- *IFIP Conferences.* A number of conferences and workshops (sponsored by IFIP Technical Committee (TC) 9) have focused on selected topics within PD—for example, Briefs, Ciborra, and Schneider (1983); Clement, Kolm, and Wagner (1994); Docherty et al. (1987); Gärtner and Wagner (1995); and van den Besselaar et al. (1991).**
- *Nordic Conferences on Human–Computer Interaction.* The Nordic Conferences on Human–Computer Interaction (NordiCHI) conference series meets on even-numbered years, with a strong emphasis on participatory work within a broader Scandinavian context (Nordichi 2006). Papers from 2002 and 2004 are available through the ACM Digital Library.
- Major papers, panels, and tutorials on PD have also appeared in the CHI, CSCW, ECSCW, and DIS conference series, beginning as early as 1988 (*Proceedings* available through the Association for Computing Machinery or through Springer for the ECSCW conference series), and in *Proceedings* of the Usability Professionals' Association†† conference series, of the INTERACT conference series, and of the Human Factors and Ergonomics Society conference series. Several papers at the Co-Designing 2000 Conference‡‡ addressed participatory themes (Scrivener, Ball, and Woodcock 2000).
- *Interaction Design and Children (IDC).* From this yearly conference's inception in 2002, researchers worldwide have published and presented papers where a surprising number discuss design methods that are inclusive of children in the development/research process (*Proceedings* are also available through the Association for Computing Machinery§§). With conference venues routinely in both Europe and the United States, a strong Scandinavian influence has been seen with the embracing of PD methods in this research area concerning children.

49.1.1.2 Books

In addition to the books cited above, major collections of papers and/or chapters related to PD appeared in Carroll's volume on scenarios in user interaction (1995; see also Carroll [2000]), Greenbaum's and Kyng's *Design at Work* (1991), and Wixon's and Ramey's collection of papers on field-oriented methods (1996). Individual books that have been influential in the field include Bødker's application of activity theory to issues of participation (1990), Ehn's account of work-oriented design (1988), Suchman's discussion of situated action (1987), and Beyer's and Holtzblatt's presentation of contextual inquiry and contextual design (1998; see also Chapter 43 in this book). A recent volume by Bødker, Kensing, and Simonsen (2004) may broaden the impact of PD among information technology departments.* Earlier influential works include a series of books on socio-technical theory and practice by Mumford (e.g., 1983; Mumford and Henshall 1979/1983), as well as Checkland's (1981) soft systems methodology. Noro and Imada (1991) developed a hybrid ergonomic approach, involving participation and quality programs, which has been influential around the Pacific Rim. For a historical PD bibliography, see the CPSR website.

49.1.1.3 Journals

Three journals have carried the greatest number of PD papers: Scandinavian Journal of Information Systems,† Computer Supported Cooperative Work: The Journal of Collaborative Computing,‡ and Human–Computer Interaction.§

49.1.1.4 Websites

CPSR maintains a set of PD resources at http://www.cpsr.org/issues/pd/.

The group of researchers working on DPD, or participation at a distance, has created a website that includes *Proceedings* from their 2006 and 2008 conference workshops, at http://extra.shu.ac.uk/paperchaste/dpd/index.html.

49.2 HYBRIDITY AND THIRD SPACE

This chapter is concerned with participatory methods that occur in the hybrid space between technology developers/researchers and end users. Why is this hybrid space important?

Bhabha (1994) made an influential argument that the border or boundary region between two domains—two spaces—is often a region of overlap or hybridity—that is, a "third space" that contains an unpredictable and changing combination of attributes of each of the two bordering spaces. His area of concern was colonization, in which some native people find themselves caught in between their own traditional culture and the newly imposed culture of the colonizers (see also Dingawaney and Maier [1994]; Karttunen [1994]). Their continual negotiation and creation of their identities, as efforts of survival, creates a new hybrid or third culture (Bhabha 1994; see also Lyotard [1984]) and even a third language (Anzaldúa 1999; Bachmann-Medick 1996). In such a hybrid space, enhanced knowledge exchange is possible, precisely because of those questions, challenges, reinterpretations, and renegotiations (Bachmann-Medick 1996). These dialogues across differences and—more importantly—*within differences* are stronger when engaged in by groups, emphasizing not only a shift from assumptions to reflections, but also from individuals to collectives (Carrillo 2000). Bhabha's conception has become highly influential. Bachmann-Medick (1996) applied the concepts to translation theory. Grenfell (1998) interpreted concepts of hybridity in a study of living-at-the-border in multicultural education settings. Evanoff (2000) surveyed a number of theoretical applications of hybridity, from evolutionary biology to constructivist perspectives in sociology to democratic responses to intercultural ethical disagreements. He explored formulations from multiple disciplines, involving "third culture" in intercultural ethics, "third perspective" involving "dynamic inbetweenness" in Asian-Western exchanges, and a psychological "third area" in the development of a "multicultural personality." A summary of the claims relating to third spaces (or hybridity) appears in Table 49.1.

TABLE 49.1
Summary of Claims Relating to Third Spaces

Overlap between two (or more) different regions or fields (inbetweenness)
Marginal to reference fields
Novel to reference fields
Not "owned" by any reference field
Partaking of selected attributes of reference fields
Potential site of conflicts between/among reference fields
Questioning and challenging of assumptions
Mutual learning
Synthesis of new ideas
Negotiation and (co)creation of…
Identities
Working language
Working assumptions and dynamics
Understandings
Relationships
Collective actions
Dialogues across and within differences (disciplines)
Polyvocality
What is considered to be data?
What are the rules of evidence?
How are conclusions drawn?
Reduced emphasis on authority – increased emphasis on interpretation
Reduced emphasis on individualism – increased emphasis on collectivism
Heterogeneity as the norm

* In addition, Pew and Mavor (2007) included participatory design among their proposed "new look" at large-systems development. However, the influence of this work has not yet been determined.

49.2.1 Hybridity and HCI

Within HCI, Suchman recently renewed her call for dialogue across boundaries between the partial perspectives of end users and developers (Suchman 2002; see also Badke-Schaub [2004]; Bødker and Buur [2002]; Fowles [2000]; Holmström [1995]; Kyng [1998]; Light and Luckin [2008]; Nygaard and Sørgaard [1987]). Suchman argued for boundary crossing and mutual learning between these different standpoints and appealed in part to recent developments in feminist epistemologies which argue that objectivity is the constructive outcome of an ongoing dialogue among multiple perspectives (e.g., Haraway 1991; Harding 1991; Hartsock 1983; see also Brereton [2009]). These concerns become more pressing when we consider the new obstacles encountered in DPD (Naghsh et al. 2008), especially when design work also spans the boundaries between the developed world and the developing world (e.g., Best et al. 2009; Bidwell and Hardy 2009; Bidwell et al. 2010). Titlestad, Staring, and Braa (2009) explained:

> “A key PD principle is to bridge and blur the user-designer distinction from both directions, through mutual learning processes .… Effective methods to achieve this usually rely on prototyping and intensive face-to-face iteration.… In the Global South, computerized information systems are still few and far between…a significant threshold hindering participation.…”

In partial agreement with Suchman, Warr (2006) argues that the solution is not to remove distance entirely, but rather to *preserve the situated nature of each participant’s own world* while creating a common space for mutual learning, creation, and problem solving.

The approach in this chapter begins with a similar recognition of diverse perspectives. However, unlike Suchman’s and Titlestad et al.’s emphasis on the boundary *between* these perspectives, this chapter is concerned with creating regions of overlap where the perspectives can come into mutual knowledge and, potentially, alliance—with the creation of the hybrid spaces in which objectivity can emerge through constructive discussion, dialogue, negotiation, and mutual learning. Similarly, this chapter pursues a different solution from the located accountability recommended by Suchman. Suchman sees each participant as located *within* a particular perspective and interest—for example, “Organizations comprise multiple constituencies each with their own professional identities and views of others” (see also the geographic limits discussed by Titlestad, Staring, and Braa [2009]). By contrast, the methods in this chapter enable the creation of new perspectives and new locations and acknowledge the possibility that each participant can make different choices at different moments about where to locate her or his perspective, standpoint, and thus accountability. In keeping with the origins of PD in class struggle (e.g., Ehn and Kyng 1987; see also Gregory [2003], for a review of “conflict-perspective” approaches), Suchman focuses on opposing interests that meet across a designated boundary. This chapter proposes to reach toward the next step—i.e., to pursue the polyvocal polity that one of us proposed (Muller 1997a) and the need identified by Bødker and Buur (2002; see also Buur and Bødker [2000]) to create a “meeting ground” for a “widen[ed]… circle of participants” that can “support the many voices being brought forth in order to create the new, and to find ways of supporting this multivoicedness.”

There have been many calls within HCI for mutual or reciprocal learning in hybrid spaces (e.g., Bødker et al. 1987, 1988; Druin 1999/2002; Druin et al. 2000; Ehn and Sjögren 1991; Floyd 1987; Kensing and Madsen 1991; Lanzara 1983; Mogensen and Trigg 1992; Muller 1997a; Muller, Wildman, and White 1994; Mumford 1983; Törpel and Poschen 2002; Tscheligi et al. 1995). Beeson and Miskelly (2000) appealed to the notion of hybridity (“heterotopia”) in describing workers who, like colonized peoples, deal “in a space which is not their own,” (p. 2) taking limited and opportunistic actions to preserve “plurality, dissent, and moral space” (p. 1). Maher, Simoff, and Gabriel (2000) described the creation of virtual design spaces for sharing diverse perspectives. Merkel et al. (2004) described a need for “a new set of skills and competencies that go beyond technical design skills … to create conditions that encourage a collaborative design process and active reflection … for working with groups … that push on the traditional boundaries between users and designers” (p. 7–8). Light and Luckin (2008) discussed hybrid methods of enfranchisement for people with diverse backgrounds. In an early formulation, Lanzara (1983) suggested that

> [A] large part of the design process, especially in large-scale projects and organizations involving several actors, is not dedicated to analytical work to achieve a solution but mostly to efforts at reconciling conflicting [conceptual] frames or at translating one frame into another. Much work of the designer is … concerned with … defining collectively what is the relevant problem, how to see it.

Tscheligi et al. (1995), in a panel on prototyping, considered that the “products” of prototyping include not only artifacts, but also understandings, communications, and relationships—a theme that was echoed in a more recent panel on modeling (Kaindl et al. 2001). Fanderclai (1995, 1996) captured a strong sense of possible new dynamics and new learnings in a hybrid online space. Finally, Thackara (2000) based part of his plenary address at CHI 2000 on the concept of the third space, providing a needed hybridity to HCI studies.

49.2.2 Participatory Design as the Third Space in HCI

In this chapter, we extend the HCI analyses surveyed in the preceding paragraphs and apply Bhabha’s perspective to the HCI problem of methods to bridge between two spaces—the world of technology developers/researchers and the world of the end users (see also Muller [1997a, b]). As noted by Suchman (2002), each world has its own knowledges and practices; each world has well-defined boundaries. Movement from one world to the other is known to be difficult (Dewulf and Van Meel 2003; Kensing and Blomberg 1998a; Kujala 2003; Luck 2003; Olsson

2004; Reymen, Whyte, and Dorst 2005; Yamauchi 2009). We can see this difficulty manifested in our elaborate methods for requirements analysis, design, and evaluation—and in the frequent failures to achieve products and services that meet users' needs and/or are successful in the marketplace.

Much of the traditional scientific practice in HCI has focused on instruments and interventions that can aid in transferring information between the users' world and the software world. Most of the traditional methods are relatively one directional—for example, we analyze the requirements *from* the users; we deliver a system *to* the users; we collect usability data *from* the users. Although there are many specific practices for performing these operations, relatively few of them involve two-way discussions, and fewer still afford opportunities for the software professionals to be surprised—that is, *to learn something that we didn't know we needed to know.*

The PD tradition has, from the outset, emphasized mutuality and reciprocity—often in a hybrid space that enabled new relationships and understandings. Bødker et al. (1988) made specific references to "the mutual validation of diverse perspectives" (see also Badke-Schaub [2004]; Béguin [2003]; Bødker and Buur [2002]; Fowles [2000]; Holmström [1995]; Kyng [1998]; Light and Luckin [2008]; Louridas [1999]; Reymen, Whyte, and Dorst [2005]; Suchman [2002]). Floyd (1987) analyzed software practices into two paradigms, which she termed product oriented (focused on the computer artifact as an end in itself) and process oriented (focused on the human work process, with the computer artifact as means to a human goal). In her advocacy of balancing these two paradigms, Floyd noted that the process-oriented paradigm required mutual learning among users and developers (see also Segall and Snelling [1996]). Most of the PD theories and practices require the combination of multiple perspectives—in part, because complex human problems require multiple disciplines (e.g., software expertise and work-domain expertise) for good solutions (e.g., Pew and Mavor 2007, 2000; Holmström 1995) and in part because the workplace democracy tradition reminds us that all of the interested parties (in the United States, we would say "stakeholders") should have a voice in constructing solutions (e.g., Ehn and Kyng 1987; Kyng 1998). In a related development, there are increasing calls for critical reflection in design, based on combining perspectives across disciplines, including the recent Aarhus Conference on Critical Computing.

Finally, the hybridity theme of novelty and creativity is echoed in participatory goals and practices. PD has often emphasized change—change in technology, change in working practices, and change in working relationships (Gregory 2003; Kensing and Blomberg 1998a). The earliest projects such as DEMOS, DUE, FLORENCE, and UTOPIA were concerned with anticipating and co-determining change that was mandated for various workplaces (Ehn and Sanberg 1979; Kyng and Mattiassen; Bjerknes and Bratteteig 1987; Bødker et al. 1987). Some of this early work took a critical stance with regard to managerial agendas; other projects specifically explored alternative designs (Bjerknes and Bratteteig 1987; Bødker et al. 1987; Ehn 1993), and more recent work (detailed below) is more directly concerned with *creating* new alternatives. This is very much the case in the extensive "codesign" work of researchers and children (Druin et al. 2009). Many of the participatory projects—and even the names of the methods—reflect an orientation toward the future—for example, future workshops (Jungk and Mullert 1987) "evoking the future" (Brandt and Grunnet 2000), "anticipating future behavior of office workers" (de Jong, Kouprie and De Bruyne 2009), "hands-on the future" (Ehn and Kyng 1991), "envisioning future practices" (Vaajakallio and Mattelmäki 2007), and "evaluation of future concepts" (Hultcrantz and Ibrahim 2002). Through careful control of design attributes such as clarity and ambiguity, formality and informality, and the judicious use of different disciplinary languages, PD practitioners create new hybrid spaces to encourage innovation and to support creativity.

49.2.3 Participatory Design Contains Its Own Third Space

The preceding argument—that PD serves as a kind of third space to HCI—might be interesting, but is hardly worth a chapter in a handbook. We now turn to the question of hybridity in methods within the field of PD itself. In their "tools for the toolbox" approach, Kensing and Munk-Madsen (1993) developed a taxonomy to analyze 30 participatory methods (see also Kensing, Simonsen, and Bødker [1996]; and, for independent convergences on the same attribute, see Gjersvik and Hepsø [1998]; Luck [2000]; Reid and Reed [2000]). The first dimension of their taxonomy contrasted *abstract* methods (suitable for a software professional's organization) with *concrete* methods (suitable for work with end users).* Muller, White, and Wildman (1993) and Muller, Hallewell Haslwanter, and Dayton (1997) elaborated on this taxonomic dimension by asking *whose work domain served as the basis for the method* (in the United States, we would call this a matter of "turf," as in "on whose turf did the work take place?"). At the *abstract* end of the continuum, the users have to enter the world of the technology developers/researchers in order to participate—for example, rapid prototyping (Grønbæk 1989) and quality improvement (Braa 1996). At the *concrete* end of the continuum, the technology developers/researchers have to enter the world of the users in order to participate—for example, ethnography (Blomberg et al. 1993; Crabtree 1998; Orr and Crowfoot 1992; Suchman and Trigg 1991; see also Chapter 45 in this book), ongoing tailoring during usage (Henderson and Kyng 1991; MacLean et al. 1990), and end-user "design" by purchasing software for small companies (Krabbel and Wetzel 1998; Robertson 1996, 1998). For the purposes of this chapter, we can now ask: What about the practices that did not occur at the *abstract* or *concrete* end points of the continuum? *What about the practices in between?* These practices turn out to occur in an uncertain, ambiguous, overlapping disciplinary domain that does not "belong" to either the technology

* Their second dimension was of less interest for the purposes of this chapter.

developer/researcher or the end users (i.e., these practices occur in neither the users' turf nor the software professionals' turf). The practices in between the extremes are hybrid practices, and constitute the third space of PD. As we explore hybrid methods that occur in this third space, we can look for HCI analogies of the attributes and advantages that are listed for third space studies in Table 49.1.

49.3 THIRD SPACE: NEGOTIATION, SHARED CONSTRUCTION, AND COLLECTIVE DISCOVERY IN PARTICIPATORY DESIGN AND HUMAN–COMPUTER INTERACTION

In the remaining sections of the chapter, we will describe a diversity of PD techniques, methods, and practices that provide hybrid experiences or that operate in intermediate, third spaces in HCI. Because our theme is hybridity, we have organized these descriptions in terms of strategies and moves that introduce novelty, ambiguity, and renewed awareness of possibilities, occurring at the margins of existing fields or disciplines (see Table 49.1). In several cases, a single report may fall into several categories. For example, Ehn and Sjögren (1991) conducted a workshop (see Section 49.4.2) in which a storytelling method (see Section 49.5.1) provided a space in which people negotiated the naming and defining of workplace activities (see 49.7.1). We hope that the strategies and moves of the PD practitioners and researchers will become clear, despite the multiple views onto individual reports.

49.4 SPACES AND PLACES

49.4.1 Sitings

One of the simplest parameters that can be manipulated to influence hybridity is the site of the work. At first, this appears to be a simple issue. As Robins (1999) says, "There are two approaches to participatory design: (1) Bring the designers to the workplace and (2) Bring the workers to the design room." This binary choice reflects the taxonomic distinctions that we reviewed above. However, even within the binary choice, the selection of the site can be important. Fowles (2000), in a discussion of participatory architectural practice, provides an insight that can apply as well for HCI: "If possible[,] design workshops should be located in the locality of the participating group and in the School of Architecture. Bringing the public into the School helps to de-mystify the profession, and taking students in the community furthers their understanding of the problem and its context" (p. 65). Pedersen and Buur (2000), in their work on industrial sites, agree (italics in the original):

> When collaborating with users *in our design environment* (e.g., a meeting space at the company), we can invite a number of users from different plants and learn from hearing them exchange work experiences.… Being in a foreign environment (and with other users), users will tend to take a more general view of things.
>
> When collaborating with users *in their work context*, users tend to feel more at ease as they are on their home ground—we are the visitors. Tools and environment are physically present and easy to refer to. This makes for a conversation grounded in concrete and specific work experiences.
>
> The idea was born to create a type of design event with activities in both environments and with two sets of resources to support design collaboration.

In a study of telephone operators' work conducted by one of us, we held our sessions at operator service offices and in research offices (Muller et al. 1995a). The work site meetings had the advantages of easy access to equipment on which we could demonstrate or experiment. During those meetings, there was a sense of being strongly tied to practice. The research site meetings were less tied to specific practices, and had a tendency to lead to more innovative ideas. Perhaps more subtly, the two different sites enfranchised different marginal participants. At the work site, it was easy to bring in additional work-domain experts (mostly trainers and procedures experts): They became adjunct members of the core analysis team for the duration of those meetings, *and* they became resources for the core team afterwards. At the research site, it was easy to bring in more technology experts, as well as the graduate students who later performed data analysis. The research site meetings became an occasion of enfranchisement, contribution, and early commitment for these additional actors. Both core and adjunct members from both sites became coauthors of our report (Muller et al. 1995a).

Brandt and Grunnet (2000) also considered site selection in their Smart Tool and Dynabook projects, which were concerned with working conditions in the office and in the home, respectively. In the Smart Tool case, they conducted dramatic scenarios in the project designers' environment. In the Dynabook case, they asked people at home to create and enact scenarios in their own living areas.

When University of Maryland researchers codesign with children, neither the school environment nor a traditional computer science lab is regularly used for ongoing PD projects that range from developing new digital libraries for children (Druin 2005) to creating new mobile storytelling devices (Fails, Druin, and Guha 2010). An after-school program that takes place twice a week during the school year and two weeks during the summer occurs in a lab that is specially carpeted for extensive use of the floor for designing. There are special windows that enable doors to be shut without concerns for safety or privacy. Although it is a lab that sits on a college campus, it is a third space where children and researchers can work together in a hybrid setting.

Brereton (2009; Segalowitz and Brereton 2009) takes an even stronger position, which combines traditional ethnography with action research. In her embedded research paradigm, the researcher lives as a member of the users' community for an extended period of time.

In addition, we note a related trend in community-based participatory research (CRPR), in which it is assumed that community members hold key knowledge and discernment about local needs, and that they can use this knowledge to help to solve both local and regional problems (Shallwani and Mohammed 2007). This approach has been used to frame technology and planning explorations for community needs (e.g., Corburn 2003; Shilton et al. (2008). Füller et al. (2006) used a variant of this idea which they called "community-based innovation" (CBI) to community sourcing of design ideas and design critiques from end users in an automotive design case.

Third space. In terms of hybridity, the selection of site can be a deliberate strategy to introduce new experiences and perspectives to one or more parties in the design process—a decentering move that can bring people into positions of ambiguity, renegotiation of assumptions, and increased exposure to heterogeneity. Returning to Bhabha's original argument, site selection initially appears to be a matter of *moving across the boundary* between different work cultures, rather than *living within the boundary*. However, the use of *common design practices across sites* makes those practices (and the membership of the design group) into a kind of movable third space. The practices and the group membership become stable features that persist across multiple sites. At the same time, the practices, and even the membership, grow and evolve with exposure to new sites and new understandings. In these ways, the practices become an evolutionary embodiment of the knowledge of the learning of the group (e.g., Floyd 1987; Muller 1997a).

Claimed benefits. What have practitioners gained through site selection, within this deliberately hybrid-oriented work area? Several themes emerge:

- *Improved learning and understanding.* Fowles (2000) described a move from a "symmetry of ignorance" toward a "symmetry of knowledge" as diverse parties educated one another through a "symmetry of learning"—and even a kind of "transformation" through exposure to new ideas (see also Carmien et al. [2003]). Brandt and Grunnet (2000), Pedersen and Buur (2000), Druin (2005), and Muller et al. (1995b) also claimed that the selection of site led to the strengthening of the voices that were comfortable at each site.
- *Greater ownership.* Petersen and Buur (2000) noted that their procedures strengthened user involvement in their project. Fowles (2000) and Muller (1995b; see also Muller, Wildman, and White [1994]) made specific reference to increases in commitment and ownership of the evolving knowledge and design of the group.

49.4.2 Workshops

Workshops may serve as another alternative to the two "standard" sites that most of us think about. In PD, workshops are usually held to help diverse parties ("interested parties" or "stakeholders") communicate and commit to shared goals, strategies, and outcomes (e.g., analyses, designs, and evaluations, as well as workplace-change objectives). Workshops are often held at sites that are in a sense neutral—they are not part of the software professionals' workplace and they are not part of the workers' workplace.

More importantly, workshops usually introduce novel procedures that are not part of conventional working practices. These novel procedures take people outside of their familiar knowledges and activities, and must be negotiated and collectively defined by the participants. Workshops are thus a kind of hybrid or third space, in which diverse parties communicate in a mutuality of unfamiliarity and must create shared knowledges and even the procedures for developing those shared knowledges.

The best-known workshop format in PD is the Future Workshop (e.g., Kensing and Madsen 1991; see also Bødker, Kensing, and Simonsen [2004]; McPhail et al. [1998]; Mørch, Engen, and Åsand [2004]), based on German civic planning (Jungk and Mullert 1987), a Future Workshop proceeds through three stages: (1) *Critiquing* the present; (2) *Envisioning* the future; and (3) *Implementing*—moving from the present to the future. These three activities involve participants in new perspectives on their work and help to develop new concepts and new initiatives.

