficial. But this could increase the congestion in the lounge area as people are moving through the line. This one example illustrates the new loads that may be added to technology users' lives by the use of PIDs. We reiterate some of the advice from Section 13.5 as this is also applicable to the use of PIDs and other portable devices.

To reduce the undesirable effects of a lack of a workstation that can lead to the users' discomfort, the following recommendations are given:

If you are using a handheld PID, you should position yourself so that your back is supported. It is preferable to use the device sitting down. Of course, if you are using the PID as you are walking, then this is not possible. If the PID has a voice interface, then use an earpiece and a microphone so that you do not have to hold it with your hand. But be sure not to overuse the device such that your voice and hearing are strained. Take frequent breaks from use to provide recovery for your voice and ears.

Never work in poor postural conditions for more than 30 minutes continuously. Take at least a 5-minute break (preferably 10 minutes) away from the laptop/PID use, put the device down (away), get up and stretch for 1 minute or more, and then walk for 2–3 minutes (unless you are already walking in which case you should sit down for 5 minutes). If you are using a handheld PID in a standing position, then during your break put it away, do 1 minute of stretching, and then sit down for 4 minutes. That may mean sitting on the floor, but preferably you will sit where you can support your back (against a wall or a seat back).

Buy equipment that provides the best possible input interfaces and displays (screens, headphones, typing pads). Because these devices are small, the perceptual-motor requirements for their use are much more difficult (sensory requirements, motion patterns, skill requirements, postural demands, and force demands). Therefore, screens should provide easily readable characters (large, understandable), and input buttons should be easy to operate (large, properly spaced, easily accessible, low force).

Do not use these devices continuously for more than 30 minutes.

13.7 CHAIR AS A CRITICAL ELEMENT OF THE WORKSTATION

It was not until the last 40 years that sitting posture and chairs (seats) became topics for scientific research, especially for ergonomics and orthopedics. Studies have revealed that the sitting position, compared with the standing position, reduces static muscular efforts in legs and hips, but increases the physical load on the intervertebral discs in the lumbar region of the spine.

The debate over what constitutes proper seated posture is not yet fully resolved. Is an upright-seated posture most healthy, or is a relaxed posture with a backward-leaning trunk healthier? Interesting experiments by the Swedish surgeons Nachemson and Elfstrom (1970) and Andersson and Ortengreen (1974) offer some guidance about this. These authors measured the pressure inside the intervertebral discs and the electrical activity of the back muscles in relation to different sitting postures. When the backrest angle of the seat was increased from 90° to 120°, subjects showed a significant decrease in the intervertebral disc pressure and the electromyographic activity of the back. Since heightened pressure inside the intervertebral discs means that they have more stress, the authors concluded that a sitting posture with reduced disc pressure is more healthy and desirable.

Most ergonomic standards for computer workstations are based on a more traditional view about a healthy sitting posture. Mandal (1982) reported that the "correct seated position" goes back to 1884 when the German surgeon Staffel recommended the well-known upright position. Mandal (1982) stated:

> *But no normal person has ever been able to sit in this peculiar position (upright trunk, inward curve of the spine in the lumbar region, and thighs in a right angle to the trunk) for more than 1–2 minutes, and one can hardly do any work as the axis of vision is horizontal. Staffel never gave any real explanation why this particular posture should be better than any other posture. Nevertheless, this posture has been accepted ever since quite uncritically by all experts all over the world as the only correct one.*

It is our observations over many years of field research and consultation that the sitting posture of computer users is very seldom an upright position of the trunk for extended periods. When seated at a computer, some people lean backward, whereas others lean forward and some sit up straight. Most people shift sitting positions when there is fatigue, discomfort, or pain in the musculoskeletal system. Based on our experience, we believe that an important consideration for seated posture is to have workstation and chair designs that allow for a variety of seated postures and movement of the computer users while they are seated.

Chair adjustability in terms of vertical height of the seat pan, the seat pan angle, and providing lumbar support help to promote trunk, shoulder, neck, and leg postures that reduce strain on the muscles, tendons, ligaments, and discs. The postural support and movement action of the chair help maintain proper seated posture and encourage good movement patterns. A chair that provides swivel action encourages movement, whereas backward tilting increases the number of postures that can be assumed.

The chair height should be adjustable so that the computer operator's feet can rest firmly on the floor with minimal pressure beneath the thighs. The minimum range of adjustment for seat pan height is provided in the ANSI/HFES-100 standard (2007).

To enable short users to sit with their feet on the floor without compressing their thighs, it may be necessary to add a footrest. A well-designed footrest has the following features:

- It is inclined upwards slightly (about 5°–15°).
- It has a nonskid surface.
- It is heavy enough that it does not slide easily across the floor.
- It is large enough for the feet to be firmly planted.
- It accommodates persons of different stature.

The seat "pan" is where the person sits on the chair. It is the part of the chair that directly supports the weight of the buttocks. The seat pan should be wide enough to permit operators to make slight shifts in posture from side to side. This not only helps to avoid static postures, but also accommodates a large range of individual buttock sizes. The seat pan should not be overly U-shaped because this can lead to static sitting postures. The seat pan dimensions are provided in the ANSI/HFES-100 standard (2007). The front edge of the seat pan should be well rounded downward to reduce pressure on the underside of the thighs that can affect blood flow to the legs and feet. This feature is often referred to as a "waterfall" design. The seat needs to be padded to the proper firmness that ensures an even distribution of pressure on the thighs and buttocks. A properly padded seat should compress about 1/2 to one inch when a person sits on it.

Some experts feel that the seat front should be elevated slightly (up to 7°), whereas others feel it should be lowered slightly (about 5°). There is some disagreement among the experts about the correct answer, and due to this disagreement, many chairs allow for both front and backward angling of the front edge of the seat pan. The operator can then angle the chair's front edge to a comfortable position. The ANSI/HFES-100 standard provides information about the adjustability range of the seat pan front edge. The seat pan height and angle adjustments should be accessible and easy to use from a seated position.

The tension and tilt angle of the chair's backrest should be adjustable. Inclination of chair backrest is important for operators to be able to lean forward or back in a comfortable manner while maintaining a correct relationship between the seat pan angle and the backrest inclination. A backrest inclination of about 110° is considered an appropriate posture by many experts. However, studies have shown that operators may incline backwards as much as 125°, which also is an appropriate posture. Backrests that tilt to allow an inclination of up to 125° are therefore a good idea. The backrest tilt adjustments should be accessible and easy to use. An advantage of having an independent tilt angle adjustment is that the backrest tilt will then have little or no effect on the front seat height or angle. This also allows operators to shift postures readily. The ANSI/HFES-100 standard (2007) provides advice about back rest adjustment ranges.

Chairs with high backrests are preferred since they provide support to both lower back and the upper back (shoulder). This allows employees to lean backward or forward, adopting a relaxed posture and resting the back and shoulder muscles. The ANSI/HFES-100 standard (2007) provides guidance on the design of the seat backrest. To prevent back strain, it is also recommended that chairs have lumbar (mid-back) support, since the lumbar region is one of the most highly strained parts of the spine when sitting.

For most computer workstations, chairs with rolling castors or wheels are desirable: These promote movement and facilitate postural adjustment, particularly when the operator has to reach for equipment or materials that are on the secondary working surfaces. Chairs should have five supporting legs.

Another important chair feature is armrests. Both pros and cons to the use of armrests at computer workstations have been advanced. On the one hand, some chair armrests can present problems of restricted arm movement, interference with the operation of input devices, pinching of fingers between the armrest and table, restriction of chair movement, such as under the work table, irritation of the arm or elbows due to tissue compression when resting on the armrest, and adoption of awkward postures. Properly designed armrests can overcome the problems mentioned above. Armrests can provide support for resting the arms to prevent or reduce arm, shoulder, and neck fatigue. Removable armrests are an advantage because they provide greater flexibility for individual operator preference. For specific tasks such as using a numeric keypad, a full armrest can be beneficial in supporting the arms. Many chairs have height adjustable armrests that are helpful for operator comfort, and some allow for adjusting the angle of the armrests as well.

13.8 ADDITIONAL WORKSTATION CONSIDERATIONS

Providing the capability for the screen to swivel and tilt up/down gives the user the ability to better position the screen for easier viewing. Reorientation of the screen around its vertical and horizontal axes can help to position a screen to reduce screen reflections and glare. Reflections can be reduced by simply tilting the display slightly back or down, or to the left or right away from the source of glare. The perception of screen reflections depends not only upon screen tilt, but also upon the operator's line of sight.

An important component of the workstation that can help reduce musculoskeletal loading is a document holder. When properly designed, proportioned, and placed, document holders reduce awkward inclinations of the head and neck and frequent movements of the head up and down and back and forth. They permit source documents to be placed in a central location at the same viewing distance as the computer screen. This eliminates needless head and neck movements and reduces eyestrain. In practice, some flexibility about the location, adjustment, and position of the document holder should be maintained to accommodate both task requirements and operator preferences. Dainoff (1982) showed the effectiveness of an in-line document holder. The document holder should have a matte finish so that it does not reflect light.

Privacy requirements include both visual and acoustical control of the workplace. Visual control prevents physical intrusions, contributes to confidential/private conversations, and prevents the individual from feeling constantly watched. Acoustical control prevents distracting and unwanted noise (from machine or conversation) and permits speech privacy. Although certain acoustical methods and materials such as freestanding panels are used to control general office noise level, they can also be used for privacy. Planning for privacy should not be made at the expense of visual interest or spatial clarity. For instance, providing wide visual views can prevent the individual from feeling isolated. Thus, a balance between privacy and openness enhances user comfort, work effectiveness, and office communications. Involving employees in decisions of privacy can help in deciding the compromises between privacy and openness.

The use of a wrist rest when keying can help to minimize extension (backward bending) of the hand/wrist, but the use of a wrist rest for operators' comfort and health has generated some debate because there are trade-offs between comfort and health. When the hand or wrist is resting on the wrist rest, there is compression of the tissue that may create increased carpal canal pressure or local tissue ischemia. On the other hand, the wrist rest allows the hands and shoulders to be supported with less muscular tension, which is beneficial to computer operator comfort. At this time, there is no scientific evidence that the use of a wrist rest either causes or prevents serious musculoskeletal disorders of the hands, wrists, or shoulders. Thus, the choice to use a wrist rest should be based on employees' comfort and performance considerations until scientific evidence suggests otherwise.

If used, the wrist rest should have a fairly broad surface (5 cm minimum) with a rounded front edge to prevent cutting pressure on the wrist and hand. Padding further minimizes skin compression and irritation. Height adjustability is important so that the wrist rest can be set to a preferred level in concert with the keyboard height and slope.

Arm holders are also available to provide support for the hands, wrists, and arms while keyboarding and have shown to be useful for shoulder comfort. The placement of the arm holder should not induce awkward postures in its use. The device should be placed within easy reach of the operator, especially when it will be used frequently during work.

When keyboard trays are used, they should allow for the placement of other input devices directly on the tray instead of on other working surfaces.

13.9 VISUAL ENVIRONMENT

Computers and PIDs have screens that are susceptible to poor viewing due to glare from high-illumination sources and particles on the screen. For instance, luminance sources in the environment can fall on the screen and wash out characters on the screen, or the accumulation of dust and/or dirt particles on the screen can block or distort images. These conditions not only affect the ability to read the screen, but can also lead to visual fatigue and dysfunction. Specific characteristics of the environment such as illumination level and glare have been related to visual strain problems of a computer operator.

The alignment of lighting in relation to the computer workstation, as well as levels of illumination in the area surrounding a computer workstation, has been shown to influence the ability of the computer operator to read hard copy and the computer. Readability is also affected by the differences in luminance contrast in the work area. The level of illumination affects the extent of reflections from working surfaces and from the screen surface. Mismatches in these characteristics as well as the nature of the job tasks are believed to cause the visual system to be overworked, which can lead to visual fatigue and discomfort. Boyce (2006) indicates that improper illumination can affect performance, visual discomfort, fatigue, and mood.

Proper illumination and glare reduction are important aspects of the visual environment that influence computer and PID screen and hard-copy readability and viewing in the general environment. The illumination required for a particular task is determined by the visual requirements of the task and the visual ability of the employees doing the task. High levels of illumination are generally bad for reading from computer and PID screens, but good for reading hard copy. Lower levels of illumination will provide better computer and PID screen image quality and reduced screen glare. Illuminance in the range of 300–700 lux measured on the horizontal working surface (not the computer screen) is normally preferable. The lighting level should be set up according to the visual demands of the tasks performed. For instance, higher illumination levels are necessary to read hard copy and lower illumination levels are better for work that just uses the computer and PID screen. Thus, a job in which hard copy and a computer screen are both being used should have a general work area illumination level of about 500–700 lux; and a job that only requires reading the computer screen would have a general work area illumination of 300–500 lux.

Conflicts can arise when both hard copy and computer screens are used by different employees who have differing job task requirements or differing visual capabilities and are working in the same room. As a compromise, room lighting can be set at the lower level (300 lux) or intermediate level (500 lux), and additional task lighting for the hard copy tasks can be provided at each workstation as needed. Such additional lighting must be carefully shielded and properly placed to avoid glare and reflections on the computer screens and adjacent working surfaces of other employees. Furthermore, task lighting should not be overly bright in comparison with the general work area lighting, since the contrast between these two different light levels may produce eyestrain.

The surface of the computer and PID screens reflects light and images from the environment. The luminance of the reflections decreases character contrast and disturbs legibility; it can be so strong that it produces a glare. Image reflections are annoying, especially since they also interfere with focusing mechanisms; the eye is induced into focusing between the text and the reflected image. Thus, reflections are also a source of distraction.

Luminance is a measure of the brightness of a surface, the amount of light leaving the surface of an object, either reflected by the surface (as from a wall or ceiling), emitted by the surface (as from the screen characters), or transmitted (as light from the sun that passes through translucent curtains). High-intensity luminance sources (such as windows) in the peripheral field of view should be avoided. In addition, a balance among luminance levels within the computer user's field of view should be maintained. To reduce environmental glare, the luminance ratio within the user's near field of vision should be approximately 1:3, and approximately 1:10 within the far field of vision. For luminance on the screen itself, the character-to-screen background luminance contrast ratio should be at least 7:1. To give the best readability for each operator, it is important to provide screens with adjustments for character contrast and brightness. These adjustments should have controls that are obvious and easily accessible from the normal working position (e.g., located at the front of the screen).

Experts have traditionally recommended a viewing distance between the screen and the operator's eye of 45–50 cm, but no more than 70 cm. However, experience in field studies has shown that users may adopt a viewing distance greater than 70 cm or lesser than 45 cm and still be able to work efficiently and comfortably. Thus, viewing distance should be determined in context with other considerations. It will vary depending upon the task requirements, computer or PID screen characteristics, and an individual's visual capabilities. For instance, with poor screen quality and poor vision, it may be necessary to reduce viewing distance for easier character recognition. Typically, the viewing distance will be 50 cm or less because of the small size of the characters on the computer or PID screen.

13.10 AUDITORY ENVIRONMENT

As the use of PIDs in a wide variety of environments increases the need for a quiet auditory environment that allows the user to easily hear and speak at a normal loudness level becomes more important. Crowded, noisy environments detract from users' ability to hear. Many PIDs have auditory interfaces such as headphones, which can concentrate the primary auditory signal and block out some of the environmental noise. One concern is that users may increase the loudness beyond levels that are safe for the auditory sensory system due to the ambient noise in the environment or for personal preference (CDC 2003). High ambient noise in the environment leads to the need for greater mental concentration (attention) to the auditory signals, increased intensity of the primary auditory signal (up to levels that may cause temporary auditory threshold shifts), and mood disturbances (irritation, anger, discouragement) (Casali 2006). These effects can result in increased mental fatigue, psychological stress; and long-term exposures may lead to discomfort and health consequences.