A number of workshops have focused on simple materials and informal diagrams, rather than on formal notations. Bødker, Kensing, and Simonsen (2004) noted that, "The tools are simple diagrams or drawings with no special formalisms… because staff members participating in the workshops, as well as those to whom the results are later presented, typically have no experience with technical descriptions using [Information Technology]-originated formalisms" (p. 252).

Sanders (2000, 2006) described a family of "generative tools," activities that are selectively combined into strategic design workshops, under an overall conceptual "say-do-make" strategy that combines market research ("what people say"), ethnography ("what people do"), and PD ("what people make"). Activities include the construction of collages focused on thinking (e.g., "how do you expect your work to change in the future?"), mapping (e.g., laying out an envisioned work area on paper), feeling ("use pictures and words to show a health-related experience in your past"), and storytelling (see Sections 49.5.1 and 49.7.2). Dandavate, Steiner, and William (2000) and Vaajakallio and Mattelmäki (2007) provided case studies of Sanders' method.

Sanders' *say-do-make* framework can also be used, in an analytic decomposition, to describe participatory opportunities in more challenging design settings. Of course, ethnography is a prime example of the "see" strategy (see Chapter 45 in this book). O'Connor et al. (2006) explored a case in which, in effect, the "*do*" aspect of Sanders' method was the only means of communication for a codesigner with severe physical and speech disabilities. Cohene, Baecker, and Marziali (2005) explored some aspects of the "*make*" strategy in work with a codesigner who had Alzhiemer's disease, and her family and caregivers. Although neither of these papers was written with Sanders' analysis in mind, the framework provided by Sanders helps us to understand the range of possibilities and the creative responses of the researchers to codesigning under constrained circumstances.

In a different setting, Buur, Binder, and Brandt (2000) developed a workshop in which workers carried a mock-up of a proposed new device (see Section 49.7.1) through an industrial plant, recording how it would be used. They then acted out a 5-minute video scenario (see Section 49.5.1.2), which they subsequently presented to other similar worker teams in a workshop. Hultcrantz and Ibrahim (2002) used a similar method to concretize workshops similar to focus groups that were held with family members in their own homes. Pedell (2004) described a lower tech story-boarding workshop format in which people created narratives using photographs, putting them in sequences and altering in many cases (typically through the addition of speech bubbles to show what people were thinking or doing). Monk and Howard (1998) used a similar method, with less emphasis on photographs, to develop a "rich picture" of a work domain.

A novel workshop solution was needed when bringing older adults together with children, ages 7–11 (Xie et al. in press)—two historically underrepresented constituencies in the design of new technologies. A community center facility was used for its familiarity and availability to the children and the elders. Because of the diversity of participants, we faced challenges of both putting the two groups at ease and developing design methods that could accommodate active children and less-active adults. Earlier work had hybridized the design session by encouraging children to treat the entire floor as a design area (Druin et al. 2009). This was no longer possible if the children wanted their elderly design partners to engage in the design experience. Instead, this 2-day workshop began with "getting to know you" experiences, followed by "low-tech prototyping," a technique widely used in PD with adults (see Section 49.7.3). Once this blue-sky brainstorming was completed, separate discussions with stakeholders nurtured ideas to be further refined. This age-bridging work provides an example of suiting a workshop setting and dynamics to the needs of diverse participants. Cameron (1998), too, faced a different setting and problem and chose a workshop solution. This project dealt with safety issues in urban design in Baltimore and—like the METRAC program in Toronto (Nisonen 1994; see also Önder and Der [2007])—invited community members to contribute their domain expertise as people who lived with safety issues on an everyday basis. Cameron provided a manual, based on a professionally developed set of safety guidelines. Community members became community organizers, bringing the project topic and the proposed guidelines to their own constituencies. Two additional workshops refined the safety audit information from the constituencies, selected priority issues to fix, and adopted an action plan. Cameron observed that,

> One of the successful aspects of the Design for Safety workshop is that it provided a forum for a diverse group of people to productively discuss common problems and work through shared solutions and consensus. The workshops also showed that crime and safety were not solely the responsibility of the police, but that public works employees, traffic engineers, and especially residents must work together to envision as well as carry out the plan… Requiring that residents share the workshop information at community association meetings further assisted the transfer of responsibility from the workshop into the neighborhood.
>
> Related work is being done in the area of CRPR (e.g., (Shallwani and Mohammed 2007; Shilton et al. 2008), as discussed above.

Several other groups have developed repertoires of multiple workshops, from which they can select the type of workshop that is needed for a particular situation, site, or problem. Svanæs and Seland (2004) described six workshops; I list four formats that they considered successful here:

- Workshop 1. Theater, modeling clay, "design by accident," and improvisation with teenagers to explore "our mobile future"
- Workshop 2. Theater, brainstorming, and improvisation with a much more structured set of props (no modeling clay) for a different telecommunications project
- Workshops 4 and 5. Theater with audience-critique of performance (similar to Boal's Theatre of the Oppressed, described below), sometimes using structured props as well as "designing on the spot" for new concepts, for a hospital communication project
- Workshop 6. Videotaped field data as a point of common reference before theatrical work similar to workshops 4 and 5

Bødker, Kensing, and Simonsen (2004) described a repertoire of workshops. One subset of workshops was differentiated largely in terms of the artifact that was cocreated by the participants, such as freehand drawing (see also Monk and Howard [1998]), collages (see also Pedell [2004]; Sanders [2000]), affinity diagrams (see also Beyer and Holtzblatt [1998]), and timelines. Dray (1992) also used freehand drawing technique, but in a round-robin brainstorming "Braindraw" format in which *n* participants collaboratively drew *n* drawings, rotating the drawings throughout the group so that each drawing contained ideas created by each of the members of the group.

Less familiar artifacts were also used to define and differentiate workshops in the Bødker et al. survey. "Dead Sea Scrolls" are textual descriptions of the history of a business process. "Roll lists" are brief textual descriptions of all of the interested parties related to a business activity or a technology artifact. "Mapping" (also called "mind mapping"—see e.g., Buzan and Buzan [1996], for nonworkshop use of this technique) is the description of a problem area, business process, function, or other matter of interest in terms of a number of briefly stated concepts, connected by lines or arcs. A special version of mapping constructs a "communication map" among persons or roles. Finally, "Prompted Reflections" can be used similarly to Dray's Braindraw technique (Dray 1992), to bring people with different design concepts into communication with one another.

In the domain of DPD, researchers have adapted old and new web technologies to support hybrid workshop-like activities. Heß, Offenberg, and Volkmar (2008) reported on the use of community servers to work with two configurations of end users—the "parliament community" and the "central committee" community. These two user forums provided guidance on the development of multimedia software for linking televisions and computers. Costabile and colleagues have developed a set of virtual workshops called "Software Shaping Workshops," in which medical staff from diverse roles in a hospital can collaborate with software technologists in design of tailored user interfaces that meet the work needs of each role or discipline of the hospital staff (Costabile et al. 2006, 2007).

Third space. The various workshop approaches have several commonalities. Each workshop brings together diverse participants to do common work, to produce common outcomes (especially Bødker, Kensing, and Simonsen 2004), and to develop a plan of joint action (especially Kensing and Madsen 1991; Bødker, Kensing, and Simonsen 2004; McPhail et al. 1998; Mørch, Engen, and Åsand 2004). They are thus opportunities that require mutual education, negotiation, creation of understanding, and development of shared commitments. Each workshop takes place in an atmosphere and (often) in a site that is not "native" to any of the participants. Thus, all of the participants are at a disadvantage of being outside of their own familiar settings, and they must work together to define their new circumstances and relationships. The combination of diverse voices leads to syntheses of perspectives and knowledges.

Claimed benefits. Advantages claimed for these experiences in hybridity include the following:

- *Development of new concepts* that have direct, practical value for product design (Dandavate, Steiner, and William 2000; Kensing and Madsen 1991; Sanders 2000) or for community action (Cameron 1998)
- *Engagement* of the interested parties ("stakeholders") in the process and outcome of the workshop (Xie et al. in press)
- *Combinations of different people's ideas* into unified concepts
- *Production of artifacts* that are the expected and useful "inputs" to the next stage of the development process (Bødker, Kensing, and Simonsen 2004; Svanæs and Seland 2004; Xie et al. in press)

49.5 NARRATIVE STRUCTURES

49.5.1 Stories

Stories and storytelling have played a major role in ethnographic work since before there was a field called "HCI" (for review, see Crabtree [1998]; Suchman and Trigg [1991]; see also Chapter 45 in this book). Stories have also had an important history in HCI (see Carroll [1995]; Erickson [1996]; Muller [1999a]; see also Chapter 48 in this book). We will not attempt to review these areas. Rather, we will focus on those aspects of story-collecting and storytelling that involve the construction of third spaces and hybridity.

Stories in participatory work may function in at least four ways.* First, they may be used as triggers for conversation, analysis, or feedback (Salvador and Howells 1998; Salvador and Sato 1998, 1999). Second, they may be told by end users as part of their contribution to the knowledges required for understanding product or service opportunities and for specifying what products or services should do (Brandt and Grunnet 2000; Lafreniére 1996; Muller 2001; Muller et al. 1995b; Noble and Robinson 2000; Patton 2000; Sanders 2000; Tschudy, Dykstra-Erickson, and Holloway 1996; Yu and Liu 2006). Third, they may be used by heterogeneous design teams (i.e., including users) to present their concept of what a designed service or product will do, how it will be used, and what changes will occur as a result (Demirbilek and Demirkan 2004; Druin 1999; Druin et al. 2000; Ehn and Kyng 1991; Ehn and Sjögren 1986, 1991; Gruen 2001; Muller, Wildman, and White 1994; Sanders 2000). Fourth, they may be constructed by designers to stand as proxies for real users (e.g., Triantafyllakos, Palaigeorgiou, and Tsoukalas 2010).

Beeson and Miskelly (1998, 2000) used hypermedia technologies to enable communities to tell their own stories, with the intention that "plurality, dissent, and moral space can be preserved" (Beeson and Miskelly 2000, p. 1). They were concerned to allow multiple authors to reuse community materials selectively, telling different stories within a common context. The different accounts were organized according to themes and laid out spatially on the image of a fictitious island for navigation by end users. Their work entered several areas or aspects of hybridity. First, the authors of the stories (i.e., community members) were using hypermedia technology for the first time, and were thus in the role of learners, even while they were the owners of the stories, and were thus in the role of experts. Second, the authors wrote from their own perspectives, which were sometimes in strong conflict with one another. Third, the authors could make use of one another's materials, effectively moving away from single-author narratives and into a kind of collaborative collage of materials, which conveyed interlinked stories. Fourth, just as the community members were negotiating and defining their roles as learner-experts, the software professionals/researchers were negotiating and defining their roles as experts/facilitators/students. Törpel and Poschen (2002) described a related

* For a survey of story genres that may be used in participatory work, see Karasti, Baker, and Bowker (2002).

method of Narrative Transformation, emphasizing workers' roles as story creators, story analysts, and originators of new concepts that could be pursued through other methods in this chapter (e.g., see Section 49.7.3).

A second line of practice and research has emphasized end users telling their stories using a system of paper-and-pencil, card-like templates. The earliest version was the collaborative analysis of requirements and design (CARD) technique of Tudor et al. (1993), later developed into a more general tool in Muller et al. (1995b) and further refined in Muller (2001). Lafreniére (1996) developed a related practice, collaborative users' task analysis (CUTA), repairing some of the deficits of CARD for his settings. Halskov and Dalsgård (2006) focused the method on combinations of "domain cards" with "technology cards" (see also Davis [2010]). Tschudy, Dykstra-Erickson, and Holloway (1996) developed their own highly visual version, PictureCARD, for a setting in which they had no language in common with the users whose stories they wished to understand. The card-based practices used pieces of cardboard about the size of playing cards. Each card represented a component of the user's work or life activities, including user interface events (i.e., screen shots), social events (conversations and meetings) and cognitive, motivational, and affective events (e.g., the application of skill, the formation of goals or strategies, surprises and breakdowns, and evaluations of work practices). The cards were used by diverse teams in analysis, design, and evaluation of work and technology. Because the cards were novel object to all the participants, they occasioned third-space questionings and negotiations, resulting in new shared understandings and coconstructions. Often, teams used the cards to prepare a kind of story-board poster, narrating the flow of work and technology use and annotating or innovating cards to describe that work. The resulting posters formed narratives of the work that were demonstrated to be understandable to end users, corporate officers, and software professionals, and which led to insights and decisions of large commercial value (see Sanders [2000], for a differently constructed example of story-board posters to describe work).

Druin (1999; Druin et al. 2000) pursued a third line of storytelling research and practice, with children as design partners in a team that also included computer scientists, graphic designers, and psychologists (for other participatory work with children, see e.g., Sanders [2000]; Hornof [2008]; Kam et al. [2006]; Large et al. [2007]; Taxén [2004]). Their purpose was to envision new technologies and practices in children's use of computers and related devices. They used both online story-boarding techniques and the construction of prototypes of spaces in which the jointly authored stories could be performed. This work kept everyone learning from everyone else—children learning about technologies and the story-boarding environment, adults learning about children's views and other adults' expertises, and everyone negotiating the meaning of new technological and narrative ideas, as well as their implementations.

So far, this section has addressed primarily the acquisition of stories. But stories are also for telling to others. Sanders (2000) described the construction of storyboards based on users' experiences. Gruen (2000, 2001) described guidelines and practices through which a diverse team could begin with a concept, and then could craft a convincing and engaging story around it. Demirkbilek and Demirkan (2004) used stories initiated by seniors in Turkey to redesign household items for greater usability by elder people. Massimi and Baecker (2006) similarly used seniors' stories for the redesign of mobile telephones.

Triantafyllakos, Palaigeorgiou, and Tsoukalas (2010) described a method for creating rich characters around which designers could consider design alternatives—an approach similar to the "personas" approach of Cooper, Reimann, and Cronin (2007).* Best et al. (2009) present a contrasting case, in which members of a diaspora community (i.e., citizens living outside of their own country) served as a proxy for their less well-traveled citizens at home, with results that in some ways showed the weakness of using proxies for actual users. Going further in the direction of contextualized knowledge, Brereton advocates for a participatory approach that she called "embedded research," in which the researcher lives as a member of the users' community for an extended period of time (2009; Segalowitz and Brereton 2009). In general, the problem of "designing for the 'other'" (Nielsen and Bødker 2009; see also Hirsch [2009]) remains an open question in PD, as in all of user-centered design (Stappers et al. 2009). That is, how can people speak for themselves if they are not even present? How can designer verify their knowledge of the users if the users are not available to discuss their needs?

Sanders' and Gruen's procedures led to hybrid experiences, in the sense that few software professionals or end users think in terms of story-construction or rubrics for effective fictions. Irestig and Timpka (2002) described a method for sharing stories from small working groups with a larger audience of decision makers.

Third space. Story-collecting and storytelling generally require a kind of third space in which to occur. Beeson and Miskelly (1998, 2000) were specifically concerned to create a new space for story-writing and story-reading and to maintain some of the most important aspects of third spaces in that new space—that is, preservation and expression of new meanings, relationships, conflicts, multiple perspectives, and "heterotopia." The three card-based practices use unfamiliar media (the cards), and made those media central to the team's activities, thus requiring conscious attention to shared conceptualizing and defining of those media, as well as the creation of new media when needed. Druin and colleagues created new software environments and new devices to craft and implement stories of futuristic technologies. Finally, Gruen engaged diverse teams in new roles as story writers, guided by

* See also critiques of the personas approach such as in Adlin et al. (2006).

expert-derived guidelines, in the writing of professionally structured and professionally paced stories for organizational or commercial use.

Claimed benefits. The story-collecting and storytelling practices are diverse, and serve multiple purposes. A brief summary of the claims of their value to projects and products is as follows:

- *Articulation* and preservation of a diverse community's views (Beeson and Miskelly 1998, 2000)
- *Practical application* to work analysis, task analysis, new technology innovation, and usability evaluation in commercially important products and services (Gruen 2000, 2001; Lafreniére 1996; Muller 2001; Muller et al. 1995b; Sanders 2000; Tudor et al. 1993; Tschudy, Dukstra-Erickson, and Holloway 1996)
- *Cocreation of new ideas* and children's articulation and self-advocacy (Druin 1999; Druin et al. 2000)

49.5.1.1 Photographs

There are many ways to tell stories. One approach that has informed recent PD work is end-user photography. Patton (2000) note that both (1) taking pictures and (2) organizing pictures into albums are, of course, familiar activities to most people in affluent countries. These activities allow end users to enter into a kind of native ethnography, documenting their own lives. In keeping with the issues raised in Section 49.5.1, it is important that the informants themselves (the end users) control both the camera and the selection of images (see Bolton [1989], for a set of discussions of the uses and abuses of documentary photography). They thus become both authors and subjects of photographic accounts of their activities. This dual role leads to one kind of hybridity, in which the photographic activities partake of both the world of common social life and the world of documenting and reporting on working conditions.

To address the problem that "rural women are often neither seen nor heard," Wang, Burris, and Ping (1996) in collaboration with the Yunnan Women's Health and Development Program, invited Chinese village women to articulate their lives through *photo novellas* created with cameras that the women controlled, with the goal of influencing policy makers. In an exploration of products for mobile knowledge workers, Dandavate, Steiner, and William (2000) similarly asked their informants to take pictures as part of a documentation of the working lives. In their study, informants were also invited to construct collages of their working lives, selectively reusing the photographs (among other graphical items) in those collages. The collages were, in effect, one type of interpretation by the photographers of their own photographs. Similarly to Patton's work, Dandavate et al. asked their informants to go out of their conventional professional roles as office workers (but well within their roles as members of an affluent culture) in the activity of taking the photographs. Dandavate et al. asked their informants to go even further out of role, through the construction of the collages based on their photographs and the interpretation of the collages. The activities were thus marginal, partaking of attributes of informal life and professional life, of familiar and unfamiliar activities. They concluded that the photographic work led to new learnings and understandings that had not been accessible through observational studies, as well as a stronger sense of ownership by their informants in the outcome of the study.

Noble and Robinson (2000) formed an alliance between an undergraduate design class at Massey University and a union of low-status service workers, developing photo documentaries of service work. The photographs served as a kind of hybrid boundary object (Star and Griesemer 1989)—for the students, the photographs were composed artifacts of design, whereas for the union members, the photographs were common and casually produced snapshots. Discussions between union members and students were rich, conflicted, and productive, as they negotiated the status and meaning of these hybrid objects. These discussions—and the exhibits and posters that they produced (i.e., the collective actions of the students and the union members)—could not have been successful without mutual learning and construction of new understandings. Photo documentaries were used by Kwok (2004) as a means of providing familiar, concrete artifacts to enable design collaborations. Mattelmäki and Batarbee (2002; see also Hulkko et al. [2004]) used photo documentaries as one component of a set of user-composed diary techniques, with a subsequent user-created collages to serve as a rich source of discussions.* Taylor and Cheyerst (2009) further pursued themes of lay photography and group reflection through a community-scaled photo display device.

Pecknold (2009) developed a novel mixture of photography, drawing, and "probes" in order to conduct remote design dialogues between her university in Canada and her informants in Rwanda. Women answered a prepared set of questions through photographs and drawings and labeled self-selected photos and drawings to correspond to further questions about hopes and desires. Like the tailoring of the workshop setting for elders and children (see Section 49.4.2), this is another example of suiting a previously well-understood set of participatory methods to the special circumstances and special needs of a new group of participants.

Third space. End-user photography is an interesting case of hybridity and the production of third spaces. Photography is a good example of an "in-between" medium—one that is part of many people's informal lives (Dandavate, Steiner, and William 2000; Noble and Robinson 2000; Patton 2000), but that is also an intensively studied medium of communication and argumentation (Bolton 1989; Noble and Robinson 2000). Photography occurs at the margin

* It is noteworthy that, in the studies reviewed here, the informants made their own decisions about what was important, and therefore what they should photograph. For a discussion of issues in more conventional, researcher-directed photographic diary studies, see Carter and Mankoff (2005).

of most people's work, and yet can easily be incorporated into their work. The resulting photographs and drawings in these projects have attributes of their dual worlds—they are partially informal and quotidian and partially formal and documentary. Discussions around the photographs and combination of the photographs into photo narratives (Kwok 2004; Patton 2000) or collages (Dandavate, Steiner, and William 2000; Hulkko et al. 2004; Mattelmäki and Batarbee 2002) can lead to mutual learning and new ideas, particularly through the inclusion of the voices of the photographers, the viewers, and especially the people depicted in the photographs (Noble and Robinson 2000; see also discussion of Isomursu, Kuutti, and Väinämö [2004], below). Because photographs are often thought of as denotative media (i.e., documenting what *is*), Pecknold's approach of supplementing photographs with more connotative drawings is very promising for helping people to express and communicate their hopes and desires about possible futures (Pecknold 2009).

Claimed benefits. The use of end-user photographs and drawings appears to be new and experimental, and there are few strongly supported claims of benefits. Informal claims of success and contribution include the following:

- *Richer, contextualized communication medium* between end users and designers (in some cases, the designers were not, themselves, software professionals)
- *Stronger engagement* of designers with end-users worlds
- *Enhanced sharing* of views and needs among end users, leading to stronger articulation by them as a collective voice
- *Expression* of emotions and other connotative concepts, as well as documentation of more denotative, fact-like information

49.5.1.2 Dramas and Videos

Drama provides another way to tell stories—in the form of theatre or of video. One of the important tensions with regard to drama in PD is the question of whether the drama is considered a finished piece, or a changeable work in progress.

Many PD drama practitioners make reference to Boal's Theatre of the Oppressed (Boal 1974/1992). Boal described theatrical techniques whose purpose was explicitly to help a group or a community find its voice(s) and articulate its position(s). The most influential of Boal's ideas was his Forum Theatre, in which a group of nonprofessional actors performs a skit in front of an audience of interested parties. The outcome of the skit is consistent with current events and trends—often to the dissatisfaction of the audience. The audience is then invited to become authors and directors of the drama, changing it until they approve of the outcome. A second technique of interest involves the staging of a tableau (or a "frozen image," in Brandt and Grunnet 2000), in which a group of nonprofessional actors positions its members as if they had been stopped in the middle of a play. Each member can tell what she/he is doing, thinking, planning, and hoping. Forum Theatre was used informally in the UTOPIA project and other early Scandinavian research efforts (Ehn and Kyng 1991; Ehn and Sjögren 1991), addressing the question of new technologies in newspaper production. Changes in work patterns and work-group relations were acted out by software professionals in the end-users workplace, using cardboard and plywood prototypes, in anticipation of new technologies. The workers served as the audience and critiqued the envisioned work activities and working arrangements. The drama was carried out iteratively, with changes, until it was more supportive of the skilled work of the people in the affected job titles. The researchers made repeated visits with more detailed prototypes, again using the vehicle of a changeable drama, to continue the design dialogue with the workers. This work was widely credited with protecting skilled work from inappropriate automation, leading to a product that increased productivity while taking full advantage of workers' skills. Brandt and Grunnet (2000) made a more formal use of Boal's Forum Theatre and "frozen images" in the two projects described above (Section 49.4.1). Working with refrigeration technicians in the "Smart Tool" project, they and the technicians enacted work dramas and tableaux around four fictitious workers, leading to insights about the technicians' work and the technological possibilities for enhanced support of that work. Here is a description of one use of Forum Theatre:

> [T]he stage was constructed of cardboard boxes which in a stylized way served as… the different locations in the scenario. At first the service mechanics sat as an audience and watched the play. After the first showing of the "performance" the refrigeration technicians were asked to comment and discuss the dramatized scenario critically…
>
> The role of the refrigeration technicians changed from being a passive audience into being directors with an expert knowledge. The users recognized the situations shown in the dramatized scenario…. Because of the openness of the scenario there was a lot of "holes" to be filled out. For instance, one…technician explained that he preferred to solve the problems himself instead of calling his boss. This information meant that the Smart Tool should be able to help him solve his problems while being in his car.… Another [technician] wanted to have personal information that his boss was not allowed…[to] access…. (p. 14)

Incidents were analyzed through tableaux. The designers positioned themselves in the "frozen image" of the work situation, and then led a discussion of (1) the work activities that were captured in the stopped action, and (2) the work relations in which each particular tableau was embedded.

Muller et al. (1994) presented a related tutorial demonstration piece called "Interface Theatre," with the stated goal of engaging a very large number of interested parties in a review of requirements and designs—for example, in an auditorium. In Interface Theatre, software professionals acted out a user interface "look and feel" using a theatrical stage as the screen, with each actor playing the role of a concrete interface component (e.g., Kim the Cursor, Marty the Menubar, Dana the Dialoguebox). Pedersen and Buur (2000; see also Buur, Binder, and Brandt [2000]), following previous work of Binder (1999), collaborated with industrial workers to make videos showing proposed new work practices and technologies. After a collaborative analysis of the work (see Section 49.6), workers acted out their new ideas and took control of which action sequences were captured on video for subsequent explanation to other workers and management (see also Björgvinsson and Hillgren [2004]; Mørch, Engen, and Åsand [2004]). Isomursu, Kuutti, and Väinämö (2004) used more informal user-produced videos based on cellphone video recordings, which included not only lay-ethnographic records of usage, but also user-originated dramas to illustrate hypothesized or desired aspects of usage. In the situated and participative enactment of scenarios method, Iacucci et al. described a projective series of improvisations with an innovative technology idea—the "magic thing"—in users' homes or workplaces (Iacucci, Iacucci, and Kuutti 2002; Iacucci and Kuutti 2002; Kuutti, Iacucci, and Iacucci 2002; see also Buur and Bødker [2002]; Bødker and Buur [2002]).

Finally, Salvador and Sato (1998, 1999) used acted-out dramas as triggers for questions in a setting similar to a focus group, and Howard et al. (2002) described the role of professional actors and directors in dramatizing attributes of proposed new products. Kantola et al. (2007; Kankainen et al. 2005) similarly used dramatic readings by "role characters" to deepen the understanding of users' situations. Enquist and Tollmar (2008) used role-playing as part of a series of workshops to envision a future health-related memory aid for pregnant women.

While all of these practices are loosely tied together through the use of drama, there are important contrasts. One important dimension of difference is the extent to which the drama is improvised in the situation, or scripted in advance. Boal's techniques make a crucial use of improvisation by the user-audience, to change the action and outcome of the drama. This theme is most clearly seen in the work of Brandt and Grunnet (2000), Ehn and Sjögren (1986, 1991), and Muller, Wildman, and White (1994). At the opposite extreme are video documentaries, which of course are difficult to change in response to discussion and constructive insight.

Third space. Taken as a somewhat diverse participatory genre, the dramatic approaches provide many of the aspects of hybridity reviewed in the cultural studies introduction to this chapter. Drama brings a strong overlap of the world of end users and the world of technology developers/researchers, showing concrete projections of ideas from one world into the other world—and, in most uses, allowing modification of those ideas. Drama is marginal to the work domains of most technology developers/researchers and most end users, and thus moves all parties into an ambiguous area where they must negotiate meaning and collaboratively construct their understandings. Agreements, conflicts, and new ideas can emerge as their multiple voices and perspectives are articulated through this rich communication medium.

Claimed benefits. Similarly to end-user photography, most of the theatrical work has the feel of experimentation. It is difficult to find clear statements of advantages or benefits of these practices (see Section 49.8). In general, practitioners and researchers made the following claims:

- *Building bridges* between the worlds of software professionals and users
- *Enhancing communication* through the use of embodied (i.e., acted-out) experience and through contextualized narratives
- *Engaging small and large audiences* through direct or actor-mediated participation in shaping the drama (influencing the usage and design of the technology)
- *Increasing designers' empathy* for users and their work
- *Simulating use of not-yet-developed tools* and technologies ("dream tools," Brandt and Grunnet 2000) to explore new possibilities
- *Fuller understanding* by focus group members, leading to a more informed discussion

49.6 GAMES

From theory to practice, the concept of games has had an important influence in participatory methods and techniques. Ehn's theoretical work emphasized the negotiation of language games in the course of bringing diverse perspectives together in PD (Ehn 1988; for applications of this theory, see Ehn and Kyng [1991]; Ehn and Sjögren [1986, 1991]). In this view, part of the work of a heterogeneous group is to understand how to communicate with one another—and of course communication is not really possible on a strict *vocabulary* basis, but requires an understanding of the *perspectives* and *disciplinary cultures* behind the words (Bachmann-Medick 1996; Muller 1997a, 1997b, 1999b). Thus, the work of heterogeneous teams is, in part, the "mutual validation of diverse perspectives" that Bødker et al. (1988) advocated.

Games have also been an important concept in designing practices, with the convergent strategies of enhanced teamwork and democratic work practices within the team.* We explained the concepts as follows (Muller, Wildman, and White 1994):

> When properly chosen, games can serve as levelers, in at least two ways. First, games are generally outside of most workers' jobs and tasks. They are therefore less likely to appear to be "owned" by one worker, at the expense of the alienation

* For an example of games used to teach *design experiences* among students, see Iversen and Buur (2002).

> of the non-owners. Second,…[PD] games…are likely to be novel to most or all of the participants. Design group members are more likely to learn games at the same rate, without large differences in learning due to rank, authority, or background.… This in turn can lead to greater sharing of ideas.…
>
> In addition, games…can help groups of people to cohere together [and] communicate better. One of the purposes of games is enjoyment —of self and others —and this can both leaven a project and build commitment among project personnel. (pp. 62–63)

Derived from Ehn's (1988) theoretical foundation, Ehn and Sjögren (1986, 1991; see also Bødker, Grønbæk, and Kyng [1993]) adopted a "design-by-playing" approach, introducing several games into PD practice:

- *Carpentopoly,* a board game concerned with business issues in the carpentry industry.
- *Specification game*, a scenario-based game based on a set of "situation cards," each of which described a workplace situation. Players (members of the heterogeneous analysis/design team) took turns drawing a card and leading the discussion of the work situation described on the card. Hornecker (2010) used a more restricted approach, in which cards primarily asked questions about designed artifacts.
- *Layout kit*, a game of floor plans and equipment symbols, for a workers' view of how the shop floor should be redesigned (see also Bødker and Buur [2002]; Horgan et al. [1998]; Klær and Madsen [1995]; and most recently Brandt and Messeter [2004], reviewed below).
- *Organization kit and desktop publishing game*, a part of the UTOPIA project (Ehn and Kyng 1991), in which cards illustrating components of work or outcomes of work were placed on posters, with annotations.

Petersen and Buur (2000) extended the Layout Kit in new ways. Collaborating with workers at Danfoss, they jointly created a board game for laying out new technologies in an industrial plant:

> A map of the plant layout served as the game board.… Foam pieces in different colors and shapes worked as game pieces for the team to attach meaning to…. Often, in the beginning of the game, the placement of the piece was only accepted when touched by almost everybody…. The participants were forced to justify the placement, which fostered a fruitful dialogue about goals, intentions, benefits, and effects. People were asking each other such things as…"what if we change this?", "on our plant we do this, because…", "would you benefit from this?".

The games became the foundation of the videos produced in collaboration with the workers (described in Section 49.5.1.2).

Buur, Binder, and Brandt (2000) extended the Specification Game, making a game from the outcome of a participatory ethnographic analysis of work at an industrial plant. They first collected video observations from work activities and developed a set of 60–70 video excerpts for further discussion. They next constructed a set of cards, one for each video excerpt, with a still-frame image from the video displayed on each card. Same participants then grouped these 60–70 cards into thematic clusters, organized their clusters, and analyzed the subsets of actions in each cluster (for a related non-game technique, see affinity diagramming in Beyer and Holtzblatt [1998]). Similar approaches were used by de Jong, Kouprie and De Bruyne (2009; Bruyne and de Jong 2008) for self-reflection by workers on their behaviors in the context of the physical workplace, and to envision future possibilities (see also Maarleveld, Volker, and van der Voordt [2009]).

The concept of games was taken in a different direction, for use in non-Scandinavian workplaces, by introducing several new games (Muller, Wildman, and White 1994):

- *CARD*, a card game for laying out and/or critiquing an existing or proposed work/activity flow (see Section 49.5.1)
- *PICTIVE*, a paper-and-pencil game for detailed screen design (Muller et al. 1995b)
- *Icon design game*, a guessing game for innovating new ideas for icons (this game assumes subsequent refinement by a graphic designer)
- *Interface theatre*, for design reviews with very large groups of interested parties (see Section 49.5.1.2)

These games emphasized hands-on, highly conversational approaches to discussing both the user interface concept itself and the work processes that it was intended to support. We attempted to foster an informal and even playful tone, for the reasons sketched in the earlier quotation. Similar approaches have been used for design across barriers of disability (Davies et al. 2004) and across barriers of language and culture (Bidwell et al. 2010; Tschudy, Dykstra-Erickson, and Holloway 1996).

Recently Brandt and Messeter (2004; see also Johansson et al. [2002]) developed a strong sequence of games. Their User Game is based on the video-collage methods of Buur, Binder, and Brandt (2000), combining brief video clips into person or role descriptions, which are then labeled evocatively by the participants. The second game in their sequence, the Landscape Game, places those user constructs into the work environment (as a board game). The Technology Game adds simple shapes that stand for technologies, again playing those shapes onto the work environment in the Landscape Game. Finally, the Scenario Game moves back to the real world, enacting possibilities based on new ideas from the preceding three games. The enactments may be video recording, both for documentary purposes and to generate further video material for another cycle of the four games.

The goal of *designing a game* can also serve as an opportunity to create a hybrid space: The design task mixes aspects of software design and implementation with game-based concepts of enjoyment, suspense, and personal outcomes. Kam et al. used this strategy to engage students, their families, and their communities in workshops in a rural Indian village (Kam et al. 2006; see also Antle [2003]).

Third space. Each of these games took all of its players outside of their familiar disciplines and familiar working practices, but strategically reduced the anxiety and uncertainty of the situation by using the social scaffolding of games. Each game required its players to work together through mutual learning to understand and define the contents of the game and to interpret those contents to one another in terms of multiple perspectives and disciplines. The conventional authority of the technology developers/researchers was thus replaced with a shared interpretation based on contributions from multiple disciplines and perspectives.

Claimed benefits. PD work with games has been claimed to lead to the following benefits:

- *Enhanced communication* through the combination of diverse perspectives
- *Enhanced teamwork* through shared enjoyment of working in a game-like setting
- *Greater freedom to experiment and explore new ideas* through flexible rules and redefinition of rules during the game
- *Improved articulation* of the perspectives, knowledges, and requirements of workers
- *New insights* leading to important new analyses and designs with documented commercial value

49.7 CONSTRUCTIONS

Preceding sections have considered hybridity in participatory activities such as sitings, workshops, stories, photography, dramas, and games. This section continues the survey of participatory practices that bring users and technology developers/researchers into unfamiliar and ambiguous "third space" settings. In this section, we focus on the collaborative construction of various concrete artifacts:

- *Physical reflections of a cocreated language* of analysis and design
- *Descriptions of work* in unfamiliar media
- *Low-tech prototypes* for analysis and design
- *High-tech prototypes* for design and evaluation

49.7.1 Language

An earlier section noted Ehn's theoretical work on *PD as language games* (Ehn 1988). Ehn's interest converges with Bhabha's "third space" argument (Bhabha 1994): Part of the characterization of hybridity was the negotiation and cocreation of working language and meaning. This section takes Ehn's position seriously and considers the role of language creation in participatory practices that lead to hybridity.

Several projects have made physical objects into a kind of vocabulary for work analysis, design, or evaluation. The cards described in the Section 49.6 are examples (Buur, Binder, and Brandt 2000; Ehn and Sjögren 1986, 1991; Lafreniére 1996; Muller 2001; Muller et al. 1995b; Tschudy et al. 1994; Tudor et al. 1993). In each of these methods, the cards became a kind of "common language" (e.g., Muller et al. 1995b) through which the design team communicated (1) with one another, and (2) with their labor and management clients. In two of the methods, the cards themselves were acknowledged to be incomplete, and part of the work of the team was to develop and refine the cards so as to reflect their growing understanding and their new insights (Lafreniére 1996; Muller 2001). Team members (users and others) were encouraged to disregard, if appropriate, the template of information on each card, up to and including the decision to turn the card over and write on its blank back. In subsequent sessions, the concepts that were written on the blank backs of cards usually became new kinds of cards. The working vocabulary of the team thus grew as the shared understanding of the team grew. This extensibility of the set of cards was observed in nearly all sessions, but was particularly important in sessions that were envisioning future technologies or future work practices. The cards thus became a point of hybridity, where assumptions were questioned and challenged, where extensive and polyvocal dialogue was required for the team to assign meaning to the cards, where conflicts were revealed and resolved, and where the team had to construct its understanding and its language. Similarly, the board games of Ehn and Sjögren, and especially of Pedersen and Buur (2000), used deliberately ambiguous playing pieces. The analysis team had to assign meaning to the pieces, and did so in a collaborative way.

Chin et al. (2000), working with a community of physical scientists who were not software professionals, introduced software-like flowcharts to their clients (see Kensing and Munk-Madsen [1993], for a discussion of the relationship between concrete tools and abstract tools). This work shared, with the other work reviewed in this section, aspects of symbol ambiguity and language cocreation:

> To attune scientists to the construction of workflow diagrams, we provided them a simple, informal example of how a meteorologist might diagram his [sic] work in collecting and reporting weather conditions.… Although we used circles and arrows in our example, we did not impose any specific symbology or rules on the scientists' construction of workflow diagrams…. At times, the scientists did struggle in developing some diagrams, but the labor was mostly centered on the elucidation of the research processes rather than the mechanics of diagramming.

Third space. Common to all of these projects was the cocreation of a physically represented language, both within the team and from the team to its clients and stakeholders. This kind of lay linguistic work requires mutual education and mutual validation for the new language components to have meaning to all of the parties. These negotiations of multiple knowledges are at the heart of the "third space" proposal of Bhabha (1994).

Claimed benefits. Most of these projects involved a number of activities and a number of aspects of hybridity. It is difficult to determine how much of their successes were due specifically to the language-related components. Benefits that *may* have resulted from the negotiation and cocreation of language include the following:

- *Enhanced understandings* of one another's perspectives and needs
- *Critical examinations of assumptions* underlying the ways that each party expressed its perspective
- *Shared ownership of the language* and its physical manifestation (cards, flowcharts, and game pieces)
- *Improved communication* within the team and from the team to interested outsiders (clients and stakeholders)

49.7.2 Making Descriptive Artifacts

Another way of moving end users into unfamiliar and hence reflective experiences is to ask them to use "projective" or artistic methods to report on their experiences and needs. In one sense, these methods produce another kind of language of expression, and therefore might have been included in the preceding section. Because the outcomes are so distinctively different from the language-oriented work of the preceding section, we thought it best to review this work in its own section.

Sanders has employed user-created collage in her participatory practice for a number of years (Sanders 2000; see also Dandavate, Steiner, and William [2000]; Sanders and Branaghan [1998]; Sanders and Nutter [1994]). The choice of collage is of course strategic: Relatively few people make collages as part of their work activities and relatively few people interpret their collages to one another as part of their work conversations. Yet the content of the collages is strongly anchored in what people know. The collages thus become marginal constructions, not part of any defined workplace field or discipline, but informed by familiar knowledges. The novelty of the collage encourages the challenging of assumptions, and the interpretation and presentation of collages encourage mutual learning across the diversity of experiences and knowledges of the participants.

For completeness, we make reference to the work of Noble and Robinson (2000) on collaborative creation of photo documentaries and of Patton (2000) on end-user creation of photo collages, reviewed in Section 49.5.1.1 Their work also produced descriptive artifacts that took users and their collaborators into unfamiliar areas.

Third space. These methods have in common the use of a nonstandard medium for making users' needs known and for developing new insights in a workplace setting. The making of collages may be new for many participants. They are thus in a kind of "third space," between their work culture and the artistic or expressive culture of collages, and they have to reflect on the differences as they construct their approach to making collages of their own experiences. It is not clear, in Sanders' work, whether the collage work is done collaboratively among end users or whether each collage is a solitary production. If the collage creation is done collaboratively, then it might give rise to some of the other attributes of hybridity in Table 49.1—for example, challenging assumptions, cocreation of meanings and collective actions, and dialogues.

Claimed benefits. Based on her claims on years of practice with collages and related practices, Sanders (2000) claims the following benefits:

- *Using visual ways* of sensing, knowing, remembering, and expressing
- *Giving access and expression to emotional side* of experience
- *Acknowledging the subjective perspective* in people's experiences with technologies
- *Revealing unique personal histories* that contribute to the ways that people shape and respond to technologies

49.7.3 Low-Tech Prototypes

Beaudouin-Lafon and Mackay have provided a chapter on prototyping—including participatory prototyping—in this book. Therefore, we have written a very brief account in this chapter so as not to duplicate their efforts.

Low-tech prototypes may lead to "third space" experiences because they bring people into new relationships with technologies—relationships that are "new" in at least two important ways. First, the end users are often being asked to think about technologies or applications that they have not previously experienced. Second, in *participatory* work with low-tech prototypes, end users are being asked to use the low-tech materials to reshape the technologies—a "design-by-doing" approach (Bødker, Grønbæk, and Kyng 1993). In this way, participatory work with low-tech prototypes involves much more user contribution and user initiative than the more conventional use of "paper prototypes" as surrogates for working systems in usability testing (e.g., Rettig 1994). The general approach of low-tech prototyping for design has been effective in many settings, including with workers (Bødker et al. 1987, 1988; Bødker, Grønbæk, and Kyng 1993; Ehn and Kyng 1991; Lafreniére 1996; Muller 1991, 1992; Muller et al. 1995b); intercultural communication (Bidwell et al. 2010; see also Bidwell and Hardy [2009]) even when there is no common language (Tschudy, Dykstra-Erickson, and Holloway 1996); with people with disabilities (Moffatt et al. 2004); and with very young users (Druin 2002; Druin et al. 2009) and very old users (Massimi and Baecker 2006; Massimi, Baecker, and Wu 2007; see also literature reviews in Massimi [2006, 2007]).

The UTOPIA project provided impressive demonstrations of the power of low-tech cardboard and plywood prototypes to help a diverse group to think about new technologies, office layouts, and new working relations that might result from them (Bødker et al. 1987, 1988; Bødker, Grønbæk, and Kyng 1993; Ehn and Kyng 1991; for other use of low-tech, substitutive prototypes, see Mørch, Engen, and Åsand [2004]). Subsequent projects to translate this work to North America led to the PICTIVE method of paper-and-pencil constructions of user interface designs by heterogeneous design teams (Muller et al. 1995b); prototyping of consumer appliances using foam core and hook-and-loop attachments (Sanders and Nutter 1994); and a more experimental simulation of e-mail, using paper airplanes (Dykstra and Carasik 1991).

In addition to these methods, many researchers who work with children in PD experiences use low-tech prototyping. The children affectionately call it "bags of stuff" (Druin et al. 2009). The types of materials that are used are intentionally three-dimensional to cut down on the "fear of drawing" and to use these artifacts as a bridge for communication and design. Everything from toilet paper rolls to clay and cotton balls are used to construct new ideas with children and adults. These artifacts are then presented to a larger group and the highlights of the design ideas are written up on a whiteboard. The ideas are then aggregated to suggest a new design direction for the team (Druin 2002).

When prototyping takes place among geographically remote participants, the new situation is hybridized almost by definition Moore (2003) proposed an experimental approach to allow end users to create the appearance of the user interface and to provide rationales for their designs; it is not clear if this approach has been tested yet.* Rashid et al. (2006) took a critique-oriented approach to solve a similar participatory-requirements-analysis problem, providing a web method for users to create annotations with screen shots, which were then conveyed to the development team. Significantly, the Rashid et al. work was done during the design process, so that users were episodically involved in design critiques. Lohmann, Ziegler, and Heim (2008) described a text-plus-gesture method for critiquing designs through web browsers and conducted preliminary testing of the system with end users (for related work, see Lohmann et al. [2009]). Also addressing the problem of distributed requirements specification, Janneck and Gumm (2008) described the commented case studies method for collecting end-user information through scenario-based design-at-a-distance, sometimes involving a "Mediated Feedback" process to collect and redact user input (Gumm, Janneck, Finck 2006). Heß, Offenberg, and Volkmar (2008) described two online forum environments in which a "User Parliament" and a "Central Committee" of users and software professionals provided guidance for the duration of a community-driven development (CDD) process; see also the work of Füller et al. (2006), mentioned above, on CBI approaches to software design-at-a-distance.

Work in this newly defined area of DPD is in relatively early stages (Nasghsh et al. 2008). Many of the experiments involve repurposing of existing Web2.0 technologies to facilitate user feedback (e.g., We look forward to the maturity of this emerging effort.).

Third space. Low-tech prototyping has a reputation for bringing new insights through the combination of diverse perspectives. The UTOPIA project is widely credited with mutual education among shop-floor print workers and computer systems researchers. Experiences with PICTIVE and its variants almost always involved mutual education. Understanding and changing the artifact become important arenas for people to explore their understandings of one another's positions, to question one another's approaches, to discover and resolve conflicts, to engage in combinations of views leading to plans for collective action, and to accommodate heterogeneity of views and interests.

Claimed benefits. The low-tech participatory prototyping approaches have been extraordinarily influential, with adoption on four continents. Claimed benefits include the following:

- *Enhanced communication and understanding* through grounding discussions in concrete artifacts (Druin 2002)
- *Enhanced incorporation of new and emergent ideas* through the ability of participants to express their ideas directly via the low-tech materials and through the construction of artifacts that can be used in other techniques, especially drama and video documentaries (above)
- *Enhanced working relations* through a sense of shared ownership of the resulting design (Druin et al. 2009)
- *Practical application with measured successes* in using low-tech design approaches to real product challenges, achieving consequential business goals

49.7.4 Evolutionary Prototyping and Cooperative Prototyping

This last section on participatory methods is concerned with software prototyping. As noted above, we are relying on the chapter by Beaudouin-Lafon and Mackay in this volume to cover prototyping in greater depth and breadth. We include this brief overview for completeness of our chapter's survey of hybridity in participatory practices.

* One of us was involved in an earlier experiment called TELEPICTIVE, which attempted to support design-at-a-distance. We provided a description of the experimental prototype, and its shortcomings, in Miller, Muller, and Smith (1995) and Muller et al.

Bødker and Grønbæk (1991) and Madsen and Aiken (1993) explored the potential of cooperative prototyping in several projects, using different technology infrastructures. In general, they found that this approach led to enhanced communication with end users, improved incorporation of end user insights into the prototypes, and stronger collective ownership and collective action-planning by the team. They also observed time-consuming breakdowns in the design process itself, when new ideas required significant programming effort.

In a different prototyping approach, a system is delivered to its end users as series of iterative prototypes, each of which gradually adds functionality (e.g., Anderson and Crocca 1993; Bertelsen 1996; Trigg 2000). What appears to be critical is that the prototype functions as a *crucial artifact* in the end users' work—for example, a resource of documents for librarians (Anderson and Crocca 1993), an online event checklist that served as the crucial coordination point for the work of diverse contributions (Bertelson 1996), or a database supporting funding work in a nonprofit organization (Trigg 2000). Trigg (2000) provided a series of observations and tactical recommendations about how to engage the users in the evaluations that both they and the software professionals had agreed were needed.

In a rich survey of prototyping practices, Lim, Stolterman, and Teneberg (2008) took a different, more philosophically pragmatic approach to prototyping. In their analysis, prototyping has become a means for exploring a design space and for provoking questions within that space. Critical aspects of the prototype become the ability to *filter*, specifically to highlight the issues to be explored, while ignoring issues that could be distracting. The two case studies in Lim et al. involved conventional unidirectional prototyping—that is, *from* designer *to* user. Thus, these ideas have not yet been explored in a participatory context. It remains to be seen how these new ways of thinking about prototyping will affect participatory prototyping.