Although headphones may provide benefits to concentrate the primary auditory signal, they also have the drawback of providing too much sound energy to the ears. Prolonged exposure to loud primary auditory signals can cause the adverse effects described above. To protect the auditory sensory system when using PIDs, we proposed the following:

Find environments to use your PID where the ambient auditory levels are 40–50 dba or less.

Do not use your PID for more than 30 minutes without taking a break where you can rest your eyes and ears. You should rest for at least 10 minutes before you start using your PID again. As your total use of the PID increases over the course of a day, then the rest breaks should become longer. Although the literature suggests that taking a break after 30 minutes of PID use should be sufficient for your eyes to recover (given a proper visual environment as defined above), there is no literature that provides guidance on the maximum amount of time of PID use before a break is necessary to provide recovery for your ears and mental mood. Nor is there literature to indicate the minimum amount of break time necessary to achieve auditory or mental recovery. Thus, we suggest a conservative approach of 15 minutes of rest away from loud sound after 30 minutes of exposure.

Keep the volume of the headphones of the PID at the lowest level necessary to hear the primary auditory signal properly. In no instance exceed 85 dba, and do not exceed 30 minutes of continuous exposure (see the above point). It is best to not exceed 70 dba, and if you adhere to 1 above, then you will not have to exceed 60–70 dba if you have normal hearing.

Be courteous when using your microphone, cell phone, and PID. Do not talk directly at other people such that your conversation may produce masking noise that interferes with their conversations or peace. Keep your voice as low as possible to allow your interface or listener to understand your signal.

13.11 ERGONOMIC IMPLEMENTATION ISSUES

Implementing a workplace change, such as improving workstation design or work methods, is a complex process because it impacts many elements of the work system (Derjani-Bayeh and Smith 1999; Smith and Carayon 1995; Hagberg et al. 1995; Smith and Sainfort 1989; Carayon and Smith 2000; Smith and Derjani-Bayeh 2003; Robertson 2007). Managers, designers, and engineers often like to believe that technological enhancements are easy to make and that performance and health improvements will be immediate and substantial. Proper implementation involves changes in more than the workstation, for instance, the work organization, job content, task improvements, job demands, training, and socialization issues need to be considered. Planning for change can help the success of implementation and reduce the stress generated by the change. But the success of implementing change depends heavily on the involvement and commitment of the concerned parties, in particular management, technical and support staff, first-line supervision, and employees.

There is universal consensus among change management experts that the most successful strategies for workplace improvements involve all elements (subsystems) of the work system that will be affected by the change (Hendrick 1986; Lawler 1986; Smith and Carayon 1995; Carayon and Smith 2000). Involvement assumes that there is an active role in the change process, not just providing strategic information. Active participation generates greater motivation and better acceptance of solutions than passively providing information and taking orders. Active participation is achieved by soliciting opinions and sharing authority to make decisions about solutions. However, one drawback of active participation is the need to develop consensus among participants who have differing opinions and motives. This usually takes more time than traditional decision making and can bring about conflict among subsystems. Another drawback is that line employees often do not always have the technical expertise necessary to form effective solutions.

Participative ergonomics can take various forms, such as design decision groups, quality circles, and worker-management committees. Some of the common characteristics of these various programs are employee involvement in developing and implementing ergonomic solutions, dissemination and exchange of information, pushing ergonomics expertise down to lower levels, and cooperation between experts and nonexperts. One of the characteristics of participatory ergonomics is the dissemination of information (Hendrick 1986; Noro 1991; Carayon and Smith 2000). Participative ergonomics can be beneficial to reduce or prevent resistance to change because of the information provided to the various members of the organization concerned with the new technology. Uncertainty and lack of information are two major causes of resistance to change and have been linked to increased employee stress. If employees are informed about potential ergonomics changes in advance, they are less likely to actively resist the change.

Training computer users about how the new workstation functions and operations are important especially if the adjustment controls are neither obvious nor intuitive. Hagberg et al. (1995) have indicated that employee training is a necessary component to any ergonomic program for reducing work-related musculoskeletal disorders. Green and Briggs (1989) and Robertson (2007) found that adjustable workstations are not always effective without appropriate information about benefits of adjustments and training in how to use the equipment. Hagberg et al. (1995) suggested the following considerations for ergonomics training programs:

Have employees involved in the development and process of training. Using employees' work experiences can be helpful in illustrating principles to be learned during training. In addition, using employees as instructors can be motivational for the instructors and learners.

Use active learning processes where learners participate in the process and apply "hands-on" methods of knowledge and skill acquisition. This approach to learning enhances acquisition of inputs and motivation to participate.

Apply technology to illustrate principles such as audiovisual equipment and computers. Much like active processes, technology provides opportunities for learners to "visualize" the course materials and to test their knowledge dynamically and immediately.

Use of on-the-job training is preferred over classroom training. Both can be effective when used in combination.

13.12 APPLICATIONS EXAMPLE: COMPUTER WORKSTATIONS IN HEALTH-CARE SETTINGS

There is a major push toward implementation of various forms of computer technology in health-care settings. Through the Recovery Act, about $19 billion is being invested in computerized medical records (http://www.whitehouse.gov/issues/health-care). The objective is to use health information technology (or health IT such as electronic medical records) to improve health-care quality and patient safety, and reduce health-care costs. Much attention has been paid to the design of health IT interface such as usability and fit of the technology with the cognitive work of health-care providers (Stead and Lin 2009); however, the issues of workstation design and physical ergonomics have been largely ignored. Given the extensive musculoskeletal problems experienced by nurses and other health-care professionals (Feyer et al. 2000; Hignett 2007), the additional physical and psychosocial workload associated with computer use may exacerbate health and safety problems.

Carayon et al. (2009) conducted an in-depth case study of the implementation of an electronic health records (EHR) technology in a small clinic. Various types of data were collected before and after the EHR implementation to assess the impact of the technology on work, working conditions, and outcomes. A work analysis showed that the amount of time spent on computer work significantly increased after the EHR implementation: from about 2% to 21% for physicians, from 4% to 11% for other clinical staff, and from 19% to 31% for administrative staff. Survey data collected from physicians, nurses, other health-care professionals, and administrative staff at the clinic showed small increase in perceived workload and a decrease in amount of control over resources. Clinic staff also reported to be significantly more dependent on computers to get their work done after the EHR implementation. With regard to health outcomes, there was a slight increase in the percentage of clinic staff who reported back pain and pain or stiffness in arms or legs, and a slight decrease in terms of swollen or painful muscles and joints. This single case study of EHR implementation in a small clinic shows that the use of computer work can produce some negative impact, such as increased workload and increased self-reported musculoskeletal problems. However, we do not know the long-term effects of EHR implementation; the data collected in the study by Carayon et al. (2009) provided information about the effect of the technology only after 1 year. In addition, we know very little about workstation design for health IT in other health-care settings, such as hospitals.

Health IT can be implemented in a range of hardware configurations, such as stationary computers, computers on wheels (COW), or other mobile configurations (e.g., notebook or Tablet PC). Andersen et al. (2009) conducted a study of computer hardware device in two hospital units in Australia. Four different hardware configurations were available: (1) stationary computer stations, (2) laptops mounted on trolleys, (3) an ergonomically designed computer on wheel (i.e., integrated computer and cart device specifically designed to be easy to use), and (4) tablet PCs. Observations and interviews were performed to understand the way nurses and physicians used the various technologies; in addition, two researchers assessed the physical characteristics and usability of the technologies. The COWs and tablet PCs were used most frequently in the patients rooms (about 57% of time) and in the corridors (about 36%). Nurses tended to prefer to use the generic COW instead of the ergonomic COW. Nurses infrequently used stationary computers to perform their tasks. On the other hand, physicians were more likely to use stationary computers, most often within their offices. When doing rounds in the hospital, physicians used primarily generic COWs (about 57% of time) and tablet PCs (about 36% of time). All nurses reported to prefer to use a generic COW over other devices; physicians used both tablet PCs and generic COWs during rounds. Nurses and physicians reported that generic COWs were easier to use because the trolley had space for storing medications, paper documents, and other equipment. Even though the ergonomic COW was better designed from a physical ergonomics viewpoint, it did not support the noncomputer tasks performed by nurses and physicians (e.g., use of paper documents, storing medications). The mobility of computer devices was a very important factor for both nurses and physicians. They perform work under high time pressure; therefore, having easy access to mobile computers is critical.

An important aspect of computer workstation design in health-care settings is the need for collaborative activities. The study by Andersen et al. (2009) shows that many computer tasks are performed in a collaborative manner, such as nurses collaborating with other nurses and student nurses and physicians on rounds collaborating with other physicians and medical students. Therefore, the design of the computer work areas needs to support the collaborative activities performed by health-care professionals. There needs to be sufficient room for several people to use computers simultaneously or work together on a single computer. Most hospital units have not been designed to accommodate the new technologies (e.g., COWs) and the new forms of work organization (i.e., teamwork and collaboration); this may lead to a range of physical and psychosocial problems that can affect the performance of health-care professionals, therefore affecting the quality and safety of care provided to patients.

13.13 SUMMARY OF RECOMMENDATIONS

A fixed computer workstation (work area) comprises a computer, input and output interfaces, the furniture where the computer is used, and the physical environment in which the computer is used. The design of these elements and how they fit together play a crucial role in users' performance and in minimizing potential adverse discomfort and health consequences. The recommendations presented in this chapter address the physical environment and implementation issues. Organizational factors and task-related factors should also be taken into account as they affect and/or depend on technology users. PIDs require creative work area and workstation solutions to achieve the same effectiveness of fixed computer workstations. PIDs pose unique problems, and users need to take actions that will minimize loads on their musculoskeletal system, sensory systems, and mental processes. PIDs have inherent ergonomic problems due to their ubiquitous applications, small size, and potential for users' overexposure to prolonged use. Using PIDs in the proper environment, limiting the extent of use by taking frequent rest breaks, and having the best possible interfaces is good ergonomic sense.

Part III

Designing Human–Computer Interactions

14 Visual Design Principles for Usable Interfaces

Everything Is Designed: Why We Should Think before Doing

Suzanne Watzman and Margaret Re

CONTENTS

Take a moment and visualize Las Vegas at night. What kind of image does this conjure up for you? Flashing lights from all directions, a hotel's lighting display designed to outdo its neighbor as well as that of the casino signage down the street. At first glance, everything is exciting, colorful, and beautiful. Now add a fireworks display to your picture. More color, more excitement. Where do you look first? There is so much going on; it is hard to see it all, but you don't want to miss a thing. Your head turns in all directions. You look there; then, out of the corner of your eye, you see something else. Look over there! Now the fireworks are at their peak, and the noise gets even louder. Any conversation with companions is impossible, yet it is also impossible to focus on any one thing for more than a split second. You are overwhelmed and overloaded. Everything is screaming for your attention. Can you manage to pay attention? For how long? Do you begin to shake your head in despair, and give up? Do you wish you were somewhere else—NOW?

14.1 MAKING THINGS EASIER TO USE AND UNDERSTAND: THINKING ABOUT THE USER'S EXPERIENCE

The previous description is unfortunately an accurate analogy of many users' experiences as they attempt to learn, work, play, and relax. New products, new services, and new technology with which you are unfamiliar can create confusion. Users of these new products, services, and technology are customers, electricians, grandparents, clerks, pilots, and students—you and me. And for most of us, it's a jungle out there! Las Vegas at night with fireworks, or monitors that are winking, blinking, distracting, disturbing, overwhelming—and, after a short time, visually deafening. Now add voices coming from boxes . . .! Although this may seem like an exaggeration, for many this situation is exactly their experience. User interface design focuses on designing flexible environments that have a positive impact on a user's ability to experience and interact with a product, whether that product is a mobile communication device, website, information kiosk, or appliance. It involves creating environments that include strong navigational devices that can be understood intuitively and used effortlessly. Designers have a responsibility to create user experiences that are simple and transparent. To do their job well, they must advocate on behalf of the user, ensuring that the interfaces they design are not just merely exercises in technology but that they truly assist and guide the user from task to task, enabling work to be done, and ultimately improving quality of life. When designers succeed, their products can be used effortlessly and are even pleasurable to use. Good design does not needlessly draw attention to itself. It just works. This is the role of good design.

14.2 DEFINING VISUAL DESIGN

The nautilus shell is an example of the synthesis between form and function found in nature (Figure 14.1). Its form is the result of evolution, which is both transparent and beautiful. The nautilus shell is a perfect analogy for design and the design process because it creates valuable user experiences and usable interfaces.

The word *design* functions as both a noun and a verb. Many people use it to refer to the outward appearance or style of a product. However, design also refers to a process—that of intentionally establishing a plan or system by which a task can be accomplished or a goal reached. It includes tangible and intangible systems in which objects or processes are coherently organized to include the environments in which these objects or processes function. Design affects all people in every aspect of what they do. Good design performs for people. It is concerned with economics and the transmission of ideas. The challenge presented to a design team is to plan a prototype with a clear purpose that is easy to use, meets user needs, addresses commercial considerations, and can be mass-produced. Its visual form, whether two- or three-dimensional, digital or analog, logically explains its purpose and efficiently leads the user through its function. Design is not a series of subjective choices based on personal preference, at best a cosmetic afterthought considered if time and

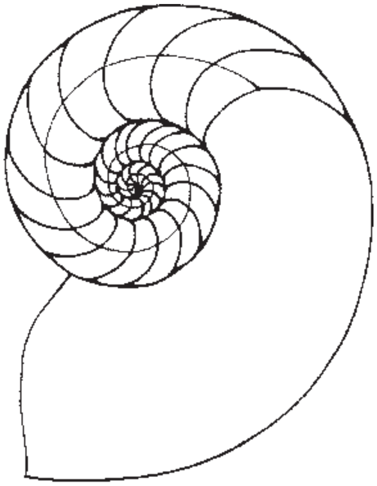

FIGURE 14.1 Nautilus shell.

money are leftover. Good design is the tangible representation of product goals. An iterative and interactive process that requires active learning, design unifies a wide range of disciplines. Good design is a significant activity that reveals multiple solutions to each problem. Design equally values different ways of thinking. It allows people with a variety of skills and learning abilities to work cooperatively to bring insights and expertise to problems and opportunities in order to better develop new and innovative solutions. Problems can be analyzed using a multitude of viewpoints and methods. Writing, drawing, statistical analysis, graphing, discussion, interviewing, personal observation, model-making, and diagramming are all legitimate methods for examination as the physical, social, and cultural contexts of possible answers are considered (Davis et al.).

14.3 DESIGN PROCESS

Design as a Catalyst for Learning, a publication funded in part by the National Endowment for the Arts, argued that effective design that responds to human problems uses the following steps (Figure 14.2):

- *Problem identification and definition*: A need or problem is identified, researched, and defined.
- *Gathering and analyzing information*: The focus is on learning what is not known. Assumptions are questioned. Wide and broad research is used to locate information and generate ideas.
- *Determining performance criteria for a successful solution*: Research continues as imagery is selected. Rules are declared and what is known is specified.
- *Generating alternative solutions and building prototypes*: Multiple solutions are generated. A variety of methods for analysis, such as drawing, interviewing, modeling or evaluating statistics, are used.

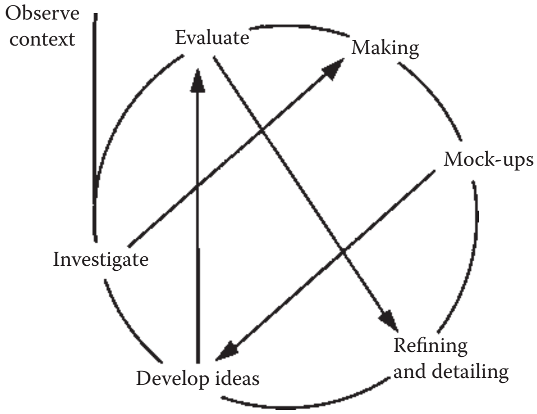

FIGURE 14.2 Interacting design loop. The interacting design loop developed by Richard Kimbell, founder of the Technology Education Research Unit at Goldsmiths College, and presented in *Design as a Catalyst for Learning*, captures the divergent, iterative and cyclical nature of the design process.