Third space. This very brief survey of cooperative prototyping and "iterative delivery" approaches shows several aspects of hybridity. In the case of cooperative prototyping, the cooperative work may be done in a physical third space that is neither the end-user's office nor the software developer's office (see Section 49.4.1). In the case of the delivery of iterated prototypes, each prototype is presented in the end-user's setting, but is unusual and only partially functional, and thus occasions reflection about its nature, its role in the end-user's work, and thus the work itself. In cases, the invitation (or perhaps the necessity) of the end-user's actions to help shape the technology becomes an important means of refocusing their attention, as well as the attention of the software developers. The ensuing conversations are concerned with the interlinked feasibility of changes to technology and to work practices, with attributes of hybridity including polyvocal dialogues, challenging one another's assumptions, and developing plans for collective actions.

Claimed benefits. Some of the virtues of the low-tech prototyping approaches have also been claimed for the cooperative prototyping and "iterative delivery" approaches:

- *Enhanced communication and understanding* through grounding discussions in concrete artifacts
- *Enhanced working relations* through a sense of shared ownership of the resulting design

Additional claims for software-based prototypes include the following:

- *Earlier understanding of constraints* posed by the practical limitations of software
- Improved contextual grounding of the design in the end-user's work practices

49.8 CONCLUSION

Our theme has been hybridity, and the ways in which selected methods in PD may bring useful attributes of hybridity or third space approaches into HCI work. We considered eight trends in PD—selection of sites of shared work, workshops, stories, end-user photography, dramas, creation of shared languages, descriptive artifacts (low-tech prototypes), and working prototypes—and we explored how each of these categories of practice may contribute to hybridity, and what advantages may result. The deliberate and selective use of hybridity has led to powerful methods in PD for increasing communication effectiveness, team coherence, innovation, and quality of outcome. Hybridity is thus at the heart of PD, fostering the critical discussions and reflections necessary to challenge assumptions and to create new knowledges, working practices, and technologies. When we consider HCI as a set of disciplines that lie between the space of work and the space of software development, we see that the hybrid third spaces developed within PD have much to offer HCI in general.

Table 49.2 summarizes the discussion of hybridity in PD, using the criteria derived from cultural studies (Table 49.1) and the experiences described in the eight areas of practice. Table 49.2 shows different patterns of hybridity for different methods, techniques, and practices.

Certain attributes are relatively common across practices—for example, inbetweenness, questioning assumptions, negotiation, and heterogeneity as the norm. Other attributes are relatively rare—for example, considerations of what constitutes legitimate data for analysis or design, how those data are analyzed as evidence, and how conclusions are drawn in each of the several fields that are represented in a team. These are difficult questions in the study of disciplinarity (Chandler, Davidson, and Harootunian 1994; Klein 1996), so it is perhaps not surprising that there is relatively weak support for

[a] Key: + practice includes this attribute of hybridity; − practice does not include this attribute; ? not sure

their exploration in participatory practices. For projects in which these are pivotal questions, we may need new methods that leverage hybridity in new ways. We hope that this survey of PD practices for creating third spaces will lead to new practices that strengthen these missing attributes. Conversely, I hope that new work in PD and HCI can help to ground discussions on some of the cultural studies in new ways.

This chapter would not be complete without a list of unsolved problems in PD:

- *Participation by nonorganized workforce.* The field of PD has long been concerned about how to engage in meaningful participative activities with workers or others who are not organized into a group with collective bargaining power or other collective representation (e.g., Greenbaum 1993, 1996; van den Besselaar, Greenbaum, and Mambrey 1996). This has been a particularly difficult problem when we have tried to compare methods from one country (and political culture) to another (e.g., Muller et al. 1991).
- *Evaluation and metrics.* One of the weaknesses of the literature on participatory practices is the dearth of formal evaluations. While there is general agreement that user involvement is beneficial in many aspects of analysis and design (e.g., Kujala 2003; see also Beyer and Holtzblatt [1998]; Cross [2001]; Dewulf and Van Meel [2002, 2003]; Garzotto [2008]; Pew and Mavor [2007]; Warr and O’Niell [2005]), the best way to structure and channel that “involvement” has been controversial (Druin 2002; Luck 2003; Olsson 2004; Reyman et al. 2005). There is a small set of papers that have examined software engineering projects across companies, and have found positive outcomes related to end-user participation (Cotton et al. 1988; Saarinen and Saaksjarvi 1990). We have been unable to discover any formal experiments comparing participatory methods with nonparticipatory methods in a credible workplace context. While it is possible to conduct design competitions in an academic environment (e.g., Peeters, von Tuijl, and Reyman 2008), the problems addressed are usually scaled to a classroom exercise, and the outcomes must be measured at a very early stage (e.g., *design* outcomes, not product outcomes). Indeed, such studies for real-world products and projects would be difficult to perform, because they would require that a product be implemented and marketed twice (once with participation and once without). The problem is made more difficult

because measurements and metrics of organizational outcomes, user participation, and user satisfaction are currently vexing research issues (e.g., Garrety and Badham 1998; Kappelman 1995; for review, see Gasson [1995]).

- *DPD*. It is already difficult to work across differences. Adding the problem of working across distances as well makes PD more difficult. In this chapter, we have reviewed work in DPD, and much of it is promising. We hope to see more specific methods and techniques that create new kinds of online spaces to continue this work.

50 Unified User Interface Development
A Software Refactoring Perspective

Anthony Savidis and Constantine Stephanidis

CONTENTS

50.1 INTRODUCTION

This chapter discusses the unified user interface development paradigm as an effective software engineering recipe for user interfaces that can be automatically adapted to individual end users and contexts of use. The distinctive procedural, representational, and programming properties of this development discipline are highlighted, qualifying it as a plausible and cost-effective approach toward the goal of developing automatic user interface personalization. The method conveys a fundamentally new perspective into the development of user interfaces, emphasizing a principled, systematic and evolutionary approach toward coping with diversity, by progressively encapsulating and coordinating in an extensible development structure all alternative interaction artifacts.

Finally, we show that runtime adaptation (adaptive behavior) is essentially a cross-cutting system concern for interactive software applications that can be gradually accommodated a posteriori through a software refactoring process. The latter represents a significant methodological leap, since it reveals that adaptive behavior may be introduced within originally nonadaptive systems through a sequence of systematic, architecture-preserving, source code transformations.

50.1.1 Automatic User Interface Adaptation

The notion of automatic user interface adaptation reflects the capability of interactive software to adapt during runtime to the individual end user and to the particular context of use by delivering the most appropriate interactive experience. The storage location, origin, and format of user-oriented information may vary. For example, information may be stored in profiles, indexed by unique user identifiers, extracted from user-owned cards, entered by the user in an initial interaction session, or inferred by the system through continuous interaction monitoring and analysis. Additionally, usage-context information, such as user location, environment noise, network bandwidth, and so forth, is normally provided by special purpose equipment, like sensors, or system-level software. To support optimal interface delivery for individual user- and usage-context attributes, it is required that for any given user task or group of user activities, the implementations of the alternative best fit interface components are either implementationally encapsulated or appropriately locatable (e.g., remote components, downloadable plug-ins, dynamically linked libraries, etc.).

50.1.2 The Concept of Unified User Interfaces

A unified user interface is the interaction-specific software of software applications or services, which is capable of self-adapting to the characteristics of the individual end user and context of use. Such an adaptation may reflect varying patterns of interactive behavior, at the physical, syntactic, or semantic level of interaction, to accommodate specific user- and context-oriented parameters. Practically speaking, from the end-user point of view, a unified user interface is actually an interface that can automatically adapt to the individual user attributes (e.g., requirements, abilities, and preferences), as well as to the particular characteristics of the usage context (e.g., computing platform, peripheral devices, interaction technology, and surrounding environment). Therefore, a unified user interface realizes the combination of the following:

- User-adapted behavior, such as the automatic delivery of the most appropriate user interface for the particular end user (requires user awareness).
- Usage-context-adapted behavior, such as the automatic delivery of the most appropriate user interface for the particular situation of use (requires usage context awareness).
- Hence, the characterization unified does not have any particular behavioral connotation, at least as seen from an end-user perspective. Instead, the notion of unification reflects the specific software engineering strategy needed to accomplish this behavior, emphasizing the proposed systematic development-oriented discipline. More specifically, to realize this form of adapted behavior, a unified user interface reflects the following fundamental development properties.
- It encapsulates alternative dialogue patterns (e.g., implemented dialogue artifacts), for various dialogue design contexts (e.g., a subtask, a primitive user action, a visualization), appropriately associated with the different values of user- and usage-context-related attributes. The need for such alternative dialogue patterns may only be dictated by the user interface design process, when, given any particular design context, for different user- and usage-context attribute values, alternative design artifacts are needed to accomplish optimal interaction.
- It implementationally encapsulates representation schemes for user- and usage-context parameters, internally utilizing user- and usage-context information resources (e.g., repositories, servers), to extract or to update user- and usage-context information.
- It encapsulates the necessary user interface design knowledge and decision-making capability for activating, during runtime, the most appropriate dialogue patterns (e.g., interactive software components), according to particular instances of user- and usage-context attributes.

The distinctive property of unified user interfaces to encapsulate alternative, mutually exclusive, user interface design artifacts, each purposefully designed and implemented as an optimal alternative for its corresponding target attributes of the user- and usage-context models, assuming a particular design context, constitutes one of the main contributions of this research work within the user interface software engineering field.

50.2 UNIFIED USER INTERFACE DESIGN

50.2.1 The Design Problem

Universal design in human–computer interaction (HCI) reflects the principle to address potentially all users and usage contexts—anyone, anyplace, anytime. Its main objective is to ensure that each end user is given the most appropriate interactive experience by supporting both accessible and high-quality interaction. In this context, to accommodate genuinely universal design in the production process of software application and services, two key issues need to be optimally addressed. The first is scientific, primarily concerning the way the particular problem is to be technically resolved, while the second is cost-specific, reflecting the criticality for cost-effective and economically viable solutions. Clearly, producing and enumerating distinct user interface designs through the conduct of multiple design processes is an impractical solution, since the overall cost for managing in parallel such a large number of independent design processes, as well as for transforming each produced user interface version into a target software implementation, would be unacceptable both for the design and the software implementation phases. Instead, a design process is required which may lead to a single design outcome that appropriately links and organizes the differentiating aspects of the resulting interactive application, around common abstract design structures and patterns, making it far easier to (a) map to a target software system implementation and (b) maintain, update, and extend the design itself.

The need for introducing alternative design artifacts, even for the same specific design context (such as a particular subtask), emerges from the fact that, in universal design, the design problem encompasses largely varying parameters, such as user- and usage-context parameters. Consequently, when designing for any particular dialogue design context, it is likely that differentiating values of those problem parameters dictate the design of diverse dialogue artifacts. This issue introduces two important requirements for pursuing a suitable design method.

The first is that such a method should offer the capability to associate multiple alternative dialogue artifacts to a particular single design context, due to the varying design problem parameters, by enabling the unambiguous association of each alternative artifact with its corresponding values of the problem parameters.

The second is that the method should emphasize capturing of the more abstract structures and patterns inherent within user interface designs, enabling the hierarchical incremental specialization toward the lower physical level of interaction, making it possible to introduce alternative dialogue patterns as close to the physical design as possible. This will make it far easier for the design space to be updated and to evolve, since modifications and extensions due to the consideration of additional values of the problem parameters (e.g., considering new user- and usage-context attribute values) can be applied locally closer to the lower levels of the design, without affecting the rest of the design space.

To demonstrate briefly the need for supporting alternative dialogue artifacts for the same design context, an example from a real-life application will be used. The AVANTI web browser (Stephanidis et al. 2001) was developed to enable web access by supporting adaptation to the particular user as well as to the context of use. During the user interface design phase, while concentrating on the design context of the link dialogue task, alternative designs have been dictated, due to varying user- and usage-context parameters considered, as shown in Figure 50.1.

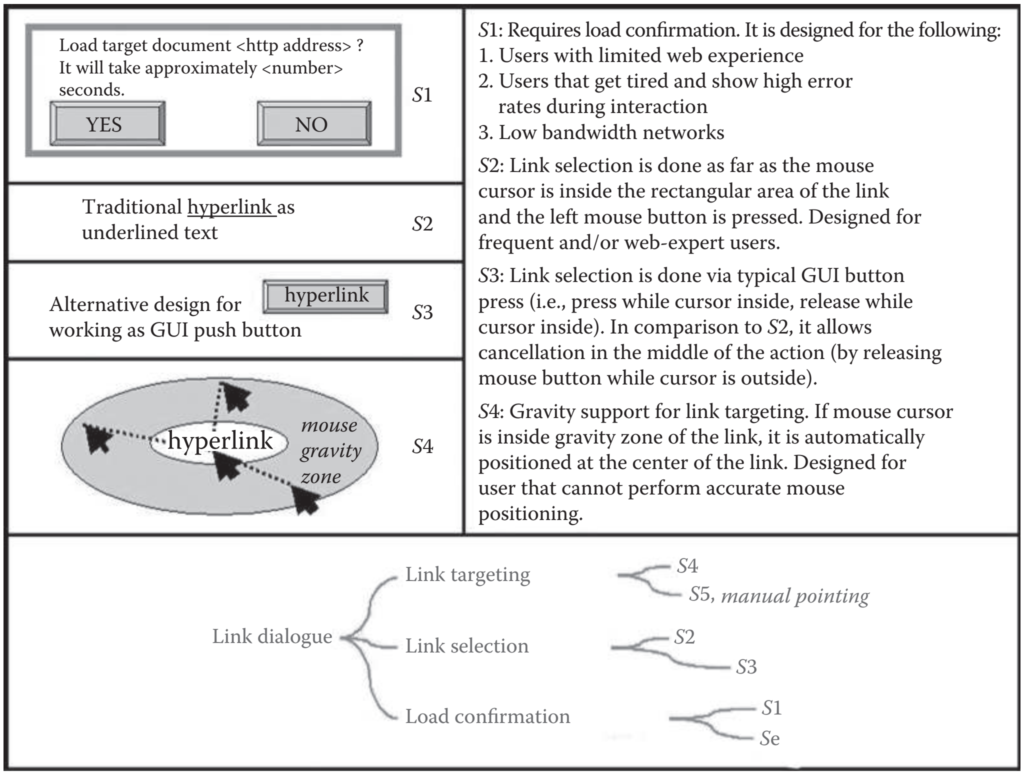
Since the differing artifacts have been part of the final AVANTI web browser user interface design, the design representation formalism is needed to enable their copresence within the resulting design space by clearly associating each artifact to the link-selection task and its corresponding values of the user- and usage-context parameters. A loose design notation is used in Figure 50.1 to show hierarchical task analysis (subtask sequencing is omitted for clarity), as well as the need for alternative incarnations of a single task (e.g., styles S2/S3 for link selection, styles S1/Se for load confirmation, and styles S4/S5 for link targeting). Following this example taken from the AVANTI web browser, during runtime, depending on the particular end user and usage-context attribute values, the appropriate corresponding implemented artifacts will only have to be activated.

50.2.2 Polymorphic Task Hierarchies

A polymorphic task hierarchy combines three fundamental properties: (a) hierarchical decomposition, (b) polymorphism, and (c) task operators. The hierarchical decomposition adopts the original properties of hierarchical task analysis for incremental decomposition of user tasks to lower-level actions. The polymorphism property provides the design differentiation capability at any level of the task hierarchy, according to particular user- and usage-context attribute values. Finally, task operators, which are based on the communicating sequential processes (CSP) language for describing the behavior of reactive systems (Hoare 1978), enable the expression of dialogue control flow formulae for task accomplishment. Those specific operators, taken from the domain of reactive systems and process synchronization, have been selected due to their appropriateness in expressing temporal relationships of user actions and tasks. However, designers may freely use additional operators as needed (e.g., the set is not closed) or may choose to document dialogue sequencing and control outside the task-structure in natural language, when it engages more comprehensive algorithmic logic (e.g., consider the verbally documented precondition if the logged user is a guest, no sign-in is required, else the access privileges should be checked and the sign-in dialogue is activated before chat).

The concept of polymorphic task hierarchies is illustrated in Figure 50.2. Alternative task decomposition is called a “decomposition style,” or simply a “style,” and is to be given by designers an appropriate descriptive name. Alternative task sub-hierarchies are attached to their respective styles. The example polymorphic task hierarchy of Figure 50.2 indicates the way two alternative dialogue styles for a “Delete File” task can be designed—one exhibiting direct manipulation properties with object-function syntax (e.g., the file object is selected prior to operation to be applied) with no confirmation, the other realizing modal dialogue with a function-object syntax (e.g., the delete function is selected, followed by the identification of the target file) and confirmation.

Additionally, the example demonstrates the case of physical specialization. Since selection is an abstract task, it is possible to design alternative ways for physically instantiating the selection dialogue (see Figure 50.2, lower-part), via scanning techniques for motor-impaired users, via three-dimensional (3D) hand pointing on 3D auditory cues for blind people, via enclosing areas (e.g., irregular rubber banding) for sighted users, and via Braille output and keyboard input for deaf and blind users. The unified user interface design



*S*1: Requires load confirmation. It is designed for the following:
1. Users with limited web experience
2. Users that get tired and show high error rates during interaction
3. Low bandwidth networks

*S*2: Link selection is done as far as the mouse cursor is inside the rectangular area of the link and the left mouse button is pressed. Designed for frequent and/or web-expert users.

*S*3: Link selection is done via typical GUI button press (i.e., press while cursor inside, release while cursor inside). In comparison to *S*2, it allows cancellation in the middle of the action (by releasing mouse button while cursor is outside).

*S*4: Gravity support for link targeting. If mouse cursor is inside gravity zone of the link, it is automatically positioned at the center of the link. Designed for user that cannot perform accurate mouse positioning.

FIGURE 50.1 Designing alternative artifacts for the Link dialogue task. *S*e is used to indicate “empty” (i.e., no load confirmation dialogue supported). *S*5 is the typical manual link targeting GUI dialogue through the mouse.

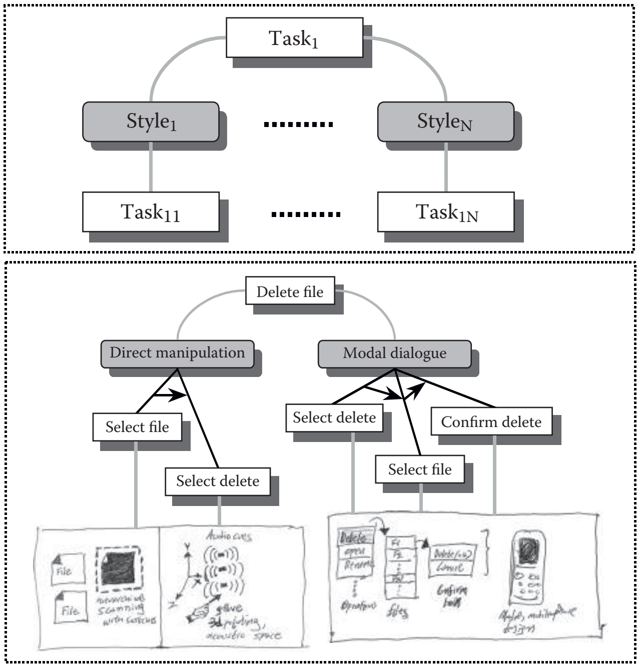


FIGURE 50.2 The polymorphic task hierarchy concept, where alternative decomposition “styles” are supported (upper part), and an exemplary polymorphic decomposition, which includes physical design annotation (lower part).

method does not require the designer to follow the polymorphic task decomposition all the way down the user-task hierarchy, until primitive actions are met. A nonpolymorphic task can be specialized at any level, following any design method chosen by the interface designer. For instance, in Figure 50.2 (lower part), graphical mock-ups are used to describe each of the alternative physical instantiations of the abstract selection task. It should be noted that the interface designer is not constrained to using a particular model, such as CSP operators, for describing user actions for device-level interaction (e.g., drawing, drag-and-drop, concurrent input). Instead, an alternative may be preferred, such as an event-based representation, such as ERL (Hill 1986) or UAN (Hartson et al. 1990).

As discussed in more detail in the subsequent sections, design polymorphism entails a decision-making capability for context-sensitive selection among alternative artifacts to assemble a suitable interface instance, while task operators support temporal relationships and access restrictions applied to the interactive facilities of a particular interface instance.

50.2.3 The Conduct of the Method

In the unified user interface design method, there are three categories of design artifacts, all of which are subject to polymorphism on the basis of varying user- and usage-context parameter values. These three categories are as follows (see Figure 50.3):

1. User tasks, relating to what the user has to do; user tasks are the center of the polymorphic task decomposition process.
2. System tasks, representing what the system has to do, or how it responds to particular user actions (e.g., feedback); in the polymorphic task decomposition process, system tasks are treated in the same manner as user tasks.
3. Physical design that concerns the various physical interface components on which user actions corresponding to the associated user task are to be performed; the physical structure may also be subject to polymorphism.

System tasks and user tasks may be freely combined within task formulas, defining how sequences of user-initiated actions and system-driven actions interrelate. The physical design, providing the interaction context, is always associated with a particular user or system task. It provides the physical dialogue pattern associated to a task-structure definition. Hence, it plays the role of annotating the task hierarchy with physical design information. An example of such annotation is shown in Figure 50.2, where the physical designs for the "Select delete" task are explicitly depicted.

In some cases, given a particular user task, there is a need for differentiated physical interaction contexts, depending on user- and usage-context parameter values. Hence, even though the task decomposition is not affected (e.g., the same user actions are to be performed), the physical design may have to be altered. One such representative example is relevant to changing particular graphical attributes on the basis of ethnographic user attributes. For instance, Marcus (1996) discussed the choice of different iconic representations, background patterns, visual message structure, and so forth on the basis of cultural background. User tasks, and in certain cases, system tasks, need not always be related to physical interaction, but may represent abstraction on either user or system actions. For instance, if the user has to perform a selection task, then, clearly, the physical means of performing such a task are not explicitly defined, unless the dialogue steps to perform selection are further decomposed.

This notion of continuous refinement and hierarchical analysis, starting from higher level abstract artifacts, and incrementally specializing towards the physical level of interaction is fundamental in the context of hierarchical behavior analysis, either regarding tasks that humans have to perform (Johnson et al. 1988) or when it concerns functional system design (Saldarini 1989). At the core of the unified user interface design method is the polymorphic task decomposition process, which follows the methodology of abstract task definition and incremental specialization, where tasks may be hierarchically analyzed through various alternative schemes. In such a recursive process, involving tasks ranging from the abstract task level to specific physical actions, decomposition is applied either in a traditional unimorphic fashion or by means of alternative styles. The overall process is illustrated in Figure 50.4; the decomposition starts from abstract or physical task design, depending on whether top-level user

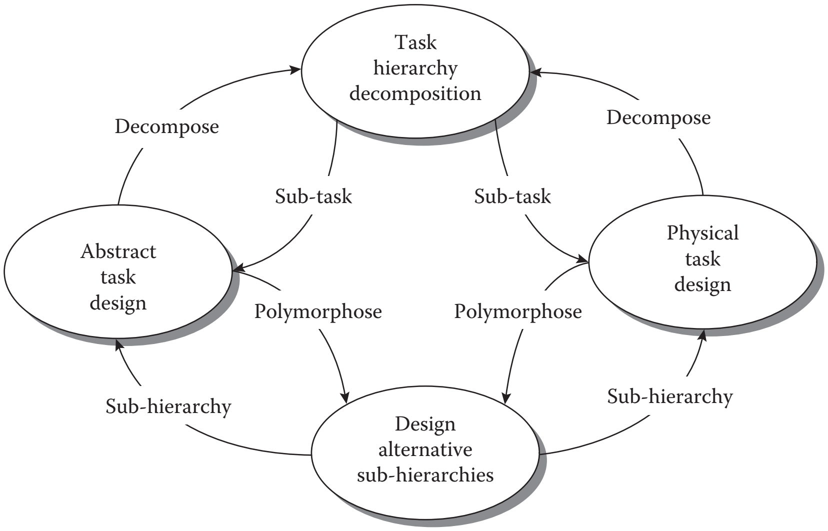

FIGURE 50.4 The polymorphic task decomposition process in the unified user interface design method.

tasks can be defined as being abstract or not. Next follows the description of the various transitions (e.g., design specialization steps) from each of the four states illustrated in the process state diagram of Figure 50.4.