- *Implementing choices*: Project content, scope, and intent are formally established. Initial possibilities are represented and presented as prototypes.
- *Evaluating outcomes*: Prototypes are assessed, tested, evaluated, and judged. The knowledge gained is incorporated into further studies and refinements.
- *Production*: A prototype, which is a synthesis of the initial solutions made using this process, and specifications are released for making multiples to a manufacturer.

14.4 ROLE OF THE DESIGNER

Visual design decisions are based on project goals, user perspective, and informed decision making. While many aspects of design are quantifiable, there are visual principles that are less measurable but equally important. Even though the necessary skills to become visually literate and make competent design decisions can be learned, design involves a highly specialized knowledge base. A unique combination of creativity and skill differentiates and makes one design more attractive and desirable than another. Both education and talent are necessary to apply the principles required to present information in its most accessible, useful, and pleasing form. The role of the designer in the development of interfaces for interactive products is to understand the product goals and ensure that information is approachable, useful, and desirable. In an environment in which the interface is the only tangible representation of a product and user perception determines product success, appropriate information presentation and visual design are key. Designers understand visual principles in context, and know how to apply them appropriately to create innovative, functional and aesthetically pleasing solutions.

14.5 PROCESS OF GOOD DESIGN—HOW DO WE GET THERE FROM HERE?

Interface designers are responsible for defining what the experience will be like when a product is used. While print media dictates that users encounter content in a largely predetermined sequence, an interface offers the user greater flexibility over how content can be accessed based on users' needs and wants. A successful interface can be easily navigated. Interface designers define, decide, and then create the experience for users, so that an experience with a product is useful, meaningful, even pleasant and empowering. The designer must maintain an attitude of unbiased discovery and empathy for the user. The designer must develop clearly defined goals in order to create a good design that includes an evaluation process that supports and enhances these goals, and includes the flexibility to respond to changes as the process continues and products evolve.

14.6 INFORMATION-DESIGN PROCESS IS AN INFORMED DESIGN PROCESS

An information-design process (IDP) is a method of visually structuring and organizing information to develop effective communication. Information design is not superficial or decorative, but is rather a merging of functional, performance-based requirements with the most appropriate form to present these requirements. A thoughtful, well-designed solution will

- *Motivate users*: It psychologically entices an audience, convincing members that information and tasks can be successfully handled.
- *Increase ease of use and accessibility*: The effort needed to comprehend information is decreased. A clear path that aids in skimming and referencing text and gives easy access is provided.
- *Increase the accuracy and retention of the information*: Users learn and retain information better when it is visually mapped and structured in obvious and intuitive ways.
- *Focus on the needs of its users*: Multiple audiences have different requirements and styles of learning. Solutions should be developed that provide alternative means of accessing information for different types of users. An information-design approach is part of a process that incorporates research, design, testing, and training to produce useful, cost-effective solutions.

14.6.1 Phase 1: Audit

The goal of the audit is to create a blueprint for the project, much like architectural drawings are developed before constructing a building (Figure 14.3). The audit process begins by asking and answering a number of questions and acknowledging ongoing change and an ever-increasing palette of products and services. Questions are asked throughout the entire product lifecycle, since the answers/design solutions reflect the user/use environment and affect the ongoing usefulness and value of the product. To create an eloquent design, continually ask and answer the following questions:

14.6.1.1 Audit Questions A

- Who are the product users?
- How will this product be used?
- When will this product be used?
- Why will this product be used?
- Where will this product be used?
- How will the process evolve to support this product as it evolves?

After the first set of questions are asked and answered, a second set of questions must be asked and answered:

14.6.1.2 Audit Questions B

- What is the most efficient, effective way for a user to accomplish a set of tasks and move on to the next set of tasks?
- How can the information required for product ease of use be presented most efficiently and effectively?
- How can the design of this product be done to support ease of use and transition from task to task as a seamless, transparent, and even pleasurable experience?
- What are the technical and organizational limits and constraints?

An audit focuses on discovery. Many disciplines and organizational resources must be consulted. Change is a given, since designers begin with assumptions and don't know all they need to know yet. The answers to their questions and their analysis in the context of organizational objectives provide the basis for the audit report, which serves as the guide in design development. The audit report can be as simple as a two-page list or as complex as a comprehensive hundred-page report. Since the goal is discovery, it includes every aspect of the organization concerned with the product-development

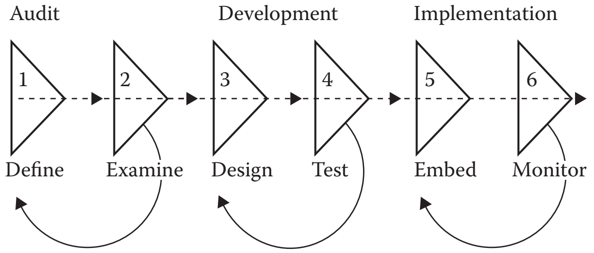

FIGURE 14.3 Information design process (IDP). IDP is phased to insure user and organizational needs are met. It is ongoing and iterative, throughout the lifecycle of a product. Any change can trigger a recycling of this process, to insure solutions remain appropriate and useful.

cycle: project management, usability engineering, technical development, user support and documentation, visual communication and design, and content management. With these goals, the result is unbiased, accurate, comprehensive information that serves as the basis for design.

14.6.2 Phase 2: Design Development

The design-development phase uses the audit report as a guideline. This is an ongoing, iterative process with each iteration incorporating user test results to make the product appropriate to the particular set of needs. In reality, the length of this process is often defined and limited by real-world deadlines such as product release dates. The design-development phase includes design and testing. The designer or design team creates a number of solutions based on results and objectives determined by the audit report as well as other project specifics. Initially, design ideas should be very broad, incorporating many ideas and options no matter how unrealistic or unusual. As ideas are tested, user feedback incorporated, and other parameters defined, solutions naturally become more defined. Surviving design ideas are then based on solid information derived from user feedback, providing a strong basis for final design decisions. In the beginning, the focus is on high-level concepts and navigation. How will the product work? What will it feel like to use? As initial concepts are refined, design details become more specific. When the conceptual model and organizational framework are approved, the design of the look or product package begins. By the end of this phase, a prototype design to be carried out in implementation and monitoring is tested, approved, and specified.

14.6.3 Phase 3: Implementation and Monitoring

The implementation phase focuses on delivering what has been defined, designed, and documented in the preceding phases. It is the final part of a *holistic* process that defines everything necessary to make a product succeed on an ongoing basis. This includes not only the implementation of the design within the technology, but also any additional support such as the creation of training materials and other reinforcements that enhance use and productivity. Continuous monitoring is key to sustained success, because a successful product responds to evolving technology and user needs. This last phase is mostly consultative and ongoing throughout the product lifecycle in order to ensure that changes such as new technology and product developments are reflected in the product itself. These may in fact trigger another audit/design/testing cycle, although usually less extensive than the initial process. Though the implementation phase is called "the last phase," it reveals the evolutionary process of design and development. The goal of ongoing monitoring of solutions is to be aware of changes in user needs, technology, and competition that impact user acceptance and satisfaction. Changes here often result in the need to reevaluate and redesign to incorporate this new knowledge gained.

14.7 VISUAL DESIGN PRINCIPLES

Interaction design bridges many worlds: that of visual design, information presentation, and usability with aesthetics. Donis (1973a), in *A Primer of Visual Literacy*, argued that art and its meaning have dramatically changed in contemporary times from one that involved a concern with function to one that views the process of creating art as that of making emotional maps that spring from the province of the intuitive and subjective. This argument extends to design. To someone unskilled in creating effective communications, visual design is often understood as personal preference limited to style or appearance. However, any form of effective design is a result of rigorous study, a concern for organization and usability combined with knowledge of the basic design principles of harmony, balance, and simplicity. Visual design is in fact a form of literacy.

14.8 UNIVERSAL PRINCIPLES OF VISUAL COMMUNICATION AND ORGANIZATION

The principles of harmony, balance, and simplicity are related yet distinct in meaning and application. *Harmony* is the grouping of related parts, so that all elements combine logically to make a unified whole. In interface design, as with other categories of design, this is achieved when all design elements work in unity. Transitions from place to place are effortless and the techniques used to achieve this harmony are unnoticed by the user. Visual harmony achieves the same goal as musical harmony in which notes combine to create a chord. The golden section, also known as the "golden mean" or "golden rectangle," is one of the most widely used methods for creating harmony. Architects, artists, musicians, mathematicians, and designers have used the golden section extensively for centuries to create proportional relationships (Figure 14.4).

Balance offers equilibrium or rest. Donis stated that equilibrium is the strongest visual reference (Donis 1973b). It provides the equivalent of a center of gravity that grounds the page. Without balance, the page collapses, all elements are seen as dispersed, and content is lost. Balance requires continual modification from page to page because while each page is part of a greater system, elements can vary and all have visual weight. In the same way that a clown balancing on a ball while juggling objects of different weights must continually make adjustments for actions that are occurring, visual balance requires the same concerns and adjustments as in the physical world. Regardless of how a design is organized, it must achieve stability and unity in order for a user to feel comfortable with the solution. Balance can be achieved a number of ways. One obvious method uses *symmetry*, such as found on a page with text and image aligned on a centered axis. Deceptively simple, symmetry form is often considered easy to make; however, unless handled carefully a symmetrical composition can be predictable, boring, and static. *Asymmetry* employs nonaxial balance and uses contrast between elements such as weight,

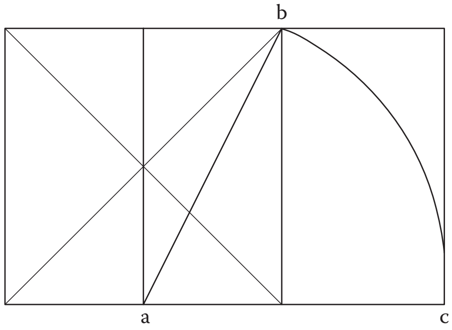

FIGURE 14.4 The golden rectangle. Divide a square to find the center point (a) from which length (ab) is found. From point (a) the length (ab) is swung as an arc to point (c) to create a rectangle that uses the proportions of the golden section.

form, and color to create visual tension and drama. Both are valid approaches and require skill and knowledge of complex visual interaction to achieve.

Simplicity is the embodiment of clarity, elegance, and economy. A solution that offers simplicity is unambiguous and easily understood. It offers clarity working effortlessly devoid of unnecessary decoration. It appears deceivingly easy, accessible, and approachable, even though it may be conceptually rich. Simplicity involves distillation—every element is indispensable, if an element is removed, the composition falls apart. Achieving simplicity is no easy task. Two guidelines for creating simple design solutions are (1) "Less is more!" (attributed to Mies van der Rohe) and (2) "When in doubt, leave it out!" (Anonymous). The most refined design is direct and includes only essential elements. Removing any element breaks the composition rendering it unintelligible or radically different.

14.9 VISUAL DESIGN TOOLS AND TECHNIQUES

New technologies are rapidly being created that extend past the simple automation of tasks and communication; they are revolutionizing processes and the resulting products. Before the revolution brought about by electronic publishing technology, many disciplines such as writing, editing, design, publishing, and programming were discrete units that handled a defined step within a larger process. Today's new publishing environments encourage the possibility of a *renaissance* publisher—a person who can create, design, publish, and distribute. Yet the process used to arrive at successful solutions is very complex and extends past technical knowledge to include a mastery of visual and verbal language in order to build effective communication. Focus must be placed on the factors that determine success with constant evaluation and adjustment of these factors in light of new developments.

14.9.1 Five Criteria for Good Design

Before any work begins, all participants in the process should have a clear understanding of the criteria for good design. The following questions are guidelines for evaluation of design solutions before, during, and after the process to ensure that all solutions remain valid as products, technology, and user needs evolve.

- ***Is it appropriate?*** Is the solution appropriate for the particular audience, environment, technology, and/or culture?
- ***Is it durable?*** Will the solution be useful over time? Can it be refined and transitioned as the product evolves and is redefined?
- ***Is it verifiable?*** Has the design been tested by typical users in the environment that it will be used in? Has feedback been properly evaluated and used to improve the product?
- ***Does it have impact?*** Does the design solution not only solve the problem, but also impact the look and feel, so that the user finds the product experience comfortable, useful, and desirable?
- ***Is it cost effective?*** Can the solution be implemented and maintained? Are individuals with the necessary skills and understanding to create, refine, and maintain the design available throughout the product's life? The cost of any design begins with the audit and design phases, but continues after the implementation phase to insure that it remains advantageous and cost-effective. The hard and soft costs of delivering the solution plus ongoing maintenance add up to the real design costs.

14.9.2 Visual Design Principles at Work

The following sections outline the disciplines and principles used to create quality design solutions. Each topic is worthy of extended study, because there is much to understand when evaluating how to effectively present information. As the design process evolves, insights and information are discovered that impact a solution. It is optimistic to base solutions on an initial exercise because the very nature of process means discovering what is unknown yet critical. Therefore, all members involved in the design process must remain open and ready to incorporate new information, which may change or delay results, but more accurately reflect user needs.

For example, if a new feature is developed that changes a product's target audience from mid-level managerial to executive users, most methods for critical interaction and content delivery should be reconsidered. Executives have less time and need different information. The result might be a simpler interface with streamlined content that uses a larger typeface and a more conservative visual language. The most important principle to remember when thinking about design is that there are no rules, only guidelines. Everything is context sensitive. Always consider and respect the users.

14.9.3 Typography

In *The Elements of Typographic Style*, the poet and typographer Bringhurst (2005) described typography as frozen language. *Typography* is the visual representation of spoken and unspoken thought that allows an idea to be shared across time and distance independent of its creator. A functional and expressive art that shares many of the same concerns as writing and editing, typography involves organizing text so that its meaning is communicated according to an author's intent. In design, a literacy that provides an understanding of typography and how text can be structured in space is as important as a literacy that understands how to structure grammar in order to explicate content.

Typography is made from type, individual characters organized by visual characteristics into typefaces. Type is the smallest definable part of a design, much like a pixel is to a screen display. Felici (2003), who has worked through evolutions in typesetting technologies in *The Complete Manual of Typography*, defined a font as the electronic file that contains the programming code needed to make the characters found in a typeface. Historically, a typeface consists of all the individual characters or glyphs at a given size: letterforms, punctuation, numbers, mathematical symbols, diacritical marks, and other accessory characters needed to fully compose a text. This definition serves as a reminder to read a text carefully and consider all needs before selecting a typeface and developing a presentation form (Figure 14.5).

Effective typography is rational. It is concerned with clarity and comprehension; the ease in which characters and word shapes are recognized in reading environments and the ease in which they can be used. It extends past the shapes of individual letters and their potential combinations to include the relationships found between word and interword shapes, functional groupings that ultimately progress into issues of type weight, slope, width and scale, characteristics that act as interpretative devices in order to create influential and persuasive form. If the principles of good typography can be understood and applied, then these same principles can be extended to more complex issues that follow such as page and product design. Typographic choice affects legibility and readability, the ability to easily see and understand what is on the page, in all media. Tracy (1986), in *Letters of Credit: A View of Type Design*, offered the most useful definitions for legibility and readability. *Legibility*, the speed at which letters and the words built from them can be recognized, refers to perception. *Readability*, the facility and ease with which text can be read, refers to comprehension. Legibility and readability are related. Regardless of media, legibility and readability are determined by variables such as point size, letter pairing, word spacing, line length and leading, resolution, color, and organizational strategies such as text clustering. Together, legibility and readability comprise typography's functional aspects. Good typography, like good design, is invisible to the user—it just works (Figure 14.6).

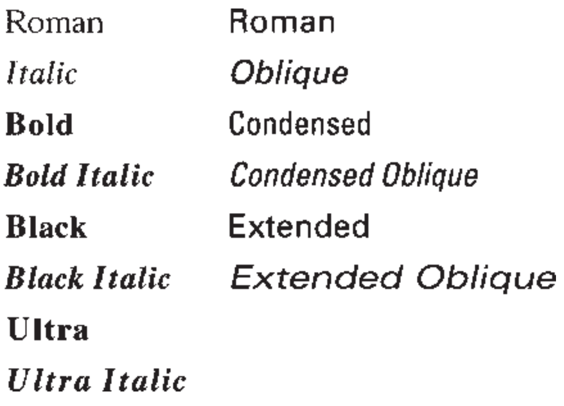

FIGURE 14.5 Type family. A type family is built around four core members: roman, bold, italic, and bold italic. Additional members may include typefaces whose weight and width are variants of the core group. A family can also contain expert sets that offer additional or alternate characters such as small caps, fractions, and non-aligning numbers.

Selecting an appropriate typeface for a specific purpose and context requires experience and understanding (Figure 14.7). With thousands of typefaces to choose from and numerous ways to manipulate them, finding the typeface best suited for an audience is not easy. With its lack of control, multiple media, and varied viewing contexts, the current publishing environment makes this a complex task.

Typeface choice impacts whether and how a communication is read. Distinct typefaces and typographic styles create environments that influence a user's perception of text. The physical nature of the presentation itself helps determine content and acceptance. A typeface with extremely thick and thin strokes may appear sophisticated and readable in print but may look naïve and render text unreadable in a digital environment. Typefaces are frequently designed to solve issues of legibility and readability created by a technology. A typeface made for online use can increase page legibility, as well as the overall perception of approachability, quality of an interface, and ultimately product acceptance (Figures 14.8 through 14.10).

An informed selection can make reading enjoyable and effortless rather than frustrating and fatiguing. Though typography might seem to be an insignificant issue to a non-designer, it affects overall usability. A clear understanding of the concepts and principles that affect legibility and readability is crucial to determining effective typography.

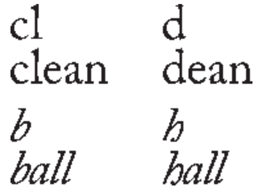

FIGURE 14.6 Legibility and readability. The letters, letter pairs, and words shown above are examples of what can happen if the designer is not sensitive to issues of legibility and readability.

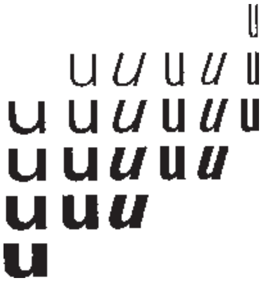

FIGURE 14.7 Univers “U”. Univers, a type family designed by Adrian Frutiger and released for commercial use in 1954, is composed of twenty-one fonts that together offer a wide range of weights, widths, and slopes that allows a text to be organized so that its form is visually coherent and easily read.

FIGURE 14.8 Bell centennial: Technology-specific typefaces. AT&T commissioned Bell Centennial, a typeface designed at a very small size, for telephone directory use, in order to solve an industrial problem created by changing typesetting and printing technologies. The resulting type family designed for maximum legibility, readability, and spatial efficiency provided the user with a clear information hierarchy. It reduced paper use and directory assistance calls. Here, Bell Centennial is shown at six point, the size at which it was intended to function.

FIGURE 14.9 Bell centennial: Technology-specific typefaces. Bell Centennial’s forms were opened to increase legibility and readability. Curved strokes were straightened and the horizontal and vertical juncture were notched so that they did not clog with ink when printed. Select letterforms shown at 32 point for Bell Centennial (bottom) and Helvetica (top) illustrate this.

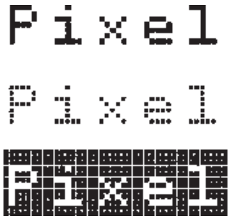

FIGURE 14.10 Pixel font. Pixel fonts are screen fonts designed specifically for use with or as on-screen navigational elements. Their block-like forms are the result of working with the actual pixels themselves.

14.10 HOW THE HUMAN EYE SEES, AND THEN READS

Spencer (1969) in *The Visible Word*, a publication with an objective of introducing and uniting those who research legibility with those who work with typography, presented that the eye uses both outline word shapes and their internal patterns to move along a text line and steps and jumps as it groups text to form comprehensible phrases of information. This motion of the eye during reading is known as “saccadic movement.” Sometimes during this process, the eye regresses and returns to what has been read. Optimal typography allows for fewer backward movements. Spencer argues that possessing a mastery of reading mechanics is important to a mastery of content. Typeface selection directly affects this skill, making it easier or more difficult for the eye to group, read, and understand information (Figures 14.11 through 14.13).

14.11 TYPEFACE SIZE AND SELECTION

Type size is given in points, a measuring system unique to typography. In digital typesetting systems, a point equals 1/72 of an inch. Type size cannot be determined by physically measuring a letterform because when type existed solely in metal, the technology in which it was first used, size was measured by the height of the metal block on which a letter sat. This is one of the reasons why the same letter repeatedly set in differing typefaces at the same point size appears dissimilar when compared. Lowercase letters set in the same point size with differing typefaces can appear larger or smaller in comparison to each other due to variations in x-height. Other variables such as stroke weight, letter width, and ascender and descender length influence size perception and help make some typefaces more or less readable and legible than others. Type size is also dependent on the resolution offered by output and viewing devices, color usage, context, and other design issues. It is crucial to understand not only the characteristics of a typeface but also usage context and application environment when selecting a typeface.

14.11.1 Serif and Sans Serif

Serif and sans serifs are general categories used for classifying type. *Serif* refers to a typeface with serifs, the short strokes that project off the end of letter strokes, as opposed to *sans serif*, a typeface without serifs. It is debatable whether serif typefaces, conventionally used for setting text in print, are more readable than sans serif typefaces, which have an even stroke weight and more open counters that have proven useful for setting text for on-screen reading. And, while sans serif is considered easier to read on screen, serifs can be made equally legible if the appropriate typeface, size, and color is specified. Some designers think that, in print, serifs aid in character recognition and readability; they help differentiate individual letters creating horizontal lines for the eye to follow. This has not been proven conclusively. Other designers hold the view that "we read best what we read most." It's likely that this discussion will continue. Recent technological developments that subdivide a pixel into red, green, and blue elements on LCD screens have resulted in new technologies that create a better immersive environment for online reading. This, in turn, will spark new explorations in typographic form and its presentation.

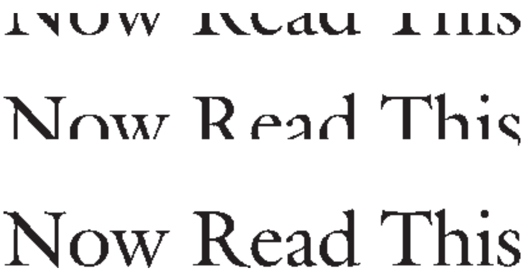

FIGURE 14.11 Now Read This. The phrase, Now Read This, is shown in full, cropped at the bottom and from the top, suggesting the importance of outline word shape and internal pattern.

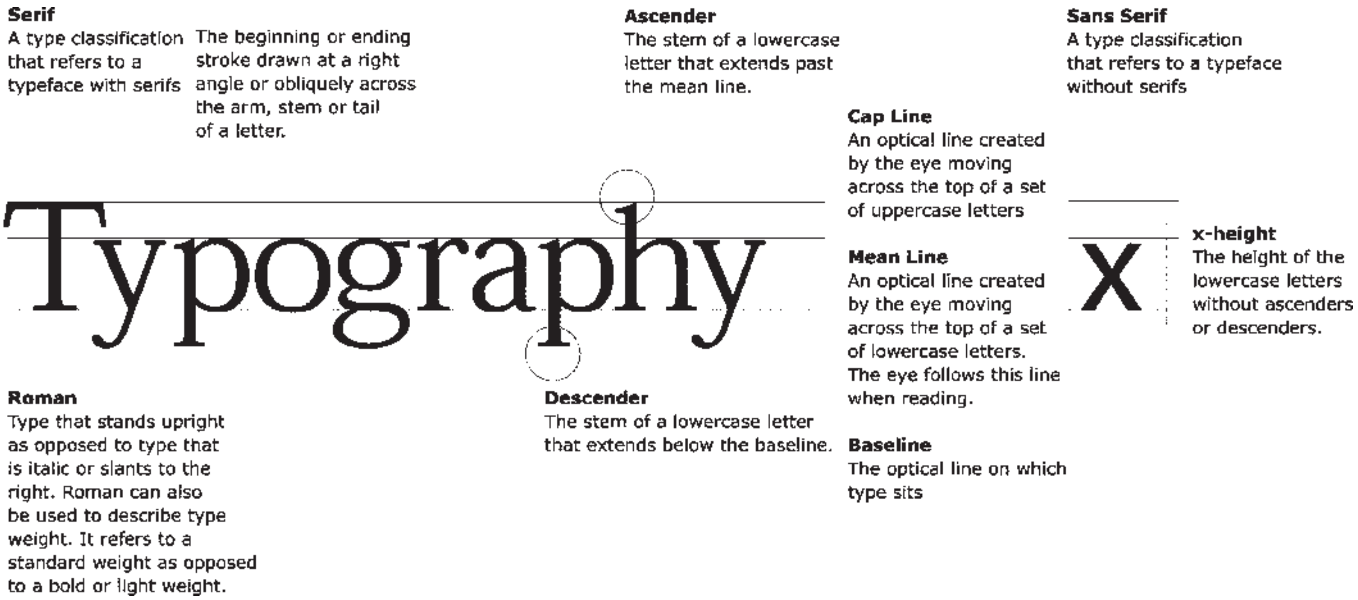
14.11.2 Families of Type

Many design students first learn to classify typefaces into five chronological families or organizational groupings popularized by Craig et al. (2006) in *Designing with Type*: (1) old style, (2) transitional, (3) modern, (4) Egyptian, and (5) contemporary. Classifying typefaces into these families makes it



Serif
A type classification that refers to a typeface with serifs
The beginning or ending stroke drawn at a right angle or obliquely across the arm, stem or tail of a letter.
Ascender
The stem of a lowercase letter that extends past the mean line.
Sans Serif
A type classification that refers to a typeface without serifs
Cap Line
An optical line created by the eye moving across the top of a set of uppercase letters
Typography
x
x-height
The height of the lowercase letters without ascenders or descenders.
Mean Line
An optical line created by the eye moving across the top of a set of lowercase letters. The eye follows this line when reading.
Roman
Type that stands upright as opposed to type that is italic or slants to the right. Roman can also be used to describe type weight. It refers to a standard weight as opposed to a bold or light weight.
Descender
The stem of a lowercase letter that extends below the baseline.
Baseline
The optical line on which type sits

FIGURE 14.12 Anatomy of a letter. The typographic terms defined and illustrated above are used by designers in discussing principles that affect the legibility of type and overall quality of the communication.

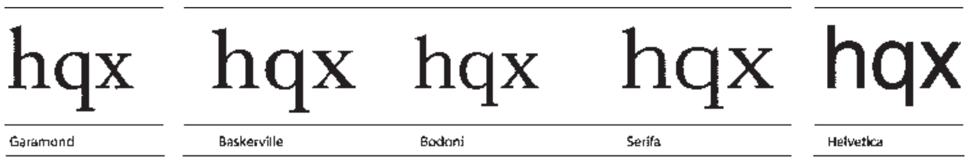


FIGURE 14.13 Hqx illustration. The x-height of a typeface (based on the actual height of a lower-case x) is a key characteristic when deciding the visual size of a typeface, particularly when readability is critical. While the above typefaces are the same point size, some seem larger (e.g., Helvetica) and easier to read than others (e.g., Serifa).

easier to understand the differences and similarities in structure and fitness. Like anything else, type design does not happen in isolation. These categories, as with those of many other classification systems, are formed around historical junctures in which the overall design of letterforms shifted dramatically in response to technological, political, cultural, aesthetic, and economic concerns. Typefaces within each set have passed through the tenures of metal, photocomposition, and have been adapted for digital technologies. Many of the problems solved through these older forms have proven inspirational to contemporary type designers who, as their predecessors did, continue to explore new forms for new purposes.

Verdana, a sans serif screen font designed by Matthew Carter, whose roots lie in the Industrial Revolution, was commissioned by Microsoft and released in 1996. Its form, which uses a visually even stroke with wide counters, helped signal a new software release. Verdana's members consist of Roman, italic, bold, and bold italic. It has two peers that use non-Latin alphabets: Verdana Greek and Verdana Cyrillic. Verdana is related to Tahoma, a condensed variation of Verdana designed for use in situations that require more information to fit in less space—such as with dialog boxes and menus; and Nina, a spatially efficient sans serif designed for situations that require more information to fit in even less space—such as with small handheld devices. Berry (2004), who writes and consults extensively on typographic matters, said in *Now Read This* that Meiryo, Verdana's daughter, evolved partially as a response to technologies that enhance photometric resolution permitting more complex writing systems such as scripts to be optimally read on screen, and a demand for a Japanese type that weaves the character sets of Kanji, Kana, Katakana and Romanji together, fashioning a favorable reading environment for screen and print. Meiryo, too, has Greek and Cyrillic companions. That one family has siblings and offspring, manufactured around a variety of alphabets and writing systems, speaks in part to the economic and political concerns of an international corporation that must respond to the demands of different cultural markets as much as it does to the need for multilingual communication (Figure 14.14).

14.12 VARIATIONS IN LETTERFORMS

14.12.1 Variations in Stress

Early type designers mimicked scribal letterforms because they knew and understood these forms. Old-style typefaces have a diagonal stress, a backwards slant—a visual remnant of the pen—that distributes weight through the thin part of the letterform. Over time, the stress traveled several degrees to the right as seen in transitional typefaces. With modern typefaces, the stress becomes rigidly vertical. Egyptians such as Century Schoolbook have a slight diagonal stress; other Egyptians with a stronger slab serif such as Serifa have no stress. Contemporary typefaces have no noticeable stress.

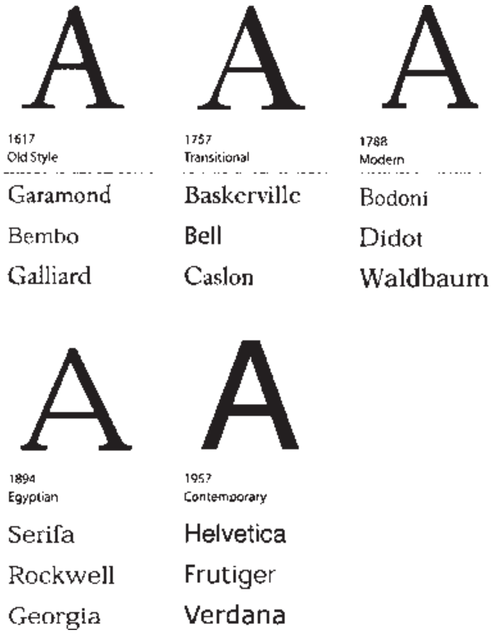

FIGURE 14.14 Type classification. These five A's are representative of typographic style from the 1600s to present day, reflecting changes in tools, fashion and current events. Ultimately, choice of output media should determine typeface selection, given details such as stress, the thick and thin parts of letterforms, negative space, viewing environment, output resolution, and so on.

14.12.2 Variation in Thick and Thin

The degree of contrast between the thick and thin strokes of the letters can vary. Old style typefaces have little contrast in strokes. This contrast increases in transitional faces. Extreme stroke contrast is a dominant characteristic of modern typefaces. Egyptian typefaces return to less contrast. Contemporary typefaces have no perceptible thick and thin strokes.

14.12.3 Variations in Serifs

Serifs differ in weight and bracket, which is the shape created by the serif joining the vertical stroke of the letter. Old-style typefaces have heavy concave serifs with thickset brackets. The meticulous serifs of modern typefaces are refined and thin and without brackets. Many Egyptians have heavy, straight serifs with little or no bracket. Sans serifs are considered contemporary typefaces (Figure 14.15).