50.2.3.1 Transitions from the Abstract Task Design State

An abstract task can be decomposed either in a polymorphic fashion, if user- and usage-context attribute values pose the necessity for alternative dialogue patterns, or in a traditional manner, following a unimorphic decomposition scheme. In the case of a unimorphic decomposition scheme, the transition is realized via a decomposition action, leading to the task hierarchy decomposition state. In the case of a polymorphic decomposition, the transition is realized via a polymorphose action, leading to the alternative sub-hierarchies design state.

50.2.3.2 Transitions from the Alternative Sub-Hierarchies Design State

Reaching this state means that the required alternative dialogue styles have been identified, each initiating a distinct sub-hierarchy decomposition process. Hence, each such sub-hierarchy initiates its own instance of polymorphic task decomposition process. While initiating each distinct process, the designer may start either from the abstract task design state or from the physical task design state. The former is pursued if the top-level task of the particular sub-hierarchy is an abstract one. In contrast, the latter option is relevant in case the top-level task explicitly engages physical interaction issues.

50.2.3.3 Transitions from the Task Hierarchy Decomposition State

From this state, the subtasks identified need to be further decomposed. For each subtask at the abstract level, there is a subtask transition to the abstract task design state. Otherwise, if the subtask explicitly engages physical interaction means, a subtask transition is taken to the physical task design state.

50.2.3.4 Transitions from the Physical Task Design State

Physical tasks may be further decomposed either in a unimorphic fashion or in a polymorphic fashion. These two alternative design possibilities are indicated by decompose and polymorphose transitions, respectively.

50.2.4 Relationships among Alternative Styles

The need for alternative styles emerges during the design process when it is identified that there are particular user- and usage-context attribute values not addressed by the dialogue artifacts that have already been designed. Starting from this observation, one could argue that all alternative styles, for a particular polymorphic artifact, are mutually exclusive to each other (in this context, exclusion means that, at runtime, only one of those styles may be active).

However, cases in which it is meaningful to make artifacts belonging to alternative styles exist, concurrently available in a single adapted interface instance. A typical case concerns file management tasks, where two alternative but compatible artifacts may coexist during runtime, such as a direct-manipulation one and a command-based one, such as task-level multimodality. In the unified user interface design method, four design relationships between alternative styles are distinguished (see Figure 50.5), defining whether alternative styles may be concurrently present at runtime. These four fundamental relationships reflect pragmatic, real-world design scenarios.

50.2.4.1 Exclusion

The exclusion relationship is applied when the various alternative styles are deemed usable only within the space of their target user- and usage-context attribute values. For instance, assume that two alternative artifacts for a particular subtask are being designed, aiming to address the user-expertise attributes: one targeted to users qualified as novice and the other targeted to expert users. Then, these two are defined

Exclusion *Relates many styles.* Only one from the alternative styles may be present.

Compatibility *Relates many styles.* Any of the alternative styles may be present.

Substitution *Relates two groups of styles together.* When the second is made "active" at runtime, the first should be "deactivated."

Augmentation *Relates one style with a group of styles.* On the presence of any style from the group at runtime, the single style may be also "activated."

FIGURE 50.5 Design relationships among alternative styles and their runtime interpretation.

to be mutually exclusive to each other, since it is probably meaningless to activate concurrently both dialogue patterns. For example, at runtime a novice user might be offered a functionally simple alternative of a task, where an expert user would be provided with additional functionality and greater freedom in selecting different ways to accomplish the same task.

50.2.4.2 Compatibility

Compatibility is useful among alternative styles for which the concurrent presence during interaction allows the user to perform certain actions in alternative ways, without introducing usability problems. The most important application of compatibility is for task multimodality, as it has been previously discussed for the file management tasks.

50.2.4.3 Substitution

Substitution has a very strong connection with adaptivity techniques. It is applied in cases where, during interaction, it is decided that some dialogue patterns need to be substituted by others. For instance, the ordering and the arrangement of certain operations may change on the basis of monitoring data collected during interaction, through which information such as frequency of use and repeated usage patterns can be extracted. Hence, particular physical design styles would need to be cancelled, while appropriate alternatives would need to be activated. This sequence of actions, for example, cancellation followed by activation, is the realization of substitution. Thus, in the general case, substitution involves two groups of styles: some styles are cancelled and substituted by other styles that are activated afterwards.

50.2.4.4 Augmentation

Augmentation aims to enhance the interaction with a particular style that is found to be valid but not sufficient to facilitate the user's task. To illustrate this point, assume that, during interaction, the user interface detects that the user is unable to perform a certain task. This would trigger an adaptation (in the form of adaptive action) aiming to provide task-sensitive guidance to the user. Such an action should not aim to invalidate the active style (by means of style substitution), but rather to augment the user's capability to accomplish the task more effectively by providing informative feedback. Such feedback can be realized through a separate but compatible style. Therefore, it follows that the augmentation relationship can be assigned to two styles when one can be used to enhance the interaction while the other is active. Thus, for instance, the adaptive prompting dialogue pattern, which provides task-oriented help, may be related via an augmentation relationship with all alternative styles (of a specific task), provided that it is compatible with them.

50.3 UNIFIED INTERFACE ENGINEERING

In the context of a unified user interface, upon startup and during runtime, the software user interface relies on the particular user and context profiles to assemble the eventual interface on the fly, collecting and gluing together the constituent interface components required for the particular end user and usage context. Such constituent components are the alternative artifacts identified during the user interface design process, which need to be appropriately transformed in the development phase to an implementation form.

Effectively, a unified user interface consists of runtime components, each with a distinctive role in performing at runtime a type of an interface assembly process, by selecting the most appropriate dialogue patterns from the available implemented design space (e.g., the organized collection of all dialogue artifacts produced during the design phase). Examples of such intelligent selection and assembly of user interface components for adapted interaction delivery are provided in Figures 50.6 and 50.7, taken from the AVANTI Project (Stephanidis et al. 2001).

A unified user interface does not constitute a monolithic software system but becomes a distributed architecture consisting of independent intercommunicating components, possibly implemented with different software methods/tools and residing at different physical locations. These components co-operate to perform adaptation according to the individual end-user attributes and the particular usage context. At runtime, the overall adapted interface behavior is realized by two complementary classes of system-initiated actions:

1. Adaptations driven from initial user and context information, acquired without performing interaction monitoring analysis (e.g., what is known before starting observing the user or the usage context)
2. Adaptations decided on the basis of information inferred or extracted by performing interaction-monitoring analysis (e.g., what is learned by observing the user or the usage context)

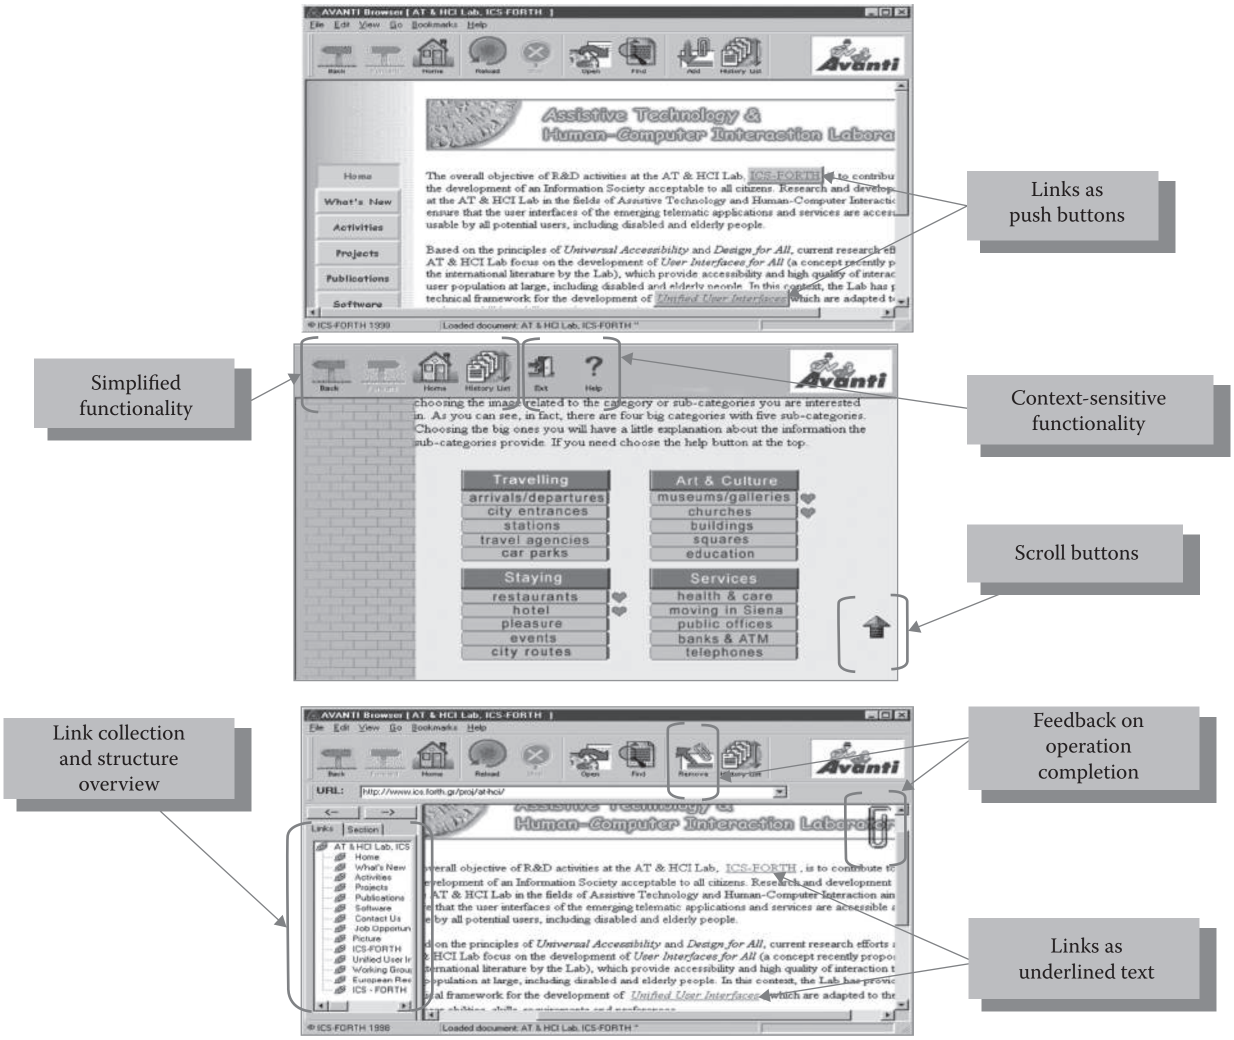

FIGURE 50.6 Three different interface versions of the AVANTI browser produced by adaptation-oriented selection of different alternative styles.

The former behavior is referred to as "adaptability" (e.g., initial automatic adaptation, performed before initiation of interaction), reflecting the capability of the interface to proactively and automatically tailor itself to the attributes of each individual end user. The latter behavior is referred to as "adaptivity" (e.g., continuous automatic adaptation) and characterizes the capability of the interface to cope with the dynamically changing/evolving characteristics of users and usage contexts. Adaptability is crucial to ensure accessibility, since it is essential to provide, before initiation of interaction, a fully accessible interface instance to each individual end user. Adaptivity can be applied only on accessible running interface instances (e.g., ones with which the user is capable of performing interaction), since interaction monitoring is required for the identification of changing or emerging decision parameters that may drive dynamic interface enhancements. The complementary roles of adaptability and adaptivity are depicted in Figure 50.8. This fundamental distinction is made due to the different runtime control requirements between those two key classes of adaptation behaviors, requiring different software engineering policies.

50.3.1 Architectural Overview

In this section, the runtime architecture for unified user interfaces will be discussed, providing an outline of the adopted architectural components with information regarding (a) the functional role, (b) the runtime behavior, (c) the encapsulated context, and (d) the implementation method. The components of the unified user interface architecture are the following (see Figure 50.9):

- User-information server (UIS)
- Context parameters server
- Decision-making component (DMC)
- Dialogue patterns component (DPC)

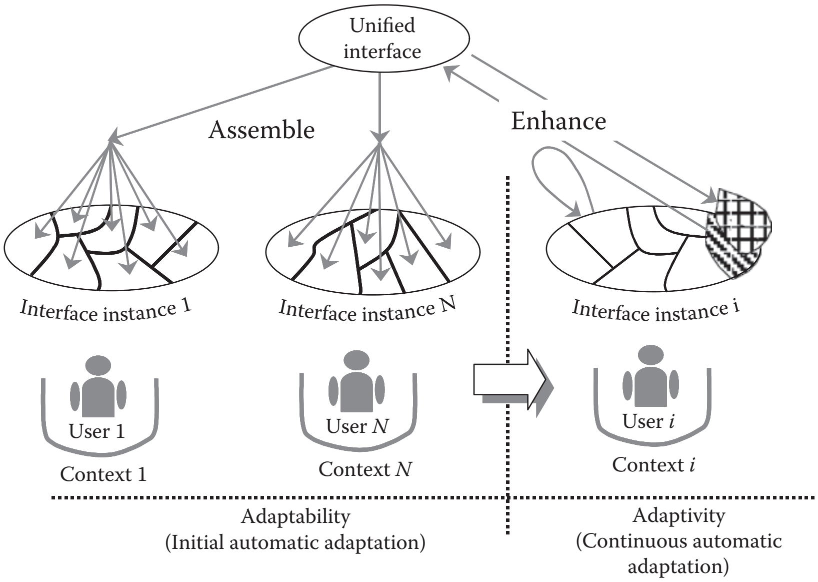

FIGURE 50.8 The complementary roles of adaptability (left) and adaptivity (right) as realized in unified user interfaces to provide user- and usage-context-adapted-behavior.

50.3.1.1 User-Information Server

Its functional role is to supply user attribute values (1) known offline, without performing interaction-monitoring analysis (e.g., motor/sensory abilities, age, nationality, etc.), and (2) detected online, from real-time interaction-monitoring analysis (e.g., fatigue, loss of orientation, inability to perform the task, interaction preferences, etc.). During runtime, it plays a twofold role: (1) it constitutes a server that maintains and provides information regarding individual user profiles and (2) it encompasses user-representation schemes, knowledge processing components, and design information dynamically to detect user properties or characteristics. This component may need to use alternative ways of representing user-oriented information. In this sense, a repository of user profiles serves as a central database of individual user information (e.g., registry). In many cases, a profile structure as a typical list of typed attributes will suffice shown; this model, though quite simple, is proved in real practice to be very powerful and flexible (can be stored in a database, thus turning the profile manager to a remotely accessed database).

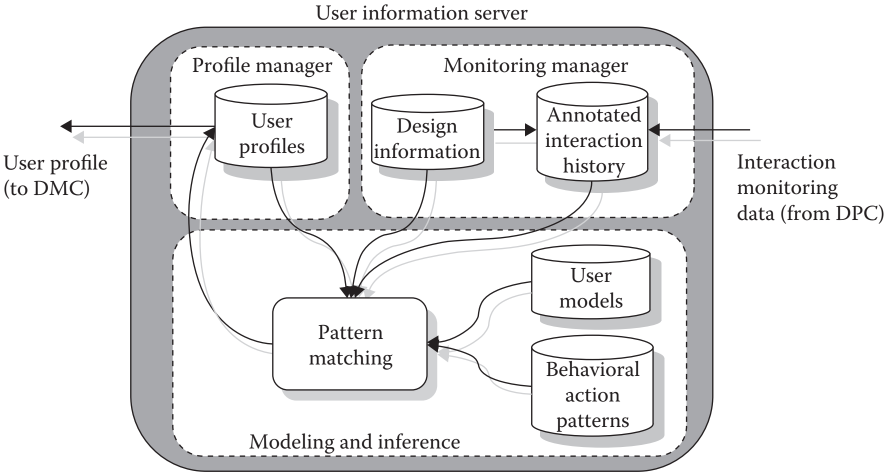

FIGURE 50.10 Internal microarchitecture of the user information server. User profile is posted to the decision-making component (DMC), while interaction-monitoring information is received from the dialogue patterns component (DPC).

Additionally, more sophisticated user representation and modeling methods can be used, including support for stereotypes of particular user categories. In case dynamic user-attribute detection is to be supported, the content may include dynamically collected interaction monitoring information, design information, and knowledge-processing components.

From a knowledge representation point of view, static or preexisting user knowledge may be encoded in any appropriate form; depending on the type of information, the user information server should feed to the decision-making process. Moreover, additional knowledge-based components may be used for processing retrieved user profiles, drawing assumptions about the user or updating the original user profiles. In Figure 50.10, the internal architecture of the user-information server used in the AVANTI web browser is presented. It should be noted that the first version of the AVANTI web browser produced in the context of the AVANTI Project used BGP-MS (Kobsa and Pohl 1995) for the role of the user-information server. The profile manager has been implemented as a database of profiles. The two other subsystems (e.g., monitoring manager, modeling, and inference) are needed only in case dynamic user-attribute detection is required. The interaction monitoring history has been implemented as a time-stamped list of monitoring events (the structure of monitoring events is described in the analysis of communication semantics) annotated with simple dialogue design context information (e.g., just the subtask name). In the user models, all types of dynamically detected user attributes have been identified (e.g., inability to perform a task, loss of orientation—those were actually the two dynamically detectable attributes required by the design in the AVANTI web browser). Each such attribute is associated with its corresponding behavioral action patterns. In the specific case, the representation of the behavioral patterns has been implemented together with the pattern-matching component, by means of state automata.

For instance, one heuristic pattern to detect loss of orientation has been defined as follows: The user moves the cursor inside the web-page display area, without selecting a link, for more than *N* seconds. The state automaton (see Figure 50.11) starts recording mouse moves in the page area, based on incoming monitored mouse moves, while finally triggering detection when no intermediate activity is successfully performed by the user. This worked fine from an implementation point of view. However, from the user interface design point of view, all such heuristic assumptions and behavioral patterns had to be extensively verified with real users so as to assert the relationship between the observable user behavior

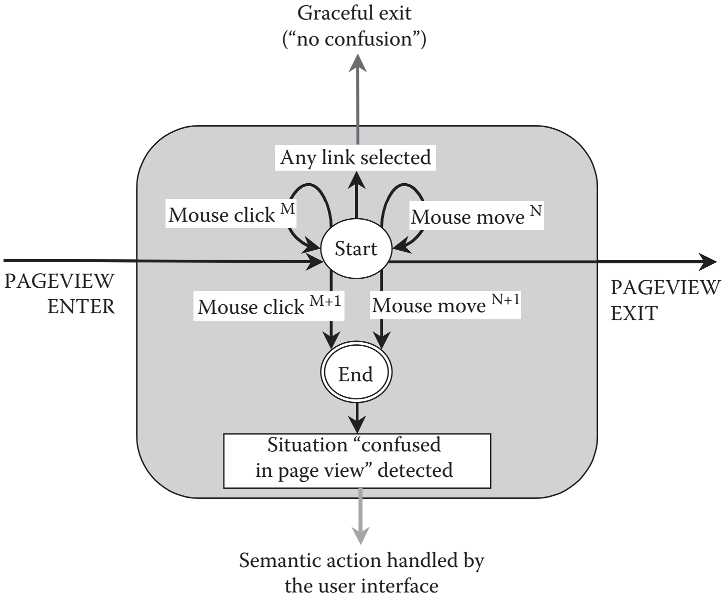

FIGURE 50.11 An example of an augmented state automaton used as an implementation technique for behavioral patterns; the state automaton is directly hard-coded in the UIS side, while multiple such automata coexist.

and the particular-inferred user attributes. This is a common issue in all adaptive systems that use heuristics for detecting user attributes at runtime, practically meaning that the validity of the assumptions inferred is dependent on the appropriateness of the specific user-action patterns chosen.

50.3.1.2 Context Parameters Server

The purpose of this component is to supply context attribute values (machine and environment) of two types: (1) (potentially) invariant, meaning unlikely to change during interaction, such as peripheral equipment and (2) variant, dynamically changing during interaction (e.g., environment noise, failure of particular equipment, etc.). This component is not intended to support device independence, but to provide device awareness. Its purpose is to enable the decision-making component to select those interaction patterns, which, apart from fitting the particular end-user attributes, are also appropriate for the type of equipment available on the end-user machine.

The usage-context attribute values are communicated to the decision-making component before the initiation of interaction. Additionally, during interaction, some dynamically changing usage-context parameters may also be fed to the decision-making component for decisions regarding adaptive behavior. For instance, assume that the initial decision for selecting feedback leads to the use of audio effects. Then, the dynamic detection of an increase in environmental noise may result in a runtime decision to switch to visual feedback (the underlying assumption being that such a decision does not conflict with other constraints).

This component encompasses a listing of the various invariant properties and equipment of the target machine (e.g., handheld binary switches, speech synthesizer for English, high-resolution display, mode 16 bits, 10243768, noisy environment, etc.). In this context, the more information regarding the characteristics of the target environment and machine is encapsulated, especially concerning input/output devices, the better adaptation can be achieved (information initially appearing redundant is likely to be used in future adaptation-oriented extensions).

The registry of environment properties and available equipment can be implemented easily as a profile manager in the form of a database. Such information will be communicated to the decision-making component as attribute/value pairs. However, if usage-context information is to be dynamically collected, such as environment noise or reduction of network bandwidth, the installation of proper hardware sensors or software monitors becomes mandatory.

50.3.1.3 Decision-Making Component

The role of this component is to decide, at runtime, the necessary adaptability and adaptivity actions and subsequently to communicate those to the dialogue patterns component (the latter being responsible for applying adaptation-oriented decisions). To decide adaptation, this component performs a kind of rule-based knowledge processing, to match end-user and usage-context attribute values to the corresponding dialogue artifacts, for all the various dialogue contexts.

This module encompasses the logic for deciding the necessary adaptation actions, on the basis of the user- and context-attribute values, received from the user-information server and the context parameters server, respectively. Such attribute values will be supplied to the decision-making component prior to the initiation of interaction within different dialogue contexts (e.g., initial values, resulting in initial interface adaptation), as well as during interaction (e.g., changes in particular values, or detection of new values, resulting in dynamic interface adaptations).

In the proposed approach, the encapsulated adaptation logic should reflect predefined decisions during the design stage. In other words, the inference mechanisms use well-defined decision patterns that have been validated during the design phase of the various alternative dialogue artifacts. In practice, this approach leads to a rule-based implementation, in which embedded knowledge reflects adaptation rules that have been already constructed and documented as part of the design stage. This decision-making policy is motivated by the assumption that if a human designer cannot decide upon adaptation for a dialogue context, given a particular end user and usage context, then a valid adaptation decision cannot be taken by a knowledge-based system at runtime. Later in this chapter, while discussing some implementation details of the AVANTI web browser, specific excerpts from the rule base of the decision engine will be discussed.

The first remark regarding the implementation of decision-making concerns the apparent awareness regarding (1) the various alternative dialogue artifacts (how they are named, e.g., virtual keyboard, for which dialogue context they have been designed, e.g., http address text field), and (2) user- and usage-context attribute names and their respective value domains (e.g., attribute age being integer in range 5 … 110).

The second issue concerns the input to the decision process, being individual user- and usage-context attribute values. Those are received at runtime both from the user-information server and from the context information server, either by request (e.g., the decision-making component takes the initiative to request the end-user and usage-context profile at start up to draw adaptability decisions) or by notification (e.g., when the user-information server draws assumptions regarding dynamic user attributes or when the context parameters server identifies dynamic context attributes).