14.13 TYPOGRAPHIC GUIDELINES

14.13.1 Combining Typefaces

Sans serif and serif typefaces can be effectively combined if changes are limited to prevent visual chaos. The key is to ensure that the result respects the content and reinforces the information hierarchy and overall design goals. When combining typefaces, decide whether harmony or contrast is important. Generally, do not use more than two different

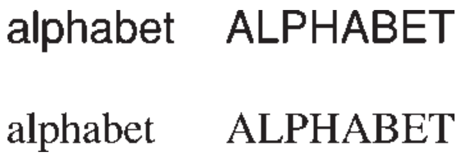

FIGURE 14.15 Serif versus sans serif. The serif typeface Century above versus the san serif typeface Univers, below. Understanding a typeface's physical characteristics and how it performs in different environments is important. Set a paragraph of text in both a serif and sans serif with exactly the same line length, size and spacing and compare the differences on screen and on paper.

type families in a document. Remember, at a minimum, a type family offers a Roman, italic, bold, and bold italic. Consider the pattern and texture that the x-heights and stroke weights weave when combined. Excellent typography does not impede the user and the information. Too many typefaces jar and confuse the reader, create visual intrusions, and slow the reading process.

14.13.2 Contrast in Weight (Boldness)

Combining two classic typefaces with a strong differential factor such as Helvetica Extra Bold with Times New Roman can add useful contrast. Be wary of combining intricate typefaces such as Gill Sans Bold and Souvenir, which have structures that may not create compatible reading environments. Too much contrast and visual complexity can be detrimental.

14.13.3 Output Device and Viewing Environment

The quality of publishing technologies and viewing environment vary greatly—laser printer versus video versus electronic media, and so on. In choosing a typeface, its style, size, spacing, and leading, think about the final output medium, and examine this technology's effect on legibility. Low-quality monitors and poor lighting have a major impact: serifs sometimes disappear, letters in small bold type fill in and colored type may disappear altogether.

14.13.4 Letter Spacing and Word Spacing

While the spaces within and between letterforms and words are determined by a type designer in order to set a rhythm that reads well, this spacing can be altered or kerned. However, be careful! When letter spacing is too tight, the letters are hard to distinguish from each other and legibility decreases. When letter spacing is too wide, letter groups are not easily recognized. Spencer argues that optimal letter spacing is inconspicuous, the user can read quickly and easily and understand content. Tight word spacing makes distinguishing individual words difficult. When word spacing is too wide, word groups fall apart. When there is greater space between words than there is between lines, the reader's eye naturally falls to the closest word, which may be below instead of across the line. This frequently occurs with low-resolution or low-cost products.

14.13.5 Line Spacing/Leading

Leading is the distance measured in points between the baseline of one line of text and the baseline of the text line below it. Ascender and descender length influences how closely lines of type can be stacked. The space between lines of text, or leading, should increase in relation to type size. This adjustment is visual not mathematical. Overall legibility may be improved by increasing the leading in relation to column width.

14.13.6 Line Length/Column Width

The correct line length is just long enough for the eye to sweep across without losing its place and easily drop down to continue reading the following lines. A good rule of thumb is that a line of average length contains between 39 and 52 characters.

14.13.7 Justified versus Ragged Right (Flush Left)

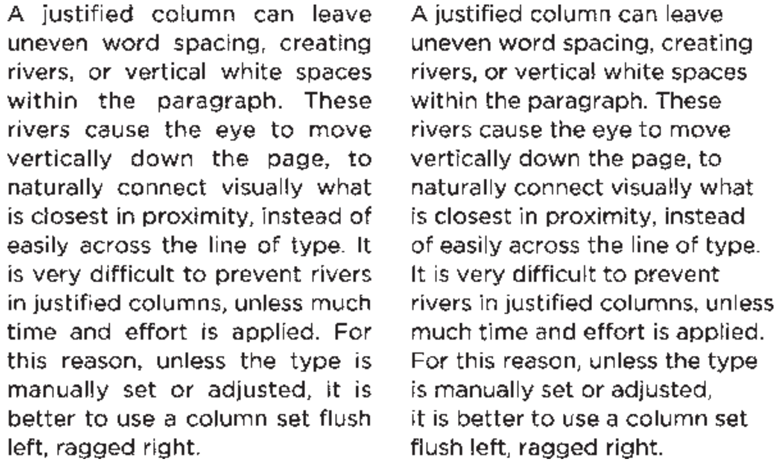
A justified text column can leave uneven word spacing, creating rivers, or vertical white spaces, within the paragraph. Rivers cause the eye to move vertically down the page, naturally connecting with what is closest in proximity, instead of moving easily across the line. It is very difficult to prevent rivers in justified text columns without spending considerable effort. Unless the type is manually set or adjusted, which is a time-consuming activity, it's better to use type that is set flush left, ragged right (Figure 14.16).

14.13.8 Highlighting with Type

Content can be highlighted by modifying type weight, slope, or case. Weight can be shifted from Roman to bold or extra bold. Slope can be altered from Roman to italic. Be mindful that italics are appropriate for short phrases and not long text passages. The italic appears lighter and smaller on the page when compared with its companion Roman and its complex forms are more difficult to read. Case can change from upper and lowercase to all capitals or small caps. Using all caps for extended text passages impedes readability since word outlines are rectangular and harder for the eye to differentiate. Limited shape and size cues are available to help differentiate between letters, words, and sentences to create meaning. Use only one highlighting technique for emphasis.

14.13.9 Decorative Typefaces

Decorative typefaces are of limited use for body text, because their irregular design lessens legibility and should be used in headlines with caution. Because they are essentially typographic fashion statements, decorative typefaces can either reinforce or distract from the overall message or brand of a particular product or organization.



A justified column can leave uneven word spacing, creating rivers, or vertical white spaces within the paragraph. These rivers cause the eye to move vertically down the page, to naturally connect visually what is closest in proximity, instead of easily across the line of type. It is very difficult to prevent rivers in justified columns, unless much time and effort is applied. For this reason, unless the type is manually set or adjusted, it is better to use a column set flush left, ragged right.

A justified column can leave
uneven word spacing, creating
rivers, or vertical white spaces
within the paragraph. These
rivers cause the eye to move
vertically down the page, to

It is very difficult to prevent
rivers in justified columns, unless
much time and effort is applied.
For this reason, unless the type
is manually set or adjusted,
it is better to use a column set
flush left, ragged right.

FIGURE 14.16 With current technology, the difference between a justified text column and ragged right text column can make a huge difference in readability. In a poorly justified column, spaces within a justified line connect vertically down the page, distracting the eye from easily reading across a line of text.

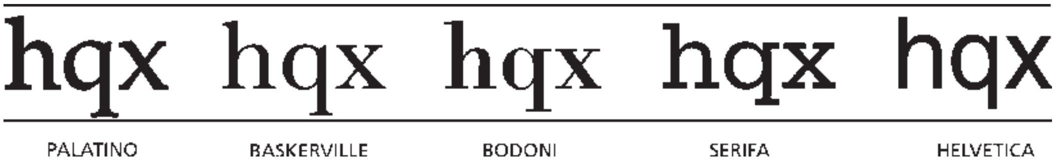

FIGURE 14.17 Black on white versus white on black. The x-height of a typeface (based on the actual height of a lowercase x) is a key characteristic when deciding the visual size of a typeface, particularly when readability is critical. While the above typefaces are the same point size, some seem larger (e.g., Helvetica) and easier to read than others (e.g., Serifa). Letterforms often appear as black/dark shapes on white/light backgrounds. The eye also reads the reverse, or negative shape around a letterform, which can create a shape that visually distracts and makes text difficult to read. Try setting a paragraph of black type on a white background, then set the same exact paragraph with white type on a black background. You can also try this same exercise with a dark color on a light background, and then try the reverse. You will notice that the greater the contrast (e.g. white type on black) the harder it is to read in large amounts.

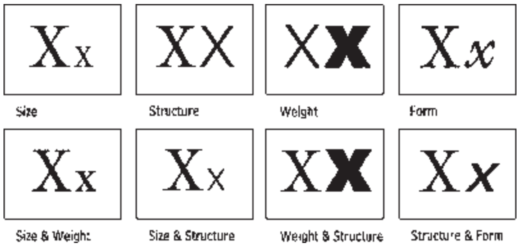

FIGURE 14.18 Typographic contrasts. This figure, which builds on the relationships of contrasts discussed and illustrated in *Design with Type* by Dair (1967), shows typographic contrasts that can be easily used to build information hierarchies.

14.13.10 Black on White versus White on Black and Dark on Light Background versus Light on Dark Background

14.13.10.1 Positive and Negative Type

White on black (or light on a dark background) is generally regarded as less legible and much more difficult to read over large areas. To the eye, white letters on a black background appear smaller than their reversed equivalent. The amount of contrast between the color of type and the background is an especially important factor for online communication. Color adds exponential levels of complexity to these considerations since displays are inconsistent from one situation to another (Figures 14.17 and 14.18) (Dair 1967).

14.14 DESIGN PRINCIPLES: PAGE DESIGN

Typography deals with legibility and *page design* focuses on readability, the ability to read and comprehend information. Can the user find what is needed on the page? The two important functions of page design are motivation and accessibility. A well-designed page is inviting, drawing the eye into the information. Users are motivated to accept the invitation. An effective page design ensures that the reader continues by increasing the ease of understanding and accessibility of the information. (For purposes of simplicity, the term *page design* is used interchangeably to mean page, screen, and document design.) Motivation and accessibility are accomplished by providing the reader with ways to

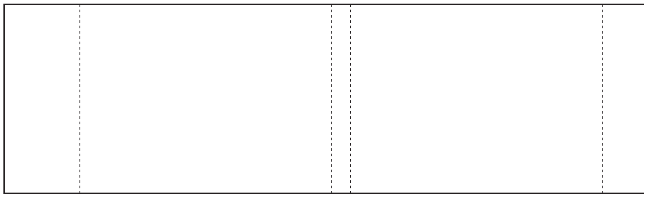

FIGURE 14.19 Grid. The lines that appear in this rectangle provide an understanding of what the grid, or underlying structure, is of this page. The grid is used as a guide to create more pages that use similar relationships for placement and alignments. It is a point of departure for one who understands the system, to create variations, be a bit more playful, yet still provide a consistent “feel” to the user.

quickly understand the information hierarchy. At a glance, the page design should reveal easy navigation and clear, intuitive paths to discovering additional details and information. This is called “visual mapping.”

A page, site, or product visually mapped for easy navigation has

- An underlying visual structure or grid, organizational landmarks, graphic cues and other reader aids (Figure 14.19)
- Distinctly differentiated information types
- Clearly structured examples, procedures, and reference tools
- Well-captioned and annotated diagrams, matrices, charts, and graphics

This kind of visual structuring helps the reader and provides an obvious path through the materials, aids in skimming, gives a conceptual framework, and prevents a feeling of information overload.

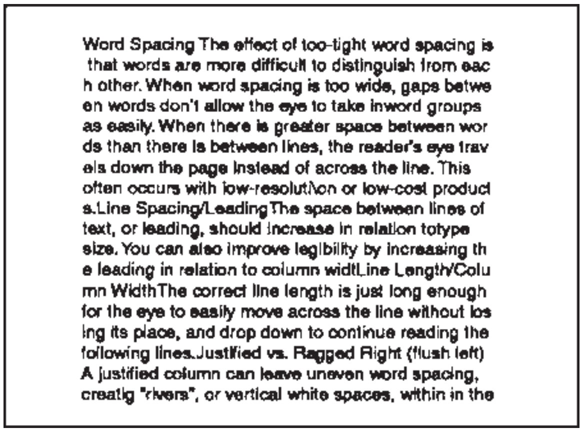
A table of contents is a simple visual map. It quickly provides a general overview of the order and some details about the structure and content. What it does not reveal, however, are priorities. Site maps or other diagrams provide this type of information as well.

14.14.1 Building the Design of a Page

Effective visual mapping is apparent in the sequence shown below that demonstrates the evolution of an accessible page from plain text. As design elements are added, the page becomes inviting to read and content becomes attainable. The final example organizes the content into units of information using line spacing and vertical thresholds or queues. Differentiation in typeface, weight, and scale reinforce structure. Information design techniques, drawn from cognitive science, can be used to improve communication effectiveness and performance.

14.14.1.1 Gray Page or Screen

Raw text interests few readers. When information is presented as a uniform, undifferentiated mass, it is difficult and irritating to use and easy to ignore (Figure 14.20).



Word Spacing The effect of too-tight word spacing is
that words are more difficult to distinguish from eac
h other. When word spacing is too wide, gaps betwe
en words don't allow the eye to take inword groups

creatig "rivers", or vertical white spaces, within in the

FIGURE 14.20 Gray page or screen.

14.14.1.2 Chunking

Structure the visual field by breaking like kinds of information into manageable groups according to subject matter. Chunks in close proximity are read as related. Graphic devices such as rules and line spaces are used to reinforce a grouping and separate chunks (Figure 14.21).

14.14.1.3 Queuing

Order information chunks visually to reflect the content hierarchy by addressing the user’s requirements of subject matter, order, and importance (Figure 14.22).

14.14.1.4 Filtering

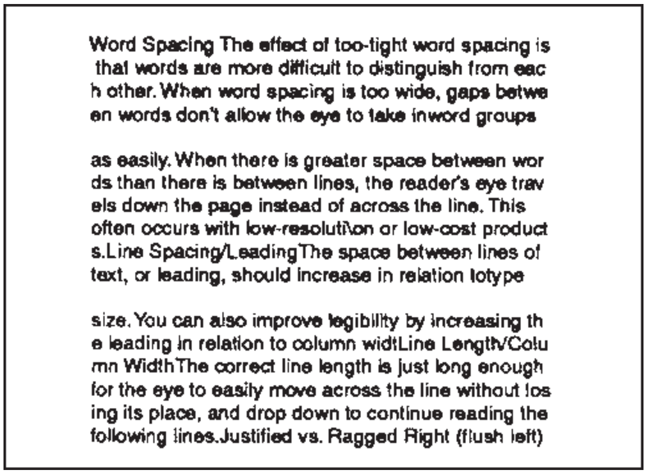
Simplify linguistic and visual order by filtering out unnecessary background noise, which interferes with the information being transmitted. Filtering builds a sense of layers of information by using color, visual cues and symbols, and bulleted lists and headers to make a page effective for a range of users and uses (Figure 14.23).

14.14.1.5 Mixing Modes

People learn through different cognitive modes or styles. Some users favor text, others may prefer illustrations, photos, diagrams, or formulas. To suit these varied learning preferences, information must be translated into several different modes that are then carefully presented to reinforce content and organization (Figure 14.24).

14.14.1.6 Abstracting

The individual page or screen is a microcosm of the complete book, site, or product. The result is a complete codified system of graphic standards, which is effective for both the reader and the producer. Abstracting builds a system of standards that simplifies text organization, creates consistent approaches to preprocessing information, and establishes a customized look for an organization’s products (Figure 14.25).



Word Spacing The effect of too-tight word spacing is
that words are more difficult to distinguish from eac
h other. When word spacing is too wide, gaps betwe
en words don't allow the eye to take inword groups

14.14.2 Other Page Design Techniques

14.14.2.1 White Space

White space (or empty space) is an underutilized but extremely effective design tool. It visually opens up a page, provides focus, helps group like kinds of information, provides resting points for the reader's eye, and creates the perception of simplicity and ease of use.

14.14.2.2 Grid

A grid is a controlled system of organization that allows for the distribution of visual elements in an intelligible order. A grid, as part of an overall design system, provides an underlying structure that determines the horizontal placement of columns and the vertical placement of headlines, text, graphics, and other artwork.

A grid is built on a series of consistent relationships, alignments, and spatial organizations. It acts as a blueprint that can be repeatedly used to create sequential pages, which are related but respond to different content. When the grid

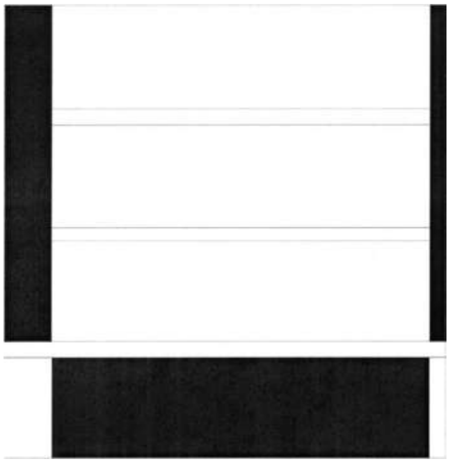

FIGURE 14.25 Abstracting.

system is understood, it forms the basis for consistent application and extension of the design by others who also understand the intention of the system. Every strong design uses an underlying structure or grid to create a consistent look and feel to any form of visual communication. An analogy can be created between the horizontal and vertical lines that compose a grid used on a page and the metal beams that systematically make up the overall supporting structure of a high-rise building. While the structural supports in a building are consistent from floor to floor, the configuration of the space within each individual floor is based on each occupant's needs. The same holds true with the grid on a page. An important tool that improves usability, a grid enables a user to navigate a page quickly and easily. A grid specifies placement for all visual elements. The user anticipates where a button will appear or how help is accessed. Product or program usefulness and ultimately success are greatly increased through the consistency offered by a grid.

14.14.2.3 Field of Vision

Field of vision refers to what a user can see on a page with little or no eye movement; it is the main area where the eye rests to view most of the page. A good design places key elements in the primary field of vision, reflecting and reinforcing the information hierarchy. Size, contrast, grouping, relationships, and movement are tools that create and reinforce field of vision. The user first sees what is visually strongest, not necessarily what is largest or highest. This is particularly true for online information due to the limitations of page real estate and dense information environments.

These concepts, as well as the strength of peripheral vision, can be experienced when viewing a page that has a banner advertisement or moving graphic.

It is virtually impossible to ignore or focus attention on the primary field of vision when there is winking and blinking elsewhere. In fact, superfluous visual devices reduce information's value by distracting and disturbing the user's desire and ability to focus, read and understand.

14.14.2.4 Proximity

This concept applies to the placement of visual elements physically close to each other so that it is understood that these are related elements.

14.14.2.5 Illusion of Depth

Though the online world exists in two-dimensions, contrast can be used to create the illusion of depth. Contrasts created through size, weight, structure, direction, color, texture, and layering can form cues that reinforce hierarchy by giving the illusion that an element is on top of or in front of another.

14.15 CHARTS, DIAGRAMS, GRAPHICS, AND ICONS

The goal of any visual device is to provide the fastest, most efficient path to understanding ideas and to make these ideas clear and compelling. Useful, effective graphics act like visual shorthand, particularly important when the real estate of the page is limited (Figure 14.26). A good visual eliminates the need for text and communicates across cultures. A bad graphic with an unclear meaning that must be reinforced by a long caption can be worse than none at all. The old clichè, a picture is worth a thousand words, is true only if the picture is efficient and effective. In stressful or difficult situations, people do *not* have time to read or the ability to focus on text and/or complex visuals. Though more difficult to achieve, brevity and simplicity in such cases have greater value. Product users prefer well-designed charts, diagrams, and illustrations that quickly and clearly communicate complex ideas and information. Studies show that visual images are retained long after the reader is finished. Designed correctly, visual images can make information memorable and effective. At a minimum, a powerful illustration or graphic can often improve performance simply because it increases user motivation. Visuals are robust communication tools used to (a) visualize and analyze data; (b) present new or abstract concepts; (c) make physical and technical concepts invisible to the eye; and (d) summarize information efficiently and effectively. Visuals explain and reinforce concepts, relationships and data, making them tangible. Photographs, charts, illustrations, icons, or diagrams become thinking tools. The information is clarified, made easier to evaluate, and has greater impact. Visuals are a very effective way to communicate a message, but choosing the appropriate presentation for a concept is critical to the user's ability to effectively comprehend a message. Understanding the limitations of the display medium is crucial to creating a successful visual.

FIGURE 14.26 Zen calligraphy is an example of the historically close relationship between word and image. The Zen master Hakuin (1768–1865) created this symbol to mean "dead," with additional notes saying "Whenever anyone understands this, then he is out of danger."

14.15.1 Tables, Charts, Diagrams

These three types of graphics are discussed in order of complexity. Tables are the least difficult to create, charts the second most difficult, and diagrams the third. Illustrations, graphics, and other images and visuals are the most complex, require more conceptual and visual sophistication, and may require a consultant to create. When is one more appropriate than the other? Determining which format is the most effective is illustrated in Figure 14.27. In addition to this list, it is important to remember that visual cues such as color, shading, texture, lines, and boxes should be considered redundant cues and only used to provide additional emphasis to support the concept.

14.15.2 Icons and Visual Cues

Icons and other visual cues are a form of visual shorthand, which helps users locate and remember information. Developing an easily understood style that is consistent with the overall program style is not easy. Choose a style that is simple and consistently reinforced throughout a product. More complex and unique symbols and icons can be used if usage takes place over a longer period, allowing product familiarity and learning to take place. The MasterCard logo consists of two intersecting circles. After many years of reinforcement, most people immediately recognize it without accompanying text or other explanation. It is very difficult to create an icon that, without explanation, communicates a concept across cultures. For example, the use of a freestanding rectangular box with an open door flap indicates mailbox or in-box. This kind of mailbox is rarely used today and was never used in Europe where mail is placed in slots or upright boxes. Even the concept of mail delivery can be considered strange. This is a case where meaning had to be learned. Although simple ideas presented as icons are appropriate, a program with many complex concepts using colloquial images can make using a program agonizing for users from other cultures. There is an important difference between an icon and an illustration, though the two concepts are often confused. If an icon must be labeled, it is really an illustration. The icon's value as visual shorthand is lost. Better to use a word or short phrase rather than word and image when screen space is at a minimum.

A successful icon is memorable with minimal reinforcement. If after viewing an icon several times a user cannot remember its meaning, then the icon is valueless and should be eliminated. Icon sets should share a similarity of style (businesslike or playful) and possess formal presentation properties consistent with the overall program or product to which they belong (Figure 14.28).

14.15.3 Illustrations and Photographs

As technology improves, the only limit placed on the use of complex images will be by the designer. The most important consideration is appropriateness of the image for the intended audience. Do not use cartoons for a company brochure, or a low-resolution photograph of a control panel when a line illustration is more effective.

	If you want to show ...	**use a ...**
Groups	Group of related items, with a specific order	Numbered list
Relationships	Relationships and steps involved in a process	Flow chart
	Relationships between categories of ideas	Table
	Relationships of tasks taking place over time	Project plan table
Evaluate/compare	Evaluate items against several criteria	Rating table
	Evaluate items against one criteria	Comparison table
	Compare more than one item to more than one variable	Matrix diagram
	Compare several things in relation to one variable	Bar chart
	Compare the relative parts that make up a whole	Pie chart
Hierarchy	Hierarchical structure of an organization	Organizational chart
Concepts	Concept	Illustration and/or text icons, other graphics
	Abstract concept	Complex images, interactive components

FIGURE 14.27 When to use what graphic.

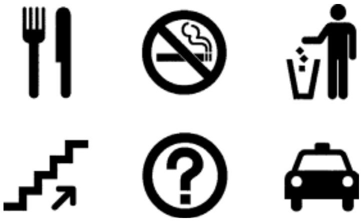

FIGURE 14.28 AIGA/DOT Icons. These six icons, all from the same set, were developed by the American Institute of Graphic Arts and the U.S. Department of Transportation for use in signage. From upper left to lower right: restaurant, no smoking, trash, stairway leading up, information, and taxi.

While understanding the meaning and implications of illustrations and photographs is no easy task, there are guidelines for making choices. A photograph can easily represent an existing object, but issues related to resolution and cross-media publishing can make it unintelligible. If a photograph can be reproduced with proper resolution, cropping and contrast, and emphasize a required detail, then photography is a good choice. A photograph can provide orientation and contextual cues that are more difficult to achieve in an illustration. No matter how simplified or cropped to focus attention, a photograph's reproduction quality is often unpredictable. In this situation, a technical illustration such as a line drawing is more effective. An obvious advantage of illustration is that it can present abstract concepts or objects that do not yet exist, or that may never exist. Another benefit is the ability to focus the viewer's attention on detail. For example, a line drawing can place attention on a specific machine part by changing line weight. To achieve a similar result in a photograph adds time, complicates the image, and possibly never simplifies the explanation.

Regardless of the method used to create a visual explanation, it must clarify and reinforce content. If the purpose of the image is to explain where to locate a piece of equipment, then an overview of the equipment in the environment is appropriate. If the goal is to show an aspect, such as a button location, then the illustration should only focus attention on that aspect. An image can be cropped to focus attention on what is being explained; it depends on the goal of the photograph or illustration.

Situations exist in which it is more effective to use a combination of photography and illustration than either alone. For example, a photograph of an object in its usage environment conveys more information than that of the object itself. If the objective is to show the location of a part of that object, then a line drawing in close proximity to or inset in the photograph is more useful than a photograph or illustration alone.

14.15.4 Guidelines

14.15.4.1 Visuals Should Reinforce the Message

Don't assume that the audience understands how a visual reinforces the argument (Figure 14.29). A clear and concise argument must still be made that helps shorten the process of comprehension and learning and causes the user to say, "Aha, that's how it works together!" Visuals should

- Clarify complex ideas
- Reinforce concepts
- Help the user understand relationships

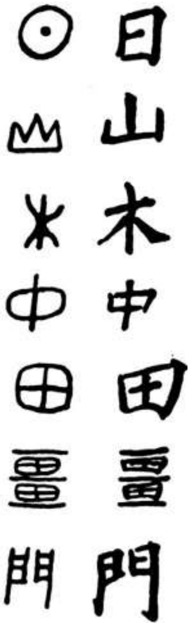

FIGURE 14.29 Thirty centuries of development separate the Chinese ancient characters on the left from the modern writing on the right. The meaning of the characters is (from top to bottom): sun, mountain, tree, middle, field, frontier, door.

14.15.4.2 Create a Consistent Visual Language

Create a consistent visual language that works within the entire communication system. Graphics attract attention. When the user sees a screen, the eye automatically jumps to a visual, regardless of the fact that it may interrupt reading. Graphics should conform to all elements on a page. Unharmonious graphics impede comprehension by increasing the effort needed to understand the relationship between the text and the visual.

14.15.4.3 Consider Both Function and Style

It is important to consider function versus decoration. Albeit wonderful to see an artistically illustrated tax form, is it appropriate to the content or image of both the message and organization it represents? The best graphic is appropriate to the context of the communication and reinforces and validates the message (Figure 14.30).

14.15.4.4 Focus on Quality versus Quantity

Graphics are only effective if they are carefully planned, executed, and used sparingly. A well-considered diagram with a concise caption is more effective than several poorly thought-out diagrams that require long explanations.

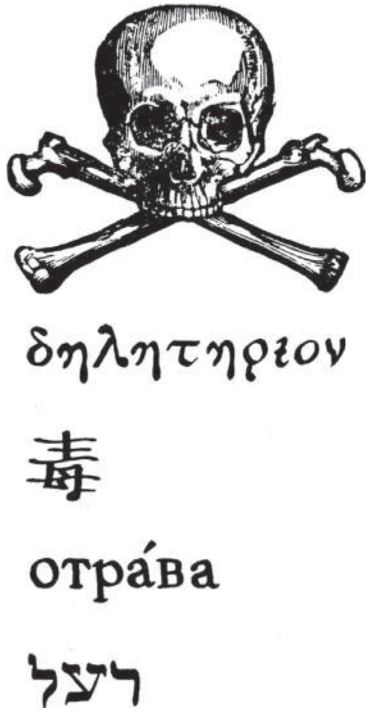

FIGURE 14.30 It is obvious which of the above examples communicates an important message most quickly. The goal for the designer is to communicate the message in the most direct way, so that the user can understand and make decisions based on that information. Obviously some situations are more critical than others, but it is no less important to begin design with consideration of the needs of users.

14.15.4.5 Work with a Professional

Many individuals within an organization can write an internal report but a writer or public relations firm is usually commissioned to find the most effective, relevant, and interesting way to communicate a public message such as presented in an annual report or company brochure. Similarly, a designer or visual communications firm should be retained to oversee the development of user interfaces, graphics, and other visual elements that impact the look and feel and ultimately the overall success of a program.

14.15.4.6 Build a Library to Create Visual Consistency, Organizational Identity, and a Streamlined Process

Because graphics require a professional, they can be very time consuming and expensive to create. Once a visual language and style are established, start building a graphics library. If concepts are repeatedly illustrated, streamline the development process by collecting the supporting illustrations and making them available for reuse. An organizational style can be created for these visual explanations. Through repetition, users can learn to associate a style and method of explanation with an organization, which aids in understanding and reinforces product brand and identity.

14.15.4.7 Reinforce Shared Meaning (Common Visual Language)

A serious issue to consider when creating graphics, particularly conceptual diagrams, is shared meaning, whether it be across an organization or the globe. Individuals can interpret the same diagram in a variety of ways based on backgrounds and experiences.

Truly effective graphics require extra time and effort, but the payoff is tremendous. Graphics are invaluable tools for promoting additional learning and action because they reinforce the message, increase information retention, and shorten comprehension time.

14.16 COLOR

Though color should be considered a reinforcing, or redundant, visual cue, it is by far the most strongly emotional element in visual communication. Color evokes immediate and forceful responses, both emotional and informational. Because color is a shared human experience, it is symbolic. And like fashion, the perception of color changes over time. In all communication, color can be used to trigger certain reactions or define a style. For example, in Western business culture, dark colors such as navy are generally considered conservative, while paler colors such as pink are regarded as feminine. In other cultures, these color choices have an entirely different meaning.

The appropriate use of color can make it easier for users to absorb large amounts of information and differentiate information types and hierarchies. Research on the effects of color in advertising show that ads using one spot of color are noticed 200% more often than black-and-white ads, while full-color ads produce a 500% increase in interest. Color is often used to

- Show qualitative differences
- Act as a guide through information
- Attract attention/highlight key data
- Indicate quantitative changes
- Depict physical objects accurately

All in all, color is an immensely powerful tool. Like the tools of typography and page design, it can easily be misused. Research shows that while one color, well used, can increase communication effectiveness, speed, accuracy, and retention, multiple colors when poorly used actually decrease effectiveness. Because it is readily available, it is very tempting to apply color in superficial ways. For color to be effective, it should be used as an integral part of the design program, to reinforce meaning and not simply as decoration. The choice of color—while ultimately based on individual choice—should follow and reinforce content as well as function.

14.16.1 Basic Principles of Color

14.16.1.1 Additive Primaries

The entire spectrum of light is made up of red, green, and blue light, each representing a third of the spectrum. These three colors are known as "additive primaries," and all colors are made up of varying amounts of them. When all three are combined, they produce white light.

14.16.1.2 Subtractive Primaries

If you add and subtract the three primaries, cyan, yellow, and magenta are produced. These are called "subtractive primaries."

Green + Blue – Red = Cyan
Red + Blue – Green = Magenta
Red + Green – Blue = Yellow

Color on a computer display is created by using different combinations of red, green, and blue light. In print, colors are created with pigments rather than light. All pigments are made up of varying amounts of the subtractive primaries. The three attributes of color are

1. ***Hue***—the actual color
2. ***Saturation***—the intensity of the color
3. ***Value***—includes lightness and brightness

"Lightness" refers to how light or dark a color appears. "Brightness" is often used interchangeably with lightness; however, lightness depends on the color of the object itself, and brightness depends on the amount of light illuminating the object.

14.16.2 How to Use Color

14.16.2.1 Less Is More . . . Useful and Understandable

Just as you can overload a page or screen with too many typefaces, you can have too many colors. Given the unpredictability of color displays, users, and viewing situations, the choice can get very complicated. Color is often best used to highlight key information. As a general rule, use no more than three colors for primary information. An example is the use of black, red, and gray—black and red for contrasting information, gray for secondary. When thinking about color online, one must remember that each display will output color in a different way. Add to that the lighting situation and a variety of users. All these factors affect color choice.