The third issue concerns the format and structure of knowledge representation. In all developments that we have carried out, it has been proved that a rule-based logic implementation is practically adequate. Moreover, all interface designers engaged in the design process emphasized that this type of knowledge representation approach is far more close to their own way of rule-based thinking in deciding adaptation. This remark has led to excluding, at a very early stage, other possible approaches, such as heuristic pattern matching, weighting factor matrices, or probabilistic decision networks.

The final issue concerned the representation of the outcomes of the decision process in a form suitable for being communicated and easily interpreted by the dialogue patterns component. In this context, it has been practically proved that two categories of dialogue control actions suffice to communicate adaptation decisions: (1) activation of specific dialogue components and (2) cancellation of previously activated dialogue components. These two categories of adaptation actions provide the expressive power necessary for communicating the dialogue-component manipulation requirements that realize both adaptability and adaptivity. Substitution is modeled by a message containing a series of cancellation actions (e.g., the dialogue components to be substituted), followed by the necessary number of activation actions (e.g., which dialogue components to activate in place of the cancelled components). Therefore, the transmission of those commands in a single message (e.g., cancellation actions followed by activation actions) is to be used for implementing a substitution action. The need to send in one message packaged information regarding the cancelled component, together with the components that take its place, emerges when the implemented interface requires knowledge of all (or some of) the newly created components during interaction. For instance, if the new components include a container (e.g., a window object) with various embedded objects, and if upon the creation of the container information on the number and type of the particular contained objects is needed, it is necessary to ensure that all the relevant information (e.g., all engaged components) is received as a single message. It should be noted that, since each activation/cancellation command always carries its target UI component identification, it is possible to engage in substitution requests components that are not necessarily part of the same physical dialogue artifact. In addition, the decision to apply substitution is the responsibility of the decision-making component.

One issue regarding the expressive power of activation and cancellation decisions categories concerns the way dynamic interface updates (e.g., changing style or appearance, without closing or opening interface objects) can be effectively addressed. The answer to this question is related to the specific connotation attributed to the notion of a dialogue component. A dialogue component may not only implement physical dialogue context, such as a window and embedded objects, but may concern the activation of dialogue control policies or be realized as a particular sequence of interface manipulation actions. In this sense, the interface updates are to be collected in an appropriate dialogue implementation component (e.g., a program function, an object class, a library module) to be subsequently activated (e.g., called) when a corresponding activation message is received. This is the specific approach taken in the AVANTI web browser, which, from a software engineering point of view, enabled a better organization of the implementation modules around common design roles.

50.3.1.4 Dialogue Patterns Component

This component is responsible for supplying the software implementation of all the dialogue artifacts that have been identified in the design process. Such implemented components may vary from dialogue artifacts that are common across different user- and usage-context attribute values (e.g., no adaptation needed) to dialogue artifacts that will map to individual attribute values (e.g., alternative designs have been necessitated for adapted interaction). Additionally, as it has been previously mentioned, apart from implementing physical context, various components may implement dialogue-sequencing control, perform interface manipulation actions, maintain shared dialogue state logic, or apply interaction monitoring.

The dialogue patterns component should be capable of applying at runtime, activation, or cancellation decisions originated from the decision-making component. Additionally, interaction-monitoring components may need to be dynamically installed/uninstalled on particular physical dialogue components. This behavior will serve the runtime interaction monitoring control requests from the user-information server to provide continuous interaction monitoring information back to the user-information server for further intelligent processing. The dialogue patterns component either embeds the software implementation of the various dialogue components or is aware of where those components physically reside by used dynamic query, retrieval, and activation methods. The former is the typical method that can be used if the software implementation of the components is provided locally by means of software modules, libraries, or resident installed components. Usually, most of the implementation is to be carried out in a single programming language. The latter approach reflects the scenario in which distinct components are implemented on top of component-ware technologies, usually residing in local/remote component repositories (also called "registries" or "directories"), enabling reuse with dynamic deployment.

In the development of the AVANTI web browser, a combination of these two approaches has been used by implementing most of the common dialogue components into a single language (actually in C11 by using all the necessary toolkit libraries) while implementing some of the alternative dialogue artifacts as independent Active X components that were located and employed on the fly. The experience from the software development of the AVANTI web browser has proved that (1) the single language paradigm makes it far easier to perform quick implementation and testing of interface components and (2) the component-based approach largely promotes binary format reuse of implemented dialogue components while offering far better support for dynamic interface assembly, which is the central engineering concept of unified user interfaces (this issue will elaborate on the conclusion section of the chapter).

The microarchitecture of the dialogue patterns component internally used in the AVANTI web browser, as outlined in Figure 50.12, emphasizes internal organization to enable extensibility and evolution by adding new dialogue components. Additionally, it reflects the key role of the dialogue patterns component in applying adaptation decisions. The internal components are as follows.

The activation dispatcher locates the source of implementation of a component (or simply uses its application programming interfaces [APIs], if it is a locally used library) to activate it. In this sense, activation may imply a typical instantiation in OOP terms, calling of particular service functions or activating a remotely located object. After a component is activated, if cancellation is to be applied to this component, it is further registered in a local registry of activated components. In this registry, the indexing parameters used are the particular dialogue context (e.g., subtask, for instance, "http address field") and the artifact design descriptor (e.g., unique descriptive name provided during the design phase—for instance, "virtual keyboard"). For some categories of components, cancellation may not be defined during the design process, meaning there is no reason to register those at runtime for possible future cancellation (e.g., components with a temporal nature that perform only some interface update activities).

The cancellation dispatcher locates a component based on its indexing parameters and calls for cancellation. This may imply a typical destruction in OOP terms, calling internally particular service functions that may typically perform the unobtrusive removal of the physical view of the cancelled component or the release of a remote object instance. After cancellation is performed, the component instance is removed from the local registry.

The monitoring manager plays a twofold role: (1) It applies monitoring control requests originated from the user-information server by first locating the corresponding dialogue components and then requesting the installation (or uninstallation) of the particular monitoring policy (this requires implementation additions in dialogue components, for performing interaction monitoring and for activating or deactivating the interaction monitoring behavior) and (2) it receives interaction monitoring notifications from dialogue components and posts those to the user-information server.

The communication manager is responsible for dispatching incoming communication (activation, cancellation, and monitoring control) and posting outgoing communication (monitoring data and initial adaptation requests). One might observe an explicit link between the dialogue components and the communication manager. This reflects the initiation

of interaction in which the dialogue control logic (residing within dialogue components) requests iteratively the application of decision making (from the decision-making component). Such requests will need to be posted for all cases involving dialogue component alternatives for which adapted selection has to be appropriately performed.

The dialogue components typically encompass the real implementation of physical dialogues, dialogue control logic, and interaction monitoring method. In practice, it is hard to accomplish isolated implementation of the dialogue artifacts as independent black boxes that can be combined and assembled on the fly by independent controlling software. In most designs, it is common that physical dialogue artifacts are contained inside other physical artifacts. In this case, if there are alternative versions of the embedded artifacts, it turns out that to make containers fully orthogonal and independent with respect to the contained, one has to support intensive parameterization and pay a heavier implementation overhead. However, the gains are that the implementation of contained artifacts can be independently reused across different applications, while in the more monolithic approach, reuse requires deployment of the container code (and recursively, of its container too, if it is contained as well).

50.3.2 Adaptability and Adaptivity Cycles

The completion of an adaptation cycle, being either adaptability or adaptivity, is realized in a number of distributed processing stages performed by the various components of the unified architecture. During these stages, the components communicate with each other, requesting or delivering specific pieces of information. Figure 50.13 outlines the processing steps for performing both the initial adaptability cycle (to

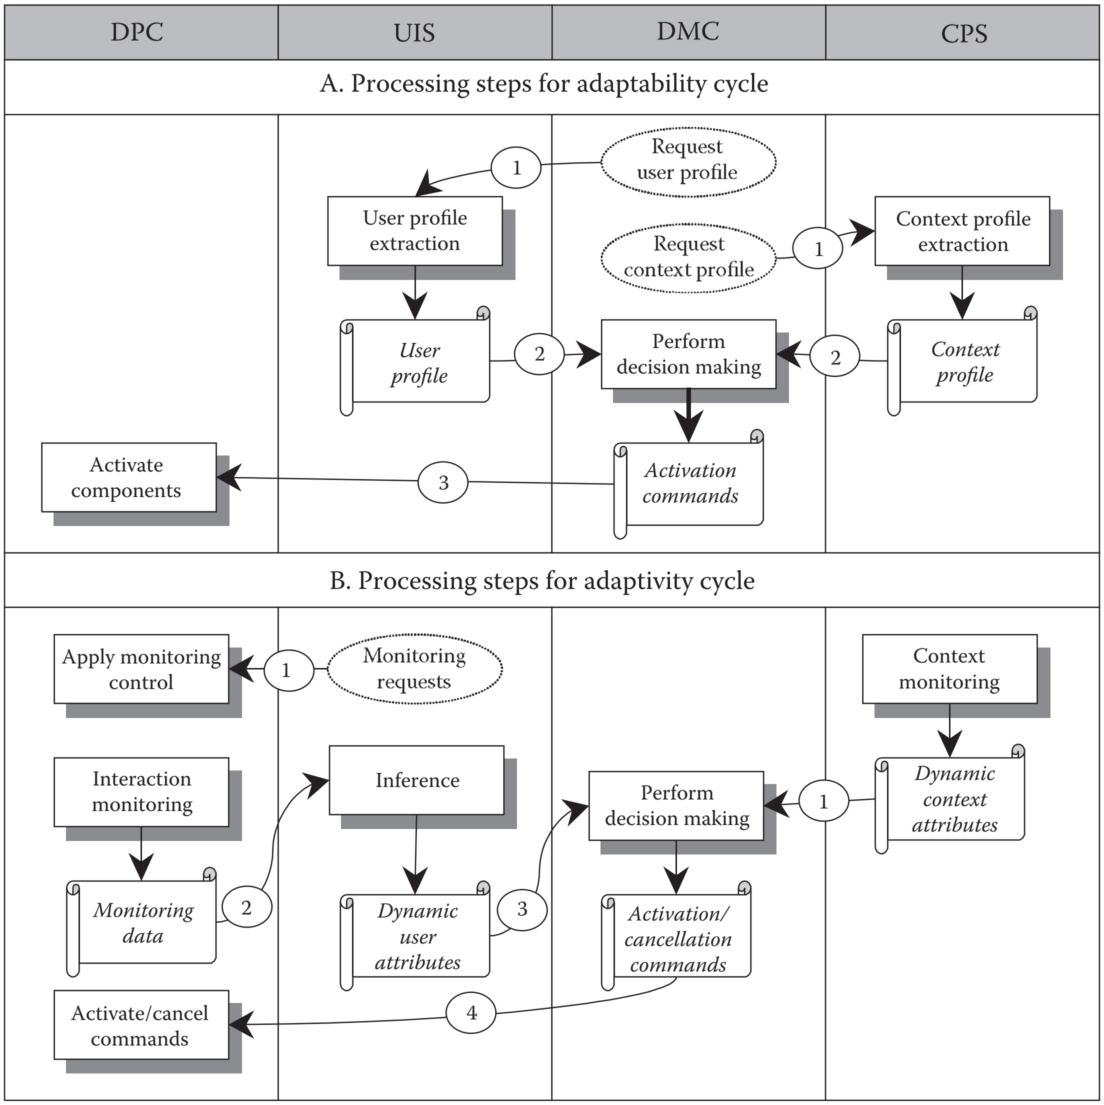

FIGURE 50.13 Processing steps, engaging communication among architectural components, to perform initial adaptability cycles (A), as well as the two types of adaptivity cycles (B). Requests originated from dialogue patterns component are indicated with dashed ovals, communicated messages are shown with special banners, processing points are drawn with shaded rectangles, while logical ordering is designated with numeric oval labels.

be executed only once) and the two types of adaptivity cycles (e.g., one starting from dynamic context attribute values and another starting from interaction monitoring control). Local actions indicated within components (in each of the four columns) are either outgoing messages, shown in bold typeface, or necessary internal processing, illustrated via shaded rectangles.

50.3.3 Dynamic User Interface Assembly

The concept of dynamic interface assembly reflects the key runtime mechanisms to support adaptability in unified user interfaces (Figure 50.14). Previous work in adaptive interaction involved techniques such as detection of user attributes, adaptive prompting, and localized lexical-level modifications (e.g., rearranging menu options, or adding/removing operation buttons). The issue of making the interface fit from the beginning to individual users has been addressed in the past mainly as a configuration problem, requiring interface developers to supply configuration editors so that end users could fit the interface to their particular preferences. However, such methods are limited to fine tuning some lexical-level aspects of the interface (e.g., toolbars, menus), while they always require explicit user intervention, for example, there is no automation. In this context, the notion of adaptability, as realized in unified user interfaces, offers new possibilities for automatically adapted interactions, while the architecture and runtime mechanisms to accomplish dynamic interface assembly constitute a unique software engineering perspective.

Some similarities with dynamic interface assembly can be found in typical web-based applications delivering dynamic content. The software engineering methods used in such cases are based on the construction of application templates (technologies such as Active Server Pages by Microsoft or Java Server Pages by JavaSoft are usually used) with embedded queries for dynamic information retrieval, delivering to the user a web page assembled on the fly. In this case, there are no alternative embedded components—just content to be dynamically retrieved—while the web-page assembly technique is mandatory when HTML-based web pages are to be delivered to the end user (in HTML, each time the content changes, a different HTML page has to be written). However, in case a full-fledged embedded component is developed (e.g., ActiveX object or Java Applet), no runtime assembly is required, since the embedded application internally manages content extraction and display, as a common desktop information retrieval application.

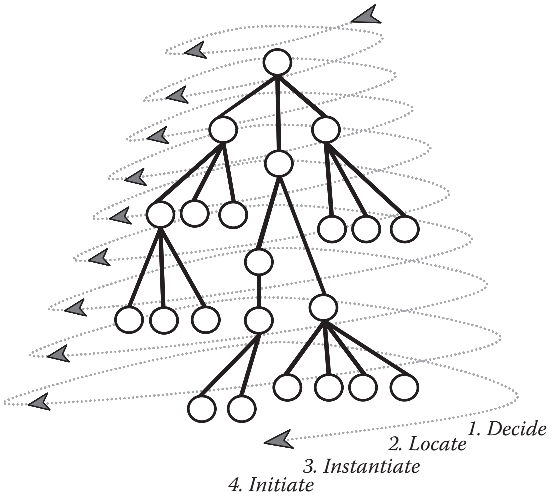

FIGURE 50.14 Illustration of the dynamic interface assembly process as an incremental hierarchical construction procedure.

The implementation of unified user interfaces is organized in hierarchically structured software templates, in which the key placeholders are parameterized container components. This hierarchical organization, as it has been reflected in the development excerpts, mirrors the fundamentally hierarchical constructional nature of interfaces. The ability to diversify and support alternatives in this hierarchy is due to containment parameterization, while the adapted assembly process is realized by selective activation, engaging remote decision making on the basis of end-user and usage-context information. The dynamic interface assembly process reflects the hierarchical traversal in the task hierarchy, starting from the root, to decide, locate, instantiate, and initiate appropriately every target user interface component (see Figure 50.15).

This process primarily concerns the interface components that implement alternative styles. From the implementation point of view, the following software design decisions have been made:

- The task hierarchy has been implemented as a tree data structure with polymorphic nodes triggering decision-making sessions (see Figure 50.15).
- Interface components have been implemented as distinct independent software modules, implementing generic containment APIs, while exposing a singleton control API for dynamic instantiation and name-based lookup.
- The interface assembly procedure is actually carried out via two successive hierarchical passes:
  - Execution of decision sessions, to identify the specific styles for polymorphic task contexts, which will be part of the eventually delivered user interface
  - Interface construction, through instantiation and initiation of all interface components for the decided styles

50.3.4 Polymorphic Containment Hierarchies

In Figure 50.16, the concept of parametric container hierarchies is illustrated, while in Figure 50.17, an instantiation of the concept is shown for the AVANTI web browser. Container classes expose their containment capabilities and the type of supported contained objects by defining abstract

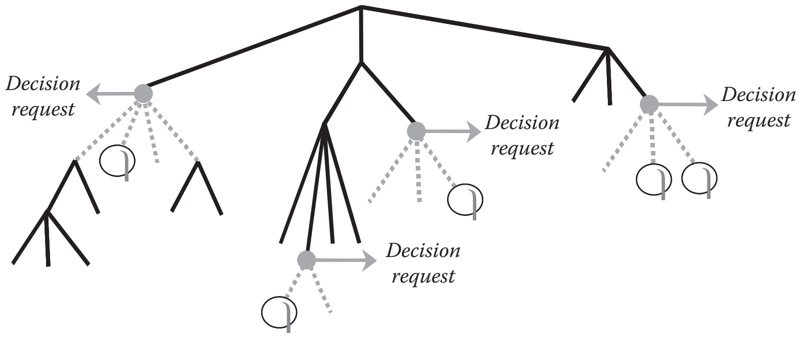

FIGURE 50.15 Illustrating the hierarchical posting of decision requests, causing decision sessions for each polymorphic task (shown with decomposition alternatives as dashed lines), and marking of selected alternative styles (i.e. interface components), after each decision session completes.

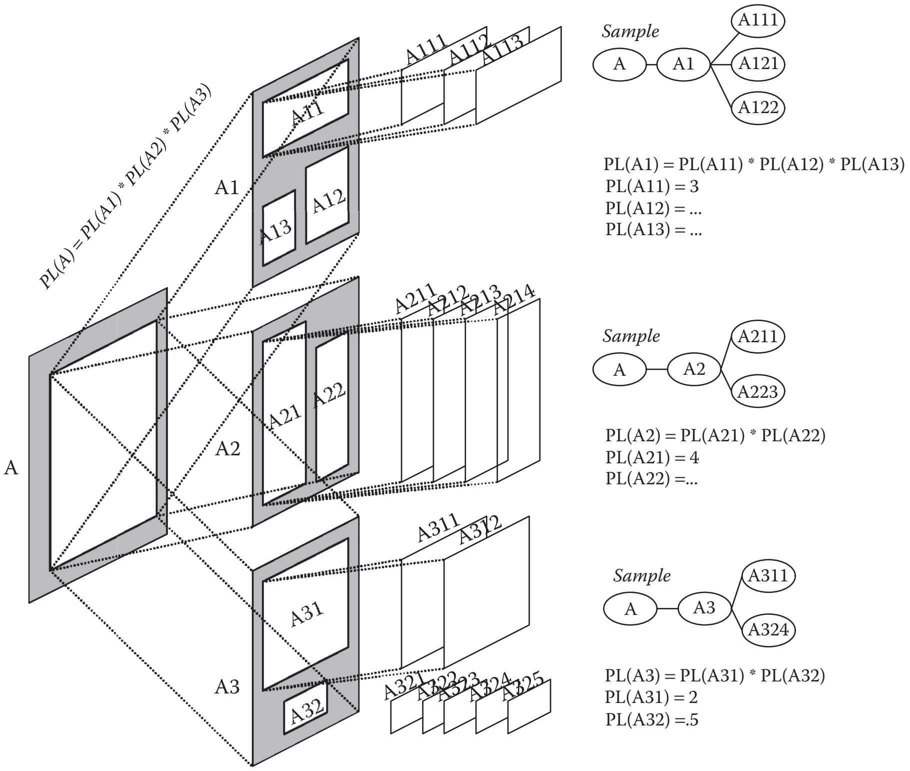

FIGURE 50.16 The structure of polymorphic containment hierarchies. Alternative contained components implement a common abstract interface that containers use and vice versa. PL indicates the maximum polymorphism factor, which provides the total number of all possible different runtime incarnations of an interface component, recursively defined as the product of the polymorphic factors of constituent component classes. Not all PL combinations may be semantically viable.

interfaces (e.g., abstract OOP classes) for all the contained component classes.

These interfaces, defined by container class developers, constitute the programming contract between the container and the contained classes. In this manner, alternative derived contained-component classes may be instantiated at runtime as constituent elements of a container. Following the definition of polymorphic factor PL, which provides a practical metric of the number of possible alternative runtime configurations of a component (not all of which may be semantically viable), the PL of the top-level application component gives the number of the possible alternative dynamically assembled interface instances. From a programming point of view, in the AVANTI web browser, the activation control of dialogue components for runtime assembly has been mainly realized through typical library function calls. Such function calls engage object instances corresponding to dialogue components, without using any component-ware technology. Hence, this runtime assembly behavior has been accomplished without the need of locating, fetching, and combining components together. Nevertheless, efforts have been devoted to applying and testing the latter approach in real practice, by using a component-ware technology (DCOM/ActiveX) for a limited number of dialogue components. This required a more labor-intensive implementation approach (from a C11 point of view, while isolated testing of components with VisualBasic was

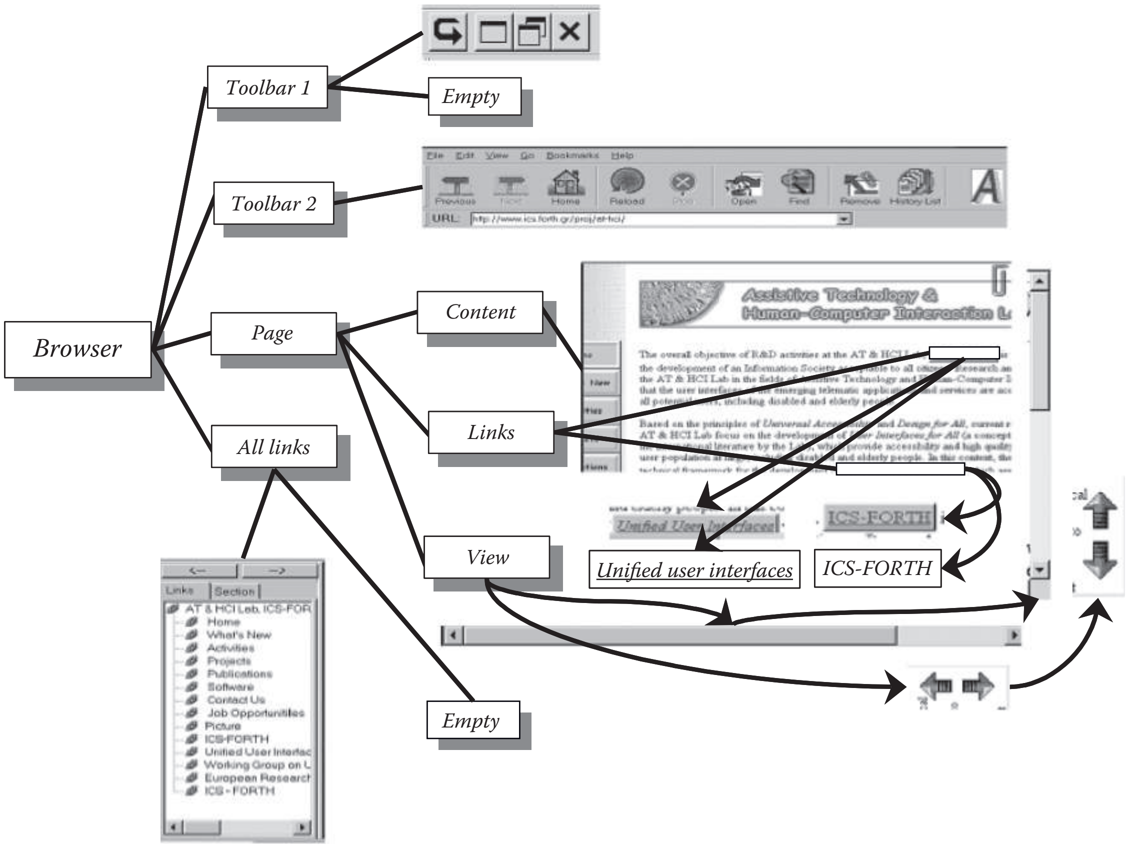

FIGURE 50.17 Parametric polymorphic containment with variant constituent components in the AVANTI browser. The indication "Empty" indicates components whose presence may have to be omitted upon dynamic interface delivery for certain user categories.

far easier) for packaging dialogues to make them component enabled, as well as for further activating and using them at runtime. However, there are some evident advantages:

- Dialogue components need not be carried altogether, but can be dynamically loaded, thus promoting a thin dialogue patterns component implementation.
- In effect, the core logic of the dialogue patterns component, apart from dialogue components, can be also packaged as a component itself, making it reusable across different applications.
- Automatic updates and extensions of components are directly supported, enabling new versions, or even new dialogue components (addressing more user- and usage-context attribute values) to be centrally installed in appropriate component repositories.

50.3.5 Decision-Making Specification

The decision-making logic is defined in independent decision blocks, each uniquely associated to a particular task context; at most one block per distinct task context may be supplied. The decision-making process is performed in independent sequential decision sessions, and each session is initiated by a request of the interface assembly module for execution of a particular initial decision block. In such a decision session, the evaluation of an arbitrary decision block may be performed, while the session completes once the computation exits from the initial decision block. The primary decision parameters are the end-user and usage-context profiles, defined as two built-in objects, such as user and context, whose attributes are syntactically accessible in the form of named attributes. The binding of attribute names to attribute values is always performed at runtime. The encapsulation of composite attributes in user and context profiles is easily allowed due to the syntactic flexibility of attribute reference. For instance, "user-abilities.vision" and "user-abilities.hearing" are syntactic sugar for "user-abilities.vision" and "user-abilities.hearing," where "abilities.vision" and "abilities.hearing" are two distinct independent ordinal attributes of the user built-in object. Consequently, even though all attributes in the decision-making specification language (DMSL) language are semantically scalar, the flexibility of attribute names allows syntactical simulation of aggregate structures.

In Figure 50.18, an example decision block is shown, being an excerpt of the implementation of the decision logic AVANTI web browser, for selecting the best alternative interface components for the link task context. The interface design relating to this adaptation decision logic is provided in Figure 50.1.

In the DMSL language, the fundamental design relationships among alternative styles are not injected as a part of the semantics but, alternatively, concrete rule patterns are delivered, effectively mapping those relationships

```

to implementation skeletons of decision blocks. This gives adaptation designers the freedom not to necessarily adopt those particular design relationships, in case, for instance, they do not choose to use unified design as the adaptation-design approach. In Figure 50.19, the DMSL decision-rule patterns are provided for the previously described four categories of style relationships.

50.4 SOFTWARE REFACTORING FOR ADAPTATION

We introduce a user-interface refactoring process to accommodate adaptive behavior into existing, even nonadaptive, user-interface implementations. Refactoring (Opdyke 1992), a term from mainstream software engineering, concerns the process of gradually applying small-scale source-level transformations (Mens and Tourwe 2004) aiming to enhance a system's software design, however, without affecting its domain-specific functionality. Refactoring is an incremental design improvement activity rather than a software reengineering process. Thus, refactoring is seen as a stepwise code evolution process to enhance an existing design, rather than to radically reform the software design itself. Radical reformations are handled by reengineering processes, being more resource demanding as they introduce severe architectural modifications.

Our approach, being a refactoring process, does not impose architectural refinements, meaning it respects the original user-interface software architecture. Instead, it emphasizes the introduction of targeted source code amendments, transforming gradually the class-level software design of user-interface components toward adaptive composition. The latter is accomplished because all transformations we adopt are existing refactoring patterns. Since refactoring is architecture-preserving refinement, so is our process. Technically, we treat adaptive user-interface composition and updating as a cross-cutting concern—sort of an aspect (Kiczales et al. 1997)—meaning it intersects with the software design at specific points, however, without affecting the global architectural picture.

Regarding adaptive user-interface behavior, there are various propositions all of which suggest customized architectures or processes for a development from scratch approach. For example, the proposal of a plasticity reference framework (Calvary et al. 2001) supports adaptation (retargeting) to different platforms. A model-driven approach for plasticity is proposed in Collignon et al. (2008). The adoption of a task-driven user-interface architecture for adaptive ambient intelligence is proposed in Clerckx et al. (2008), while adaptive information retrieval is addressed in Wen et al. (2007) as a way of adaptive content composition. As with the previous propositions, our work on unified user-interfaces also requires early adoption of our suggested user-interface architecture. All previous methods tend to be impractical for updating existing software systems to accommodate adaptive behavior for two primary reasons: (1) the adaptive behavior is imposed as the dominant view of the user-interface architecture, although the domain-specific noninteractive source code may be orders of magnitude larger compared to adaptivity-specific code and (2) they are quite diverse and their combined adoption in a single system is not investigated and might introduce practical issues due to differing architectural styles implied by varying goals: user intention extraction, dialogue automation, content adaptation, context adaptation, and cross-platform delivery.

Naturally, propositions that do not address user-interface engineering but focus on the reasoning to decide adaptation, such as Paternò et al. (2008), may be adopted once they do not require architectural refinements. In the context of our work, we investigated the underlying software engineering disciplines to support adaptive behavior, seeking for a common denominator amongst the alternative approaches. It quickly turned out that, irrespective of the eventual adaptive behavior, all methods entail three fundamental concepts:

- User-interface component alternatives
- Rationale runtime component selection
- Adaptive activation or replacement

Dynamic activation and replacement were very early recognized as the fundamental system actions to realize adaptive behavior (Cockton 1993). Thus, once supported, virtually any designed adaptation scenario is implementable. The complexity, size, and type of components widely vary, ranging from widgets to comprehensive dialogues, while adaptive activation may imply standalone presence, composition (aggregation), and replacement (substitution). In fact, these disciplines proved to be so fundamental that we could directly generalize from adaptive user-interfaces to adaptive software in general (Savidis 2004). However, even in this general proposition the practicality issue was not resolved: the original system architecture had to be always refined since a software reengineering process was suggested. At this point, our proposal for a refactoring process addresses this issue, showing that we can effectively enable adaptive behavior by treating adaptive composition as a cross-cutting concern that can be accommodated with well-defined incremental source-code transformations. We continue with an elaboration of this refactoring process.

50.4.1 Process Outline

We adopt a role as a responsibility-based notion for user-interface components, essentially abstracting over user-interface operations and requirements to denote functional requirements specific to roles. The latter reflects recent trends in software-design (Wirfs-Brock and Mc Kean 2003), where the emphasis is shifted from functionality-driven class-based design to responsibility-driven role-based design. We can have alternative implementations for a given role, role implementations being actual components, with *r*(*a*) denoting the role of user-interface component α. Following this, we define how relationships among components emerge by respective relationships among their actual roles:

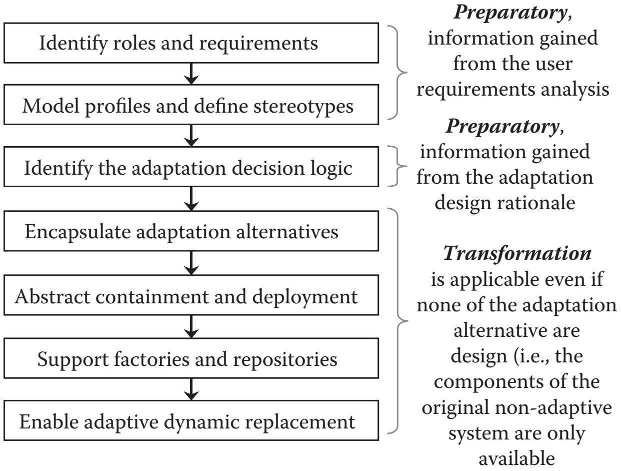
Component *a*	⇒	*a* implements *r*(*a*)
Adaptive component *a*	⇒	*a* implements adaptive *r*(*a*)
a contains *b*	⇒	*r*(*a*) contains *r*(*b*)
a deploys *b*	⇒	*r*(*a*) deploys *r*(*b*)
a indifferent *b*	⇒	*r*(*a*) indifferent *r*(*b*)

It should be noted that contains and deploys relate to aggregation and deployment at the functional level, not the user-interface layout. The previous definitions state that component relationships are implied by the relationships of their abstract operations or roles. Implementation wise, roles map to components, and components map to concrete classes, modules, or packages. We rely on these two fundamental software relationships to drive structural transformations for all adaptively contained or deployed components.

Our overall software refactoring process is outlined under Figure 50.20, prescribing (1) three preparatory activities to extrapolate, model, and represent information from data already available at the end of the user-interface (re)design phase and (2) five concrete source code transformation activities to actually implement the adaptive behavior. We continue with an elaboration of the transformation phases, focusing on the preparatory phases not relating to source-code updates. The details of the user-interface source-code updates are provided under Savidis and Stephanidis (2010).

50.4.2 Identify Roles and Requirements

As mentioned earlier, adaptive composition involves at runtime the adaptation-driven selection and activation of



Identify roles and requirements
Model profiles and define stereotypes
Identify the adaptation decision logic

LinkTargeting	Allows targeting to a specific link

FIGURE 50.21 An example of user-interface component roles and respective requirements.

dialogue components, from a pool of related alternatives, with the design aim to optimally support respective user tasks. To refactor a system for adaptivity, we should initially associate concrete roles to all implemented user-interface components and identify their respective functional requirements. As an example, consider the roles and requirements defined in Figure 50.21 for the adaptive browser. What the specific list states is that Link is a user-interface role whose primary functional requirement is to facilitate activation of a target page. In case such brief information is not already part of the user-interface documentation, it can be easily extrapolated by reviewing the user-interface design outcomes or by referring to the designers.

50.4.3 Model Profiles and Define Stereotypes

Supporting adaptation means delivering appropriate variations of system behavior according to different deployment profiles. For interactive systems, such profiles concern user and usage contexts. Practically, the user-interface system exposes different user-interface profiles in response to deployment profiles. We use the term interface profile model to denote the model expressing the domain of variations of user-interface behavior. Such a model enumerates the viable alternatives for adaptive roles. For example, the model of Figure 50.22 relates to the adaptive browser (a specification pseudo language is used). This model designates the number of different adaptive composition possibilities in the browser, since every interface profile instance essentially represents a separate user-interface setup. Additionally, besides concrete roles like Links and Scroller, cross-cutting user-interface features, like Language, Audio Feedback, and so on, can be well expressed. Using this model, we can identify distinct setups as appropriate for sets of deployment profiles. For instance, let us consider the instantiations of our sample interface profile model, called stereotypes, also depicted under Figure 50.22.

Intuitively, there is a rationale link between the chosen stereotype names, like ForNaiveUsers, and the respective values given to the fields of the interface profile model. Such interface profile instances are called user-interface stereotypes and they document in a readable way key scenarios of adaptive setup, making more explicit the deployment profile accommodated with such setups. For example, one anticipates that the ForNaiveUsers stereotype is normally targeted to user profiles implying a “naïve end-user.” This step of distinguishing specific user-interface setups is optional. Its objective is to provide an initial understanding regarding the adaptivity potential of the original or refined user-interface implementation.

The next step is to define the deployment profile model representing information about the end-user and the usage context. User information may be stored in profile databases, may be gained from servers via unique user identifiers, can be extracted from a smart card, may be required user-input in a startup interaction session, or can be inferred at runtime from interaction monitoring and analysis. Similarly, context information, like location, environment noise, network bandwidth, and machine setup, may be provided using special-purpose equipment like sensors (for changing features) and a system-level profile (a registry for static features). Clearly, the definition of the deployment profile model should reflect information about the actual user population and the real environments of the use of the software system. An excerpt of the user profile model and a stereotype for the adaptive browser is provided under Figure 50.23.

```
interface profile model {
Link          : { NoCancellation, WithCancellation }
Scroller             : { OutsidePage, InsidePage }
AllLinks             : { Supported, Unsupported }
LinkTargeting : { Manual, Assisted }
}
interface stereotype ForNaiveUsers {
 Link         = WithCancellation
Scroller             = OutsidePage
AllLinks             = Unsupported
LinkTargeting        = Assisted
}
interface stereotype ForExpertUsers {
 Link         = NoCancellation
Scroller             = InsidePage
AllLinks             = Supported
LinkTargeting = Manual
}
```

FIGURE 50.22 An example of the user-interface profile model with two stereotypes.

```
user profile model {
ComputerLiteracy            : { Good, Average, Some, None }
WebUse                      : { Frequent, Casual, None }
UserAge                     : { 4 .. 90 }
NativeLanguage              : Language
LanguagesSpoken             : list of Language
}
user stereotype Naïve {
    ComputerLiteracy        in { Some,   None}      or
    WebUse                  in {Casual, None}
}
```

FIGURE 50.23 An example of the user profile model with one stereotype.

It should be noted that during this phase the focal point is not on user modeling, but on profile modeling. The latter is technically straightforward, with complexity analogy to definition of database records, aiming to identify the structure of end-user records. The former is a rather complicated activity, entailing the modeling of user populations for reasoning or inference purposes, and is not required as such in our proposed refactoring process. However, the latter is not restrictive, in the sense that user-interface developers may well incorporate user models and reasoning components to support various intelligent user-interface functions.

50.4.4 Identify the Adaptation Decision Logic

Typically, during an adaptation-oriented (re)design phase, the concrete design rationale of every adaptive user-interface component is defined and documented. Such rationale encompasses the actual conditions regulating the delivery and presence of an adaptive component during interaction (runtime). In other words, it defines when adaptive activation of components should be performed and which of the available alternatives of adaptive components should be chosen. Only once such information is available the design phase gracefully concludes. Conceptually, such rationale constitutes a form of decision logic for adaptive component activation or deactivation of user-interface components. Additionally, such logic rationally links the deployment profile with designed user-interface components, meaning it is user and context dependent. Linking with our recent definitions, the adaptation decision logic links directly deployment profile attributes to interface profile attributes. As a trivial example, the end-user native language is typically used to choose the user-interface language. Examples of adaptation rules expressed in our Decision-DMSL (Savidis and Stephanidis 2005) supporting declarative rules with an imperative syntax are provided under Figure 50.24; notice the use of stereotypes in decision conditions (Link being an adaptive component).

Practically, developers may collect and implement the decision logic using any convenient method, including hard-coding in the user-interface implementation language, while express all profiles directly in XML. The most common approach is to introduce a separate special-purpose class responsible for decision making during runtime. Later, once the entire adaptation logic is consolidated and implemented and the system is transformed to an adaptive one, alternative implementation techniques may be explored better fitting the notion of a decision-making module (like rule-based systems or logic programming methods). Because of the simplicity of this implementation task and because it does not affect the existing user-interface system, we consider it more of a preparatory action rather than a transformation step. Summing up, the job of this phase is the collection and formulation