14.16.2.2 Create a Color Logic; Use Color Coding

Use a color scheme that reinforces the hierarchy of information. Don't miscue the audience by using different colors for the same elements. Whenever possible, try to use colors that work with the project identity or established visual language. Create a color code that is easily understood by the user and reinforces the information.

14.16.2.3 Create a Palette of Compatible Colors

Harmonious color is created by using a monochromatic color scheme or by using differing intensities of the same hue. However, make them different enough to be easily recognized and simple enough to be easily reproduced, no matter what medium you are using.

14.16.2.4 Use Complementary Colors with Extreme Caution

These are colors that lie opposite each other on the color wheel. Let one dominate and use the other for accents. Never place them next to each other because the edges where they meet will vibrate. Though this was the goal of pop art in the 1960s, it makes pages impossible to read. One must check each particular display, as the calibration of monitors can unexpectedly cause this to happen.

14.16.2.5 Decisions Regarding Color in Typography Are Critical

Colored type appears smaller to the human eye than the same type in black. This is important to consider when designing user interfaces. One must also consider the "smear" effect on typography in displays, based on the color chosen and interaction with colors around it. Additionally, quality and calibration of displays impact characteristics of color online.

14.16.2.6 Consider the Viewing Medium

The same color looks different when viewed on different viewing media such as a computer display, an LCD projector, color laser printer versus dot-matrix output, glossy versus dull paper.

14.16.2.7 Context Is Everything

Though printed color is very familiar and more controllable, projected color is inconsistent and varies depending on such things as lighting, size of the color area, size and quantity of colored elements, lighting, and output device. One must check all output/viewing possibilities to insure that a color is readable as well as legible, and not depend on cross-media specification for insuring consistency. What might look good on a laptop may not be readable when projected in a room for hundreds of people to view, and may look completely different when printed in a corporate brochure. The amount of color will affect how it is viewed as well as the best background choice. A blue headline is very readable on a white background, but if that background becomes a color, then readability can be reduced dramatically, depending on how it gets presented on each particular display.

14.16.2.8 Contrast Is Critical When Making Color Choices

Contrast is the range of tones between the darkest and the lightest elements, whether one is considering black and white or color. The desired contrast between what is being "read" (this includes graphics, photographs, etc.) must be clearly and easily differentiated from the background it is presented against. If there is not enough contrast (of color, size, resolution, etc.), it will be difficult or impossible to read. This is particularly a problem with online displays, as the designer has no control of quality of the output display.

14.16.2.9 Quantity Affects Perception

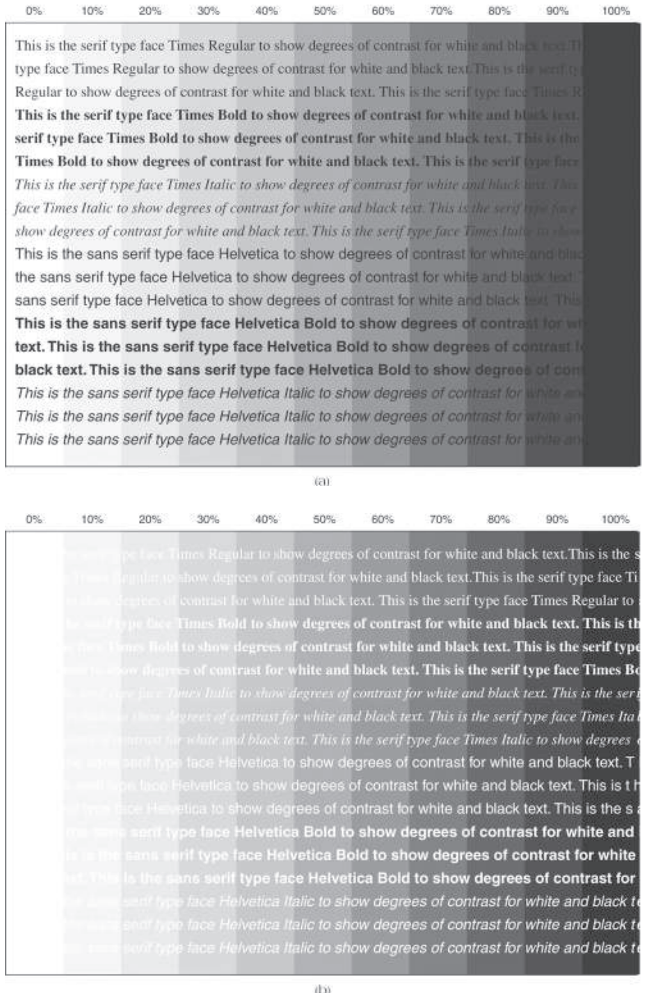
A small amount of color will be perceived differently than the same color used in a large quantity. In the smaller area, the color will appear darker; in the larger area, the color will appear lighter and brighter.

14.16.2.10 Use Color as a Redundant Cue When Possible

At least 9% of the population, mostly male, is color-deficient to some degree, so it is generally not a good idea to call out warning points only through color. With a combination of color and a different typeface, and so on, you won't leave anyone in the dark.

14.16.2.11 We Live in a Global World, So When in Rome . . .

Remember that different colors have different connotations within various cultures, religions, professions, and so on. For example, in the United States on February 14, red means love, but in Korea, red means death, and in China, red is used in weddings and symbolizes good luck and fortune. In many other countries, red means revolution. To a competitor, red means first place, and to an accountant, red means a negative balance. To a motorist, red means stop, and in emergencies, a red cross means medical help (Figure 14.31).



(a)

(b)

FIGURE 14.31 Trying Examples in Your Context. Since color is not available in this particular edition, try your own experiment. Take a look at this illustration, and recreate a paragraph of text, with the background graded from 100% to 0%, choosing one color for the background. Then set lines of type in a variety of typefaces and sizes, to see where it becomes legible or totally impossible to read. The important thing to remember is to test out whatever choices you make within the particular context and parameters, including viewing/projecting devices. Such things as lighting, projection distance, and users' physiological constraints can make all the difference as to whether something can be read or not.

14.17 CREATING A SYSTEM: GRAPHIC STANDARDS

With the explosion of new publishing media in a global marketplace, the need for guidelines for developing and producing consistent, quality communication has taken on a new urgency. New technologies make it easy to generate images, offering a wealth of options for experienced and inexperienced publishers alike. The danger lies in creating visual chaos, with every element demanding attention beyond the point of sensory overload. With new tools, chaos can happen faster, at a lower cost, and with greater distribution. A graphic standards manual prevents this confusion.

A *graphic standards manual* is the physical manifestation of an identity system. The design historian and educator Meggs (1998) writes in *A History of Graphic Design* that identity systems arose in the 1950s with the rise of multinational corporations that began to recognize the value and power found in presenting a cohesive visual image globally. A quality-control agent, a standards manual allows an organization to document guidelines and provide tools for organizing and structuring communications and reinforcing brand identity to diverse internal and external audiences. It explains the methodology behind the design, specifies written and visual language, production materials, and methods, and gives examples of how to and not to use the identity system so that standards can be implemented by different people, in different places, at different times. A standards manual supports expansion by explaining how to maintain a consistent brand and organizational look and feel as new products, features, and technology are introduced.

A graphic standards system provides

- Built-in quality: The system ensures that the correct organization/product image is communicated to all audiences. Standards promote consistency in handling information across product lines, divisions, projects, and so on.
- Control over resources: A system provides dramatic managerial control over resources that use time, money, and materials. Well-developed standards build in flexibility. New communications are

easily developed without the original designer and in many instances are developed within the organization itself.

- Streamlined development process: A graphic standards system helps structure thinking for content, design, and production by providing a guideline of predetermined solutions for communication problems. Typical problems are solved in advance or the first time they occur. Most importantly, a graphics standards system encourages the organization as a whole to progress to higher-level issues of communication effectiveness.

14.17.1 What Does a System Cover?

Graphic standards historically have been applied to an organization's logo, stationery, business cards, and other printed materials. As the online portion of an organization's identity dominates, providing for cross-media guidelines is even more critical. Graphic standards are generally communicated to the organization in print and electronic form. Documentation often includes

- Corporate identity manuals: Style guides available in print and online illustrate the application of the standards across the company's publications and provide specifications for production and expansion.
- Templates and guidelines: Templates and guidelines are available in paper and electronic form and are used to develop pages for both environments.
- Editorial style guides: Editorial guides determine the use of product/service names, punctuation, spelling, and writing styles.

14.17.2 Developing the System

When developing a corporate graphics standards system, consider the global publishing needs of the company, the resources available for producing documents, and the skill level of those in charge of production. To responsibly determine overall needs, a team effort is required. Personnel from areas such as information systems, graphic design, usability, and marketing along with engineers, writers, and users should be involved in the process. This team approach helps build support for, and commitment to, the corporate standards. The development of a comprehensive system follows the information design process of audit, development, and implementation.

14.17.3 Audit

The audit is a critical step in determining the scope and parameters of an organization's corporate graphic standards. Specific questions for the audit phase include

- What is the purpose?
- Who are the audiences?
- What are the differences and similarities between audiences?
- Who will do the work?
- How long will it take?
- What tools will be used?
- What is the desired company or product image?

14.17.4 Development

Goals for the development phase include: (1) the design of standards that are easy to read, use, and project a consistent corporate image; and (2) design of products that fit within the production parameters of the company.

14.17.5 Implementation

The implementation phase must ensure that the system is accepted and used properly. This requires training and support, easy procedures for distributing and updating materials, and a manual explaining how to use the system. The development of standards is in itself an educational process. It requires all participants to be aware of communication objectives and what is needed to meet them. As alternatives are developed and tested, management has the opportunity to evaluate its company's purpose, nature, and direction as well as its working methods and communication procedures. The process requires commitment and involvement across many departments and levels. The result is an empowering of the organization—planting the seeds for growth and increased effectiveness.

14.18 DESIGNING THE EXPERIENCE

The heart of interface design is to define and create the user's experience; what it is really like for people facing the monitor, using a cell phone, or an ATM. Though presentation possibilities are expanding day by day, our capacity to understand, use, and integrate new information and technology has not grown at the same rate. Making the most appropriate media choices, whether image, animation, or sound, to explain complex ideas to widely varied audiences is no easy task. The most important guideline is to understand that there are no rules, only guidelines. It is a generalization to say that a visual principle works a certain way because any change in context changes the application of the principle. For example, in the early days of the software industry, research showed that a specific blue worked well as a background color. Now, however, depending on monitor calibration, as well as environmental lighting, that blue could be a disaster. In fact, that blue can often vibrate if type in particular colors is placed on it. Of course, it depends on the type quantity, size, weight, viewing situation, and so on. Sound complex? For this reason, it's important to understand the principles, test the ideas, and then test results on every output device that will be used. Putting known guidelines together with experience continually gathered from the field allows the designer to develop a clear understanding of what works well in a well-defined environment and user situation. The next key guideline is to keep it simple. Although many tools are available, there is only one goal: to clearly communicate ideas. The designer must always ask, "What is the most efficient and effective way to communicate this idea?" A good illustration might work better (and take less bandwidth) than an animated sequence. Text set in a simple bold headline might allow the user to read the page more efficiently than text placed in a banner moving across the top of a page that constantly draws the eye upward. Animated icons are entertaining, but are they appropriate or necessary for serious financial information? It's tempting to use new tools. The best tip is to use a tool only if it can explain an idea better than any other tool, enhance an explanation, or illustrate a point that otherwise could not be made as effectively or efficiently. The best design is not noticed; it just works. Products are used to accomplish tasks, *not to draw attention to the design*. The best test of product success is the ease with which a user can understand and complete a task and move on to the next task. Real estate and online real estate are alike in that they both stress location, location, location! With such a premium on space, and so much to accomplish in so little time, be considerate and efficient with online real estate.

Use the elements found in a product's graphic standards appropriately. Constantly consider choices and context and review design principles. The following are issues and considerations to continually evaluate when presenting interactive information.

14.18.1 Effective and Appropriate Use of the Medium

Transitioning a print document to an online environment requires rethinking how the document is presented. Viewing and navigating through online information requires radically different design considerations and methods. Users do not necessarily view the information in a linear way, in a specific order, or timeframe. Interactive media viewed on computer screens have quite different characteristics and potential, particularly as information crosses platforms, resolutions, and environments. The rich medium of print allows a book—a product—to be held, viewed, and read in a sequence determined by the user. The physicality of a book provides sensory cues that are not present on a two-dimensional monitor. Interface designers must find ways to provide equivalent cues that encourage people to handle products comfortably and with confidence.

14.18.2 Element of Time

The element of time is the critical difference between static and interactive media. The sense of interaction with a product impacts the user's perception of usefulness and quality. Animated cues such as blinking cursors and other implied structural elements like handles around selected areas become powerful navigational tools if intuitively understood and predictably applied. Consider how the product will be used. Will the user sit down and calmly use the product or will he or she panic and fumble with a keypad? Will the task be completed at one time or at intervals over hours, days, months, and years? The element of time contributes to the design criteria and choices.

14.19 CONSISTENT AND APPROPRIATE VISUAL LANGUAGE

A major issue is the unpredictability and vastness of products. Providing way-finding devices that are easy to recognize, understand, and remember, include

- Clear and obvious metaphors
- Interface elements consistent with the visual style of other program parts, including consistent style for illustrations, icons, graphic elements, and dingbats
- Guidelines for navigational aids such as color, typography, and page/screen structure that are consistent with other parts of product support

14.19.1 Navigational Aids

Progress through a book is seen and marked in many ways. Bookmarks and turned corners serve as placeholders. Pens act as mnemonic devices highlighting or underlining text. Table of contents and indexes reveal content location. A finger marks a passage to be shared with a colleague as a book is cradled.

Unlike a book, a digital document or program cannot be seen or touched in its entirety. If a document cannot be held, how is specific location known in relation to overall location? How do users return to or move forward through content? How do users travel through unfamiliar space?

Navigational aids provide users with highways, maps, road signs, and landmarks as they move through the online landscape. They enhance discovering and communicate the underlying structure; thereby providing a sense of place so that users know where they are, where they have been, and how to move elsewhere or return to the beginning. Using or building on already familiar visual elements, such as those found in other products and earlier releases, leverages existing knowledge. Graphic standards support this as well. Consistent use of page layout and grid structure makes it easier to remember how information is organized and where it is placed or zoned. This ensures that whatever visual cues are applied can take advantage of the user's experience, ultimately saving time for both the designer and user.

14.19.2 Graphics/Icons

Visual representations such as site maps, graphics, and icons are effective devices for orienting users within a program. A site map offers an overall product view and shows sections or units of information and how these units are related. In the digital environment, graphics and icons assume the role of contents, indexes, and page numbers and can be more effective guides through and around a program than their counterparts in print, because tools such as roll-overs highlight functionality. Creating effective graphics and icons requires that intent and action are defined and designed.

14.19.3 Metaphor

Prior knowledge makes it easier to learn because it provides a conceptual framework on which information can be associated and expanded. When it was first introduced, the metaphor of a desktop with a filing system for a software interface that organized data in a program was easy to grasp because it built on a known experience. Using familiar visual analogies helps users easily understand and organize new information.

14.19.4 Color

Color is a free and very seductive design tool once a monitor is purchased. Use it intelligently. A monitor offers limited workspace. Color can replace or reinforce written explanations when meaning is assigned to it and it is applied methodically. A blue background is always utilized in a testing section and a yellow background in a section overview.

14.19.5 Legibility

Legibility is the ability to read information on the page. The page can be a screen, and as such, has special considerations. Color, size, background, movement, viewing environment, lighting, and resolution play a critical part in legibility.

14.19.6 Readability

Readable screens demand intelligent visual representations and concise, unambiguous text. Meaning can be implied or inferred by the placement of elements in designated areas or zones reserved for distinct information. This makes optimal use of a limited space and increases comprehension and accessibility.

14.19.7 Guidelines

14.19.7.1 Use the Analogy of a Poster as a Guide to Design

A home page is the equivalent of an attention-grabbing poster unpredictably placed in uncontrollable locations. Unlike a home page were a mouse-click on a speaker's name can give biographical information and a click on location can find directions, a poster's static format restricts the amount and depth of information that it can offer.

In print, information is presented in a fixed order. On the web, information is organized hierarchically in a manner that is radically different. Individual users can access the information offered on a website in a sequence that suits their intents and purposes. Online environments offer little regulation over how and in what order the product is accessed. While designers can make suggestions and guesses, this lack of control requires fundamental differences in information presentation. A well-designed home page, like a well-designed poster, should hint at all topics contained in the site, provide high-level information about these topics, and suggest easy paths to access this information. If information goes beyond a single screen, its design must visually communicate location through strong visual hints, so that the user investigates beyond what is immediately visible. Imagine the design considerations required for smaller, handheld, voice-activated devices.

14.19.7.2 Design for the Most Difficult Common Denominator

Design the interface in anticipation of a worst-case scenario. If a manager will use a product in a quiet office with a fast connection, perfect lighting, and a large monitor, then the problem is different from that of a contractor accessing critical information on a laptop in the field. User profile is often unknown because *new technologies define new categories as new opportunities are recognized*. Consider the breadth of possibilities. Design from the user's perspective. Testing, viewing, and questioning can make the difference of product acceptance or not.

14.19.7.3 Avoid Overuse of Saturated Colors

Saturated colors such as red tend to jump out at the viewer and can be distracting and irritating. Red is usually not a good choice for large areas of on-screen color. High impact is dependent on the contrast between background and foreground colors. On a black background, both yellow and white have a higher impact than red. Consider variations in every viewing situation including how these variations affect contrast among page elements and overall legibility and readability.

14.19.7.4 Consider Different Users' Levels of Skill

Navigational tools should be simple enough for a novice to use, but should not impede an expert. Detailed visual maps and other graphics should be available for those who need them, without hindering an experienced user who wants to bypass an explanation.

14.19.7.5 Be Aware of the Fatigue Factor

Although there is no definitive answer on fatigue caused by looking at a computer screen for long periods of time, it is a central factor to consider. According to *Color and the Computer*, by H. John Durrett, looking at a well-designed computer screen should not cause any more fatigue than reading a book or writing a report. Though some would disagree with this statement, many people spend more time with their computer than a book and no doubt could offer additional opinions on this subject. As interactive media becomes a commodity, the focus will not be on what a program does, but on how it does it. This will make the difference between product acceptance and product failure. Success or failure will be judged by the ease with which a product is used and how easily users perceive its interface.

14.19.7.6 Other Differences to Consider

There are many differences that impact how and why interfaces are designed, and many of these differences are discussed in more detail in other chapters. A designer should never forget that physical and mental impairments impact an ability to read, comprehend, and use interfaces.

14.19.7.7 Use the "Squint Test" to Check the Design

The squint test is a very simple self-test that checks visual hierarchy. Simply squint at the page so that details are out of focus. What is the first, most dominant element on the page? Is this what should be seen first? What has secondary importance? Cognitive psychology calls this "visual queuing." Successful interaction design creates a visual order that the user can easily follow.

14.20 CHALLENGES AND OPPORTUNITIES

14.20.1 Creating Your Own Guidelines

Interactive communication designers face great challenges. How can products that are seen, read, understood, and acted upon be created? Given increasing variety and complexity, how can the power of new technologies be harnessed? How can informed visual choices be made? **WARNING**: No book, seminar, or technology will turn someone into a professional designer! Design is not a craft dependent upon aesthetic ability. Design requires education, training, and experience in a variety of related disciplines equivalent to that of an architect, engineer, surgeon, or cabinetmaker. The following guidelines are offered as starting points, first steps in understanding how to make informed design decisions—design that provides the best, most thoughtful, and appropriate integration of both form and function.

- There are no universal rules, only guidelines. If there were rules, everything would look the same and work perfectly according to these rules. Each situation is different with its own context and parameters.
- Remember the audience: be a user advocate. Think about audience needs first throughout the development process. Who is in the audience? What are their requirements? How and where will the audience use the product? The evaluation criteria used in the design-development process springs from the answers to these and other questions. Designers must understand and advocate for the user.
- Structure the messages. Analyze content to create a clear visual hierarchy of major and minor elements that reflects the information hierarchy. This visual layering of information helps the user focus on context and priorities.
- Test the reading sequence. Apply the squint test. How does the eye travel across the page, screen, or publishing medium? What is seen first, second, and third? Does this sequence support the objectives and priorities as defined in the audit?
- Form follows function. Be clear about the user and use environment first. An effective interface design represents and reinforces these goals.
- Keep things simple. Remember the objective is to communicate a message efficiently and effectively, so that users can perform a task. Fewer words, type styles, and graphic elements mean less visual noise and greater comprehension. An obvious metaphor enhances intuitive understanding and use. The goal is to transfer information, not show off features or graphics.
- People don't have time to read. Write clearly and concisely. Design information in an economical, accessible, intuitive format that is enhanced by a combination of graphics and typography. Graphics, if well thought out and designed as an integral part of the page, are very powerful and can efficiently and effectively provide explanations while saving space on a page.
- Be consistent. Consistent use of type, page structure, and graphic and navigational elements creates a visual language that decreases the amount of effort it takes to read and understand a communication piece. The goal is to create a user experience that seems effortless and enjoyable throughout.
- Start the design process early. Don't wait. Assemble the development team of designers, usability professionals, engineers, researchers, writers, and user advocates at the beginning of the process. With interactive media, the traditional review and production process will change. The process is less of a handoff and more of a team effort; it's more like making a film than writing a book. Successfully applying the principles of good design enables an organization to communicate more effectively with its audiences and customers, improving the worth of its products and services and adding value to its brand and identity.
- Good design is not about good luck. Good design for usable interfaces appropriately applies the fundamentals of visual design to interactive products. Creating the most useful, successful design for an interactive product is difficult. The design process is iterative and experiential. There are usually several possible ways to solve a problem, and the final design decision is dictated by the best choices that work within the parameters at any particular time. Advocate on behalf of the user. Users are why designers are here and have this work to do. Users are everywhere, often in places not yet imagined. As the world grows smaller and becomes even more connected, the opportunity lies in where and what has not been discovered.

15 Globalization, Localization, and Cross-Cultural User-Interface Design

Aaron Marcus and Emilie W. Gould

CONTENTS

15.1 OVERVIEW

User-interface (UI) design enables people around the world to access data and functions. Issues of effective communication for diverse sets of users can take various forms: internationalization of inputs and outputs, translation of text and messages, revision of graphics and text to localize the product/service, and implementation of new communication approaches, including cognitive and rhetorical techniques. Often, appropriate localization of the UIs of products/services combines a mixture of partially universal and partially local solutions, depending on a needs analysis of the users and a business justification for globalization.

As in all good design, global UIs require attention to the product/service UIs essential metaphors, mental models, navigation, interaction, and appearance. In addition, the UI development process must also pay special attention to the user group and its culture. Cultural dimensions, that is, those patterns of behavior and thinking proposed by anthropologists and other analysts of culture, can provide insight and help designers adjust UIs to better serve users. By recognizing similarities/differences and managing users' experiences of familiar structures and processes, the UI designer can achieve more compelling and successful solutions. Facilitating users' engagement with products and services to enhance their productivity and enjoyment should be the primary design objective. Paying attention to culture can assist.

Culture should be considered from the start of the design process. If the functions and data are likely to be of value to target populations outside of the original market, it is usually worthwhile to plan for international and intercultural factors during initial development, so that the product/service can later be efficiently customized (e.g., placing text in separate files for easy translation). Rarely can a product achieve worldwide acceptance with a "one-size-fits-all" solution. Making products ready for global use generally increases international sales. However, in some countries, monolithic domestic markets inhibit awareness of, and incentives for, globalization. For example, because the United States has been such a large producer and consumer of software in the past, it is not surprising that some U.S. manufacturers still focus only on domestic users. However, as U.S. industries like moviemaking and games development have discovered, non-U.S. sales can be a significant portion of total sales or may be even larger than domestic sales. In addition, middle-class consumer markets have arisen in China and India that are larger than the entire populations of the United States or European Union. Consequently, more and more software developers of products/services are considering international and domestic markets as part of the initial design. This change of attitude leads to greater interest in and involvement with cross-cultural communication issues.

Of course, globalization tends to increase initial development costs. Consequently, some software products are initiated with international versions (e.g., typically 5 to 7 languages for global products originating in the United States, or 10 to 15 languages for European Union websites) that are released in sequence because of limited development resources. As needs or opportunities arise, other products are "retrofitted" to suit the needs of a particular country, language, or culture. However, ad hoc solutions often fail because of the lack of original planning for globalization. Good planning minimizes globalization costs by building in the infrastructure for internationalization, translation, and localization.

At first, global enterprises distributed computer-based products and services with minimal changes to their most important international markets to achieve cost-efficient production, maintenance, distribution, and user support. However, the concept of modifying software and hardware to accommodate national conventions for input and output has been considered since at least the early 1980s when such companies as IBM (at its IBM Toronto lab) began identifying software requirements for internationalization. In the early 1990s, a number of software-related working groups focused on overcoming the obstacles to a multilingual World Wide Web (Nicol 1994). A few years later, the growing disparity in access to computers (and the Internet) between people in developed and developing countries sparked discussion of a "digital divide." Stephanidis, among others, promoted the availability of appropriate UIs for all peoples in all countries worldwide regardless of ability, disability, or culture and produced significant compilation documents advocating a "universal access" or "user interfaces for all" approach (2000, 2009). By the beginning of the twenty-first century, Warschauer (2003) noted that the digital divide was no longer just about access to technology; rather, technology must be successfully integrated into the lives of people from developing countries and allow them to engage in socially meaningful practices. It has become increasingly important, technically viable, and economically necessary to produce localized versions of programs, web pages, and applications for specific global markets. Consequently we are now at a point when UIs should be designed for specific user groups, not merely translated and given a superficial "local" appearance for quick export to different countries.

Insufficient attention to global UI design can lead to undesired, sometimes embarrassing, and sometimes critically misunderstood communication. Inexpert internationalization of data fields makes it difficult or impossible for international customers to enter shipping addresses. Anecdotes of poor translation abound in books about international marketing. For example, it has been claimed (though not fully proven) that Pepsi's slogan "Come alive with Pepsi" was interpreted in China as, "Pepsi brings your ancestors back from the grave" (Hendrix 2001; Snopes.com 2007). However, there are several well-documented situations where differences of culture have had significant business implications. In 2001, Saudi Arabia's Higher Committee for Scientific Research and Islamic Law banned Pokémon video games because they felt the cards "possessed the minds" of Saudi children, included Christian and Zionist symbols, and "resembled a game of gambling," thus closing off one of the Middle East's largest markets to Japanese Nintendo's multibillion dollar enterprise (Associated Press 2001; BBC, 2001). More recently, a Saudi court convicted a Lebanese man of sorcery for telling horoscopes (Death Penalty News 2010), which prompted one software company to remove an icon representing a "magic wand" for fear of offense.

By contrast, effective internationalization of input and output data fields facilitates international sales. Appropriate language translation leads to greater comprehension, and customer service costs drop when instructions are displayed in users' native languages. Moreover, allowing users/customers to pick their language leads to greater attention and retention. This implication is especially significant for web-based communication and commerce, where Forrester Research (1998) first reported that visitors remain twice as long reviewing local-language sites as they do English-only sites, and business users are three times more likely to buy when communication is in their own language. Forrester Research Inc. (2009) continues to make the case that internationalization, translation, and localization are necessary for online retailers to sell internationally.

This chapter discusses the development of global UIs intended for users in many different countries with different languages and cultures. The text presents a survey of important issues, as well as recommended steps in the development of UIs for various platforms (desktop, web, mobile devices, and vehicles), for international and/or multicultural user populations. With the rise of the Internet and application-oriented websites and mobile devices, the challenge of designing good UIs has become an immediate, practical matter, rather than a theoretical issue.

In this chapter, the topic is discussed from a user perspective, rather than a technology or code perspective. The chapter will accomplish the following:

- Introduce fundamental definitions of UI design and globalization processes for design.
- Demonstrate why globalization is vital to the success of computer-based communication products/services.
- Outline critical areas for globalization with specific guidelines.
- Introduce various concepts of culture, particularly cultural dimensions.
- Recommend other issues that relate to culture and design.

15.2 USER-INTERFACE DESIGN AND GLOBALIZATION PROCESSES

15.2.1 Definitions

By managing the user's experience with familiar structures and processes, preferences, expectations, and enjoyment of novel approaches, the UI designer can achieve compelling forms that enable the UI to be more usable, useful, and appealing. The International Organization for Standardization (ISO) in Switzerland defines *usable* interfaces as effective, efficient, and satisfying (ISO 1998). Further effort to globalize UI design, whose content and form are so dependent upon effective input/output, languages, and effective communication, improves the likelihood that computer-based products and services on all platforms (e.g., desktop, mobile, home appliances, and vehicles) will be successful in many different locations globally. Global product distribution requires a strategy and tactics for the design process that infuse international and cultural requirements into product development, marketing, distribution, and maintenance.

From the designer's perspective on a corporate team, the two primary objectives are as follows:

- Provide a consistent UI and, more generally, design a satisfying user experience that extends across all appropriate products and services.
- Design products and services with their necessary support systems that can be appropriately localized, translated, and designed for specific markets.

As in all usability-oriented development, the first objective requires attention to the context, objectives, and goals of the users and to the five essential components of UI designs as defined below. All design efforts must begin with a profound understanding of intended users, who are generally characterized on the basis of their demographics, experience, education, and organizational or leisure roles. Their individual needs and wants, as well as their group roles, define their tasks. User-centered, objective-, and task-oriented design methods facilitate effective UI designs that acknowledge and respect users' goals.

UIs conceptually consist of five components: (1) metaphors, (2) mental models, (3) navigation, (4) interaction, and (5) appearance (Marcus 1995, 1998, 2006).

- *Metaphors*: Essential concepts conveyed through words and images, or through acoustic or tactile (haptic) means. Metaphors embrace both individual items as well as overarching concepts that characterize interaction, such as the specific "trash can" denoting "deletion" within the general "desktop" metaphor, or the "shopping cart" denoting selection of items intended for purchase within a "shopping" website.
- *Mental models*: Organization of data, functions, tasks, roles, and people in groups at work or play. The term is similar to, but distinct from the notion of cognitive models, task models, user models, and so on. A mental model is intended to convey the organization observed in the UI itself, which is presumably learned and understood by users and which reflects the content to be conveyed, as well as the user tasks.
- *Navigation*: Movement through mental models, afforded by windows, menus, dialogue areas, control panels, touch screens, and so on. The term implies dialogue and process, as opposed to structure; it focuses on potential sequences of actions to access dynamic content, not only static content.
- *Interaction*: The means by which users communicate input to the system and the feedback supplied by the system. The term implies all aspects of command-control devices (e.g., finger gestures, keyboards, mice, joysticks, microphones, etc.), as well as sensory feedback (e.g., changes of state of virtual graphical buttons, auditory displays, and tactile surfaces).
- *Appearance*: Verbal, visual, acoustic, and tactile perceptual characteristics of displays. The term implies all aspects of visible, acoustic, and haptic languages (e.g., typography or color; musical timbre, or cultural accent within a spoken language; and surface texture or resistance to force), as well as the level of abstraction or realism in graphic imagery.

Based on knowledge of the users, developing a UI suitable for global deployment may affect each of these components: from choices of metaphorical references to hierarchies in the mental model, from navigation complexity to decisions on appropriate input techniques, and from selection of character sets, graphics, colors, sounds/voice/music to the alternative use of vibration.