```
component Link {
      if   Naïve then            activate WithCancellation
      else                       activate NoCancellation
}
component LinkTargeting {
      if   Naïve or Elderly then activate Assisted
      else                       activate Manual
}
```

of the adaptation design rationale in a more formal style, being closer to a logic or algorithm form, that is, a computable representation. Clearly, this preparatory phase reflects an intention to make interactive systems capable to execute adaptation-related logic so as to realize a runtime decision making for required adaptation actions.

50.4.5 Apply Source Code Transformations

The application of source code transformation steps aims to gradually bring the implementation into a form where adaptive *composition* and *replacement* are fully supported as key functional features. Architecturally, these two disciplines will affect only microscopically the system design, down to the level of component interactions and dependencies, as outlined in Figures 50.25 and 50.26. Technically, the refactoring process will bring the source code into an eventual state where all adaptation-specific user-interface components may be essentially plugged in well-defined points, in a modular and extensible manner. As mentioned, the details of the source transformation steps are provided in Savidis and Stephanidis (in press).

50.5 CONCLUSIONS

Currently, the required technical knowledge to build user- and usage-context adapted interfaces includes user modeling, task design, cognitive psychology, rule-based systems, network communication and protocols, multiplatform interfaces, component repositories, development tools, and core user interface software engineering. Software development firms apparently prefer incremental engagement strategies, allowing a stepwise entrance to new potential markets, by delivering successive generations of products encompassing layers of novel characteristics. Similarly, the development of software applications supporting automatic user interface adaptation, for the broadest end-user population, requires a concrete strategy supporting evolutionary development, software reuse, incremental design, scalability, and modular construction. The unified user interface development discussed claims to offer a software engineering proposition that consolidates process-oriented wisdom for constructing automatically adapted user interfaces. Evolution, incremental development, and software reuse are some of the fundamental features of unified user interface development. These are reflected in the ability to progressively extend a unified user interface by incrementally encapsulating computable content in the different parts of the architecture, to cater for additional users and usage contexts, by designing and implementing more dialogue artifacts, and by embedding new rules for the decision-making logic. Such characteristics are particularly important and relevant to the claimed feasibility and viability of the proposed software engineering process and directly facilitate the practical accomplishment of universally accessible interactions.

The concept of unified user interfaces reflects a new software engineering paradigm that addresses effectively the need for interactions automatically adapted to the individual end-user requirements and the particular context of use. Following this technical approach, interactive software applications encompass the capability appropriately to deliver on the fly an adapted interface instance, performing appropriate runtime processing that engages the following:

- Utilization of user- and usage-context-oriented information (e.g., profiles), as well as the ability to detect dynamically user- and usage-context attributes during interaction.

- Management of appropriate alternative implemented dialogue components, realizing alternative ways for physical-level interaction.
- Adaptation-oriented decision making that facilitates (a) the selection, before initiation of interaction, of the most appropriate dialogue components comprising the delivered interface, given any particular dialogue context, for the particular end-user and usage-context profiles (e.g., adaptability) and (b) the implementation of appropriate changes in the initially delivered interface instance, according to dynamically detected user- and usage-context attributes (e.g., adaptivity).
- Runtime component co-ordination and control to dynamically assemble or alter the target interface; this user interface is composed on the fly from the set of dynamically selected constituent dialogue components.

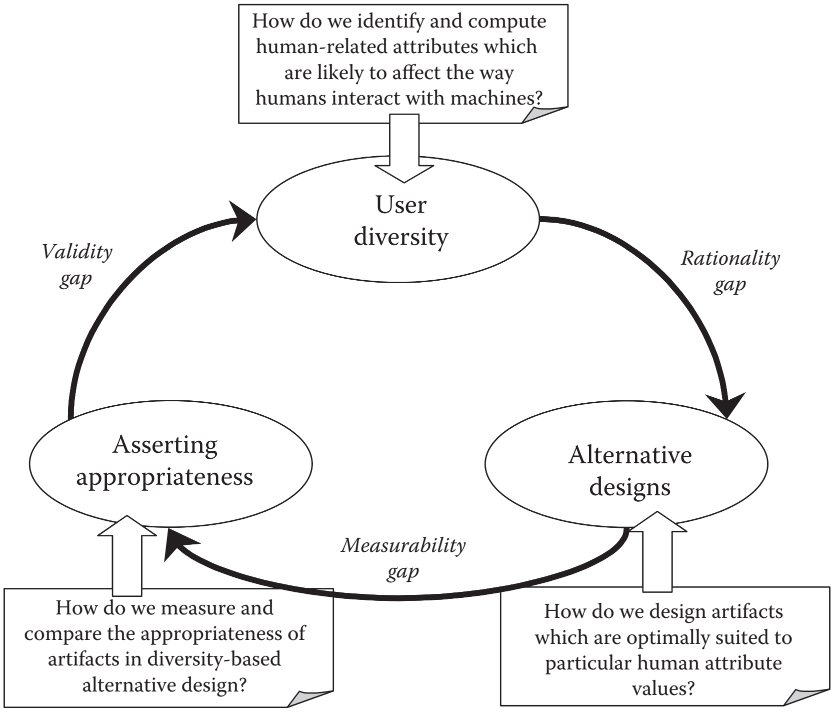
The unified user interface development strategy provides a distributed software architecture with well-defined functional roles (e.g., which component does what), intercommunication semantics (e.g., which component requests what and from whom), control flow (e.g., when to do what), and internal decomposition (e.g., how the implementation of each component is internally structured). One of the unique features of this development paradigm is the emphasis on dynamic interface assembly for adapted interface delivery, reflecting a software engineering practice with repository-oriented component organization, parametric containers with abstract containment APIs, and common interaction-monitoring control with abstract APIs. Although the method itself is not intended to be intensively prescriptive from the low-level implementation point of view, specific successful practices that have been technically validated in fieldwork regarding decision making and dynamic user-attribute detection have also been discussed, focusing on microarchitecture details and internal functional decomposition.

In this context, this development method has been systematically deployed and tested in practical situations where automatic personalization of computer-based interactive applications and services was the predominant issue. It introduces the fundamental notion of adapted interface delivery before initiation of interaction and addresses the technical challenges of coping with the inherent runtime dynamic interface assembly process.

Additionally, the basic software engineering strategy of unified development, in particular abstract objects and polymorphic containment, has been deployed in leading-edge developments, to deliver applications with ambient mobile user interfaces running on wearable pocketsize processing units.

The proposed approach establishes one possible technical route toward constructing automatically individualized best fit user interfaces: it enables incremental development and facilitates the expansion and upgrade of dialogue components as an on-going process, entailing the continuous engagement and consideration of new design parameters, and new parameter values. It is anticipated that future research work may reveal alternative approaches or methods. At the same time, further research and development work for unified user interfaces is required to address some existing challenges, mainly related to design issues (see Figure 50.27).

Following Figure 50.25, one top-level issue concerns the way that specific varying user attributes affecting interaction



How do we identify and compute human-related attributes which are likely to affect the way humans interact with machines?
User diversity
Validity gap

Asserting appropriateness
Alternative designs
Measurability gap
How do we measure and compare the appropriateness of artifacts in diversity-based alternative design?
How do we design artifacts which are optimally suited to particular human attribute values?

FIGURE 50.27 Open research questions in design for all.

are to be identified. In other words, there is a need to identify diversity in those human characteristics that are likely to dictate alternative dialogue means. Subsequently, even if a set of those attributes is identified, it is still unclear how to conduct a design process to produce the necessary alternative dialogue artifacts for the different values of those attributes. Hence, it is necessary to design for diversity relying upon appropriate design rationale clearly relating diverse attribute values with specific properties of the target dialogue artifacts. Currently, there is only limited knowledge about how to perform effectively this transition from alternative user-attribute values to alternative design artifacts, and it can be characterized as a rationalization gap.

The issue of how to structure appropriately alternative patterns for diverse user-attribute values should be addressed in a way that the resulting designs are indeed efficient, effective, and satisfactory for their intended users and usage contexts. Such a process requires appropriate evaluation methods and the capability to measure the appropriateness of designed artifacts. At present, this is still a missing link, characterized as the measurability gap. Unless we are able to assert the appropriateness of the alternative dialogue artifacts designed for diverse user attributes, we cannot validate the overall dynamically delivered interface. The inability to formulate and conduct such an evaluation process creates a validity gap. Work currently underway, as well as future work, is expected to address these issues in an attempt to bridge the identified gaps.

Finally, we outlined a software refactoring process to support adaptive user-interface composition and replacement for systems not originally designed to support such adaptive behavior. Our work is motivated by the fact that, while adaptivity gains broad interest for software products and services, all known propositions imply development from scratch and adoption of architectural styles that may not necessarily interoperate with the domain-specific software architecture. Our focus on software refactoring rather than on software reengineering is fundamental. More specifically, via reengineering, we need a process to fuse two parallel system designs and architectures together: the original domain-specific system design and architecture and the one implied by the need for adaptive behavior. Not only do we lack today such processes for interactive systems, but we lack software reengineering processes for software systems in general. By adopting a refactoring process, we have the extra key benefit that after every transformation activity the system is always in a fully working state. Overall, we believe that analogous refactoring processes for different categories of demanding user-interface features may lead to their easier adoption in real production systems.

ACKNOWLEDGMENTS

Recent work regarding the software refactoring process for adaptive user-interface behavior has been carried out in the context of the Ambient Intelligence Programme (AmI) of ICS-FORTH (http://www.ics.forth.gr/ami/index.html). This effort has been motivated by the observation that during the development of diverse and demanding applications in an AmI environment, it was impractical to simultaneously focus on the delivery of user-interface adaptation and radically new interaction metaphors. Thus, we needed an effective and efficient software transformation process to retrofit any AmI application to adaptation demands emerging after development.

51 Usability + Persuasiveness + Graphic Design = eCommerce User Experience

Deborah J. Mayhew

CONTENTS

51.1 DEFINING eCOMMERCE USER EXPERIENCE

In 1995, most websites were informational rather than transactional, the dot-com boom was in its infancy, and the web development world was only just beginning to rub shoulders with the longstanding field of software usability engineering. That year, Amazon and eBay were launched and Yahoo! was incorporated.

By 2000, the first U.S. dot-coms started to go out of business. But in spite of the bubble bust, over the past 10 years, eCommerce has become ubiquitous on the web, and the field of software usability has become much more visible and active in the web development world. As the web has matured with respect to usability, the field of traditional software usability (which dates back to the late 1970s) has come to recognize—and integrate with—other qualities of what is now referred to as the web "user experience." As web capabilities increased, *graphic design* has become a key quality of the user experience. And in the case of eCommerce websites, a relatively new quality of the user experience design has emerged: *persuasiveness*. At this point, any eCommerce designer or developer needs to recognize the importance of five different qualities of the user experience:

1. Utility
2. Functional integrity
3. Usability
4. Persuasiveness
5. Graphic design

These are defined in Sections 51.1.1 through 51.1.5.

51.1.1 UTILITY

It is easy to overlook *utility* as a quality of a website's user experience, as it is perhaps the most fundamental. The utility of a website refers to the usefulness, importance, or interest of the site content (i.e., of the information, products, or services offered by the site) to the visitor. It is of course relative to any particular site visitor—what is interesting or useful to you may not be to me. It is also a continuous quality, that is, some websites will feel more or less useful or interesting to me than others. For example, many web users love to use social networking sites like YouTube or Facebook, while others find these a total waste of time. I will have no need for a website that sells carpenter's tools, while my neighbor might visit and use that site on a regular basis.

51.1.2 FUNCTIONAL INTEGRITY

A website's *functional integrity* is simply the extent to which it works as intended. Websites may have "dead" links that go nowhere, they may freeze or crash when certain operations are invoked, they may display incorrectly on some browsers or browser versions, they may download unintended files, and so on. A lack of functional integrity is the symptom of buggy or incorrect code. Functional integrity is a continuous quality—some websites may only have a few insignificant bugs, others may be almost nonfunctional, and anything in between is possible.

51.1.3 Usability

Usability of course refers to how easy to learn (for first time and infrequent visitors) and/or use (for frequent visitors) a website is. A site can have high utility and high functional integrity and still be very difficult to learn or inefficient and tedious to use. For example, the website you use to submit your tax returns may be implemented in flawless code and be relevant to almost every adult, with great potential for convenience and cost savings, but be terribly hard to learn or inefficient to use. Conversely, a site can be very usable, but not very useful, or have low functional integrity. It might be very easy and intuitive to figure out how to perform a task, but the site may consistently crash at a certain point in the task flow so that the task can never be accomplished.

51.1.4 Persuasiveness

Utility, functional integrity, and usability are qualities important to virtually any website based on any underlying business model. When we focus on eCommerce sites in particular, another quality—*persuasiveness*—becomes very important.

Persuasiveness refers to the extent to which the user interface of a website encourages and promotes "conversions." What constitutes a conversion varies from site to site, and even non-eCommerce sites may be promoting some type of conversion (e.g., newsletter signup, switching to online tax filing). But persuasiveness is a particularly important user experience quality on an eCommerce site, and the primary type of conversion in this case is a sale. So in the case of eCommerce sites, persuasiveness refers mainly to the extent to which the user experience encourages and promotes sales.

Two key aspects of the quality of persuasiveness involve the presence and location of two types of information: *vendor* information (e.g., company name, physical address and contact information, company history, testimonials of past customers, etc.) and *product* information (things like product color, material, care instructions, etc.). Visitors look for evidence that they can trust an online vendor, especially if they have never heard of them before. And they are often unwilling to order a product if they do not know everything they need to know to judge whether it will meet their needs. This is why many people will often look for a product on Amazon.com first—because it is a trusted vendor, and it usually provides comprehensive product information, including detailed reviews by other customers. These two types of information are key to persuasion on eCommerce websites. And note that a website can be fully functional, highly usable in terms of task completion, and offer just what a visitor is looking for—but if it lacks key aspects of persuasiveness such as adequate vendor and product information, potential sales may be lost.

If, for example, I can easily find an attractive suit on an apparel site and easily check out, but I cannot tell if the suit requires dry cleaning, I will probably not order it. Similarly, if I cannot tell what the shipping charges will be before entering my credit card number, I may not order it. It is not that I cannot figure out how to complete the purchase process (usability), nor that I am put off by the look and feel of the website (graphic design), nor that the site crashes during the checkout process (functional integrity), nor that I cannot find a product I want (utility). What happens in these examples is that the website fails to give me adequate product information, or fails to keep me engaged in the purchase process by failing to give me the information I need (shipping costs) when I need it to make my buy decision.

51.1.5 Graphic Design

Finally, the "look and feel"—that is the *graphic design*—of a website can be a key part of the user experience. The graphic design of a website—primarily the way colors, images, and other media are used—invoke emotional reactions in visitors that may or may not contribute to the site's goals. A website's graphic design may strike a visitor as appealing, entertaining, or pleasing, or it may impress them as unprofessional, boring, or even offensive. As with other user experience qualities, each visitor's reaction to a given graphic design may be different. You may be bored by soft pastel colors while I may feel reassured and calmed by them. You may find a straightforward and simple graphic design boring while to me it may feel professional and reassuring. I may be put off by sound and animation, while you may find it exciting and appealing.

While utility and functional integrity are fairly independent qualities, the lines between usability, persuasiveness, and graphic design are more blurred. Clearly, usability and effective graphic design will contribute to persuasiveness, and graphic design can contribute significantly to usability. Nevertheless it is useful to consider these qualities separately to understand their importance and apply them effectively during design.

51.2 ACHIEVING A GREAT USER EXPERIENCE

On eCommerce websites, a great user experience is achieved by optimizing each of the user experience qualities defined earlier, relative to the intended market. Whole professions have evolved around each of these qualities.

The prerequisite of a great eCommerce website user experience is of course *utility*. Nothing else will help if a site does not offer anything of use or interest to a given visitor or market. Website businesses that do not do the research to determine the viability or competitiveness of particular products or services will not succeed regardless of other qualities of their site design. The age-old profession of *market research* is the relevant discipline to use here. Potential web-based businesses need to establish that they have a product or service that there is a market for and that they can compete with current vendors effectively.

Clearly, web businesses must insure that in the end, before launch, their website is comprehensively debugged and works without problems on at least the major browsers/browser versions used by their intended market. Nothing is more frustrating, and feels more unprofessional, than a website that breaks down. Visitors are not likely to return. Competent *web development* professionals are necessary to ensure *functional integrity*.

eCommerce websites need to be intuitive or at least easy to learn for first time and infrequent visitors, and if a website has them, efficient and easy to use for power visitors. *Software and web usability engineering* is the expertise needed to achieve the quality of *usability* in eCommerce user experience design.

eCommerce websites need to provide all critical information to support visitor decision making around their needs and desires and to provide it at the right time in the conversion task flow. There is a currently small but growing field of experts with experience applying marketing and *persuasion psychology* to eCommerce web design.

Finally, an eCommerce website needs a graphic design that inspires trust and is appealing and motivating to its intended market. *Graphic design* professionals specializing in website design provide the design skills and expertise in branding that eCommerce businesses need.

The real key here, beyond simply finding resources with the above skill sets, is to build an effective interdisciplinary design team. Often, professionals with these different backgrounds and skill sets are unfamiliar with the other disciplines and how they must work together to achieve an optimal user experience design for a given market. At the very least, eCommerce businesses need team members respectful of the expertise of others and with a willingness to learn to collaborate effectively to achieve the common goal of an optimized user experience design.

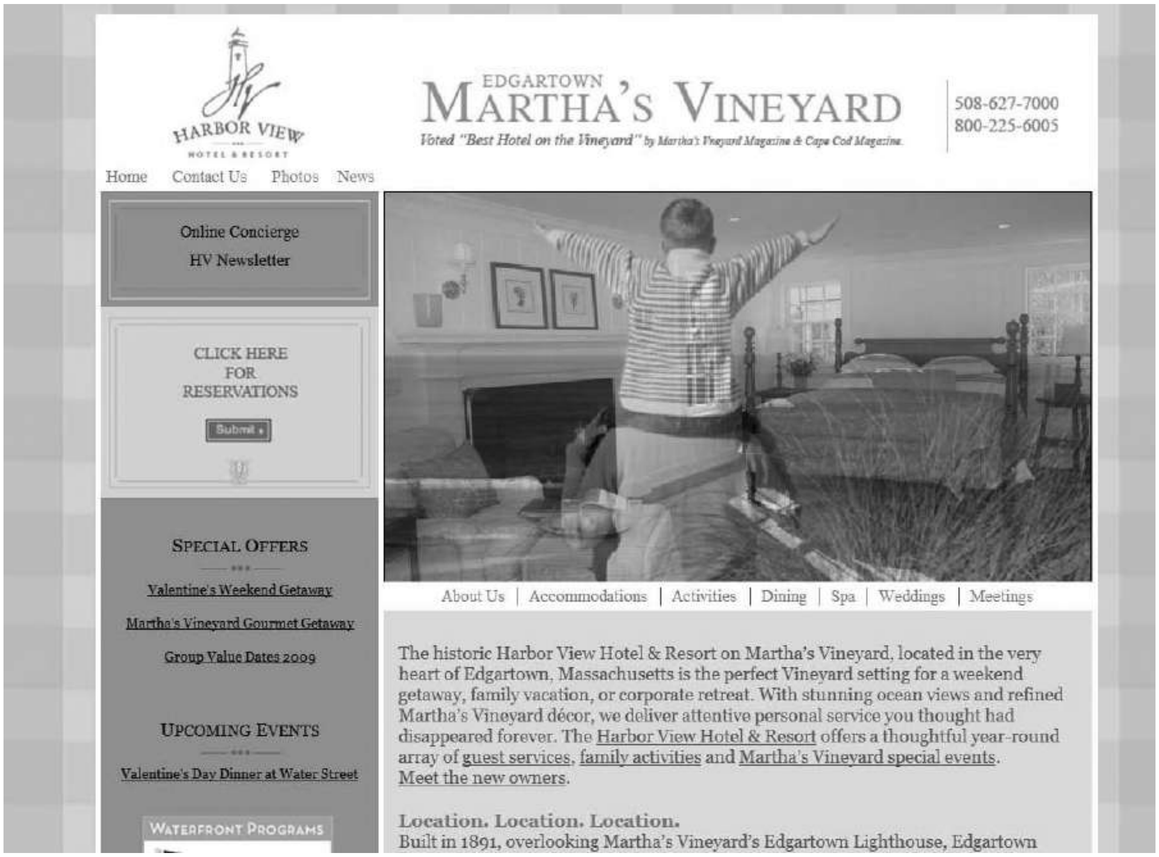
To make the differences between the different user experience qualities—and the disciplines behind them—more concrete, let us look at some existing eCommerce website pages with these qualities in mind. We will focus on the three qualities that are most visibly part of the user experience:

1. Usability
2. Persuasiveness
3. Graphic design

51.2.1 Usability

Figure 51.1 shows the home page of a hotel site (http://www.harbor-view.com/). At the top you may notice that the large image area is in the process of fading out of one photograph into another. This area offers an automatic slide show of lovely and appealing images of the hotel and surrounding areas. In fact, if visitors would like to, they can take control of this slide show by clicking anywhere in the image area; then the automatic slide show ceases and subsequent clicks will move through the images at the visitor's preferred pace.

However, how would a visitor know this? There are no instructions and no visible control to click on. This is an example



The historic Harbor View Hotel & Resort on Martha's Vineyard, located in the very heart of Edgartown, Massachusetts is the perfect Vineyard setting for a weekend getaway, family vacation, or corporate retreat. With stunning ocean views and refined Martha's Vineyard décor, we deliver attentive personal service you thought had disappeared forever. The Harbor View Hotel & Resort offers a thoughtful year-round array of guest services, family activities and Martha's Vineyard special events. Meet the new owners.

Location. Location. Location.
Built in 1891, overlooking Martha's Vineyard's Edgartown Lighthouse, Edgartown Harbor and Chappaquiddick Island, the hotel is flanked by historic homes from 19th Century whaling captains. With stately elm trees lining the streets, you can walk from the Harbor View Hotel & Resort to everything in Edgartown Massachusetts. Explore our quaint town on a bicycle or a short walk. With golf, dining, beaching, sailing, outdoor heated pool and much more, you're going to love Martha's Vineyard!

With the ocean just outside. And the rest of the world a million miles away.

FIGURE 51.2 Usability: affordances. http://www.harbor-view.com/.

of a usability issue known as "invisible functionality"—there is nothing visible on the page to let visitors know that this functionality is available or how to invoke it. While the graphic design is appealing and the photos certainly contribute to the persuasiveness of the site, this invisible functionality represents a shortcoming in usability.

If visitors scroll down, as shown in Figure 51.2, they may note a number of images at the very bottom and in the left hand nav (navigation) bar. Are these just pictures or are they in fact active links? It is true that if visitors roll the cursor over an image, the cursor will let them know if an image is a link by changing shape (e.g., in MS IE, from an arrow to a hand icon). But there is nothing in the design of the images themselves to help the visitor distinguish between images that are links and images that are not. In fact, in this case, the "Best of the Vineyard" and "Best of New England" images are just images, while the other three are active links.

In addition, two of the image links shown in Figure 51.2 take you to another internal page on this site, while the third takes you outside this site to another website. Can you tell which does what? In fact, there is no cue to distinguish between internal and external links. In this case, the "Editor's Pick" image takes you to an external site, while the others take you to internal pages. In a related example, the logo shown at the top of Figure 51.1 is not a link. Since having a logo represent a link to a site's Home page has become a de facto standard on websites, this may violate visitors' expectations. Being able to quickly determine what on a web page is an active link and what is not, as well as which links are internal and which external, is an aspect of usability. Links designed to make it clear they are links and clarify important differences in their behaviors are said to have good "affordances."

Other examples of poor affordances can be seen back in Figure 51.1. In the left hand nav bar, sometimes all caps are used to designate headers (Special Offers, Upcoming Events), while other times they are used for text links (Click Here for Reservations). Also, sometimes text links are displayed with no underline but take on an underline when a visitor points to them (Online Concierge, HV Newsletter), while other text links are displayed underlined and do not change in any way when pointed to (Valentine's Weekend Getaway, Martha's Vineyard Gourmet Getaway). Generally speaking, there is very little consistency in the way text links are designed across this site, making it hard for visitors to learn and remember which text phrases are links and which are not.

Now imagine visitors to this hotel site go to an internal page, say the "Water Activities" page, which is available from a drop down menu from the "Activities" link on the main nav

If you're fond of sand dunes, and salty air, *plus* lots of water!...

On Martha's Vineyard, life is lived close to the water! As a Harbor View guest, we make it easy for the whole family to explore the ocean playground that surrounds us. Enjoy a relaxing harbor tour or sunset cruise aboard the Hotel's recently restored flagship and classic luxury picnic yacht, *Stardust*; or take an adventure to explore the ocean from

FIGURE 51.3 Usability: "you are here" cue. http://www.harbor-view.com/activities_water.asp.

bar under the slide show area, shown in Figure 51.3. Let us say they scroll through this page reading for a while, then perhaps are interrupted for a while, then eventually return to viewing this page, scrolling back up to the top where they can see the main nav bar.

What page are they on? How did they get there? There is no way to tell. No meaningful page title. No breadcrumbs. Not even a cue in the main nav bar to tell them they are somewhere down the "Activities" link pathway. Cues that help visitors get oriented and learn their way around a site's information architecture are known as "you are here" cues. They are especially important for first time and infrequent visitors. This site lacks them. Visitors get lost, cannot find their way back to content of interest, and miss finding a lot of content on sites lacking "you are here" cues.

The above examples represent poor usability. Now let us visit a site that follows a number of principles of usability: the multiple-award-winning (http://www.crunchbase.com/company/netflix) mail order movie rental site Netflix (http://www.netflix.com/). Figure 51.4 shows the Netflix home page as of this writing.

First, note the two levels of navigational links at the top and the embedded "you are here" cues that let you know where in the information architecture you are at the moment (white in the tabbed top level, gray in the second level menu bar). Next, note the personalization on this page once you are logged in. This is very helpful information to regular visitors, making it easier to find movies of interest in a huge product space. Now let us look in the visitor's movie queue, shown in Figure 51.5.

The pop up movie summary shown is invoked by hovering the cursor over a movie title in the list for about a second. No click is required to either invoke or close this pop up, just mouse movement. This provides a very efficient way to browse a little more content about movies, compared to using the movie title links to navigate to another page and then navigate back. Visitors can slowly drag their cursor down the list and get summaries of any movie quickly, then move on quickly, without losing the context of the whole list.

It is also true that if the visitor drags the cursor more quickly down the list, the pop ups *would not* come up, which is equally important, to avoid a lot of pop ups coming and going when the visitor is really just trying to move the cursor to another movie title.

51.2.2 Persuasiveness

Next let us look at some examples of eCommerce website persuasiveness. Recall that one important aspect of persuasiveness is establishing trust, especially for vendors that are

Format: DVD and streaming

4.1 Our best guess for Deborah

FIGURE 51.5 **(See color insert.)** Usability: efficiency. http://www.netflix.com/Queue?lnkce=sntQu&lnkctr=mhbque.

not already well-branded and known to visitors. Figures 51.6 and 51.7 show the home page of a garden supply vendor (https://www.tomatogiant.com/).

Note that when you arrive on this site, while there is a reference to what looks like a company name (Gardener's Choice), there is no "About Us" page, no "Contact Us" page, and no corporate address. It is hard to judge who this vendor is, and in fact the website seems to offer only a single product. With website scams becoming more and more common, more and more visitors will be skeptical of unfamiliar brands and will be looking for evidence that a website vendor is trustworthy. This site does not do a good job of establishing trust.

Second, as visitors read through the product information on this page, they may find themselves a little confused about what this product actually is. Is it seeds? A partially grown plant? If a plant, how big: 1 inch? 1 foot? Do you grow it in what it comes in, in a pot, or in a garden? Indoors or outdoors? Most of the images on the page show individual tomatoes. Only when the visitor scrolls down to the bottom of the page do they see one small image of a tomato plant (and you cannot tell if it is growing in an included container, a pot, or a garden) and read in the fine print that the product comes in "nursery packs." The product is frequently referred to as a "tomato" or a "tree tomato," rather than as a "tomato tree" or "tomato plant," adding to the uncertainty. There is also a statement in the middle of the page that reads "Each Set You Order Contains Plants!" Each set of what? Tomatoes? Plants? All in all, it is likely a visitor will be left quite uncertain about what this product actually is. At best, it takes reading every word on the page to come to a conclusion about what it *probably* is. And if a visitor cannot tell who the vendor is and cannot tell what the product is, what is the likelihood of a sale?

By contrast, let us take a look at a site offering flower delivery. Figures 51.8 and 51.9 show the home page of the Pro Flowers website (http://www.proflowers.com/), which has a conversion rate of over 30% (http://www.grokdot-com.com/2009/03/18/top-10-online-retailers-by-conversion-rate-february-2009/).

Here you see both "About Us" and "Contact Us" links (although at the bottom of the page and perhaps not as noticeable as they should be), and if you follow them, you can read trust-building information, such as the fact that the company has been in business since 1998 and currently has over seven million customers (although apparently no physical address). On the home page there is a reference to an endorsement by the Wall Street Journal, a very credible entity, and also a prominently displayed phone number at the top. These elements help establish credibility and trust.

In addition, if visitors drill down to inspect particular flower arrangements, there is ample product information including excellent photographs of the arrangements and vase choices, and listings of exactly how many of what types of flowers and greens are included. The combination of evidence of trustworthiness and adequate product information with attractive and clear product photographs surely accounts in part for the very high conversion rate on this website.

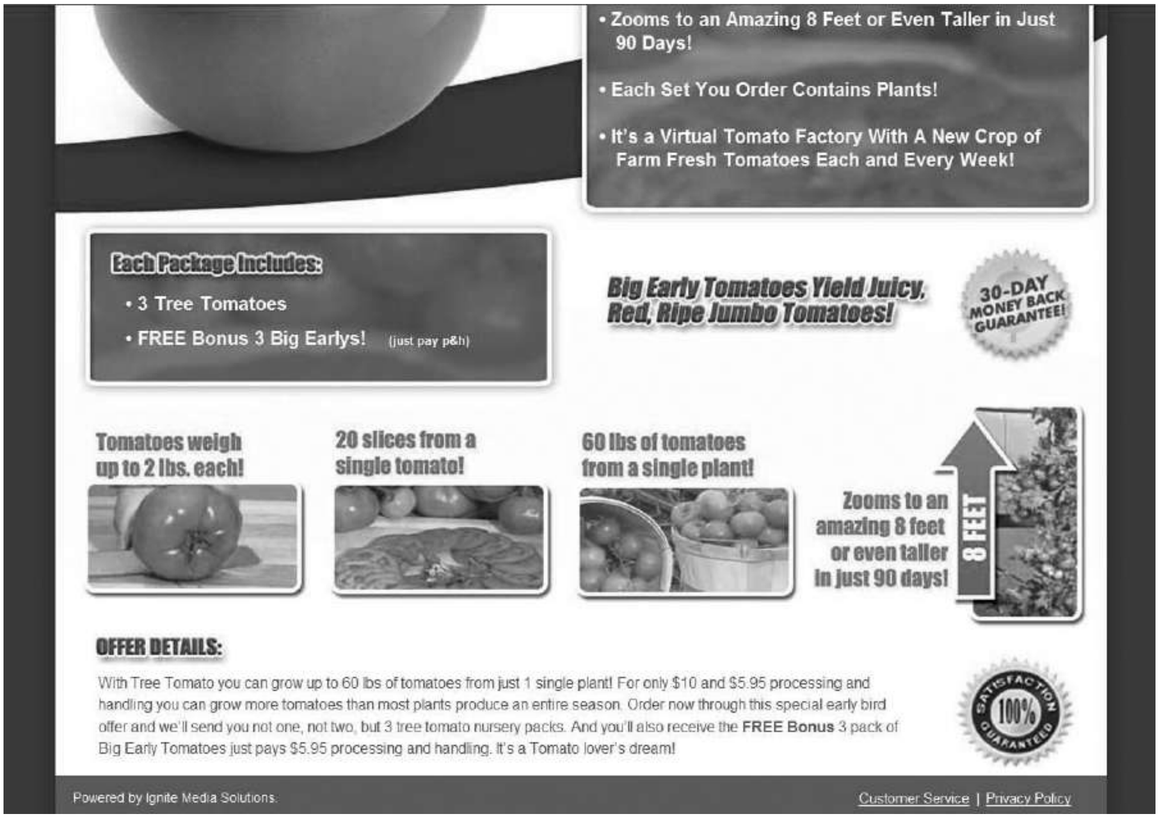
Tree Tomatoes come in easy to plant, pre-seeded professional nurseryman packs!
• Produce up to 180 Pounds of SuperSize Tomatoes for Less Than a Penny a Piece!

FIGURE 51.6 Persuasiveness: trust. https://www.tomatogiant.com/.



- Zooms to an Amazing 8 Feet or Even Taller in Just 90 Days!
- Each Set You Order Contains Plants!
- It's a Virtual Tomato Factory With A New Crop of Farm Fresh Tomatoes Each and Every Week!

Each Package Includes:

- 3 Tree Tomatoes
- FREE Bonus 3 Big Earlys! (just pay p&h)

Big Early Tomatoes Yield Juicy, Red, Ripe Jumbo Tomatoes!

30-DAY MONEY BACK GUARANTEE!
Tomatoes weigh up to 2 lbs. each!
20 slices from a single tomato!
60 lbs of tomatoes from a single plant!
Zooms to an amazing 8 feet or even taller in just 90 days!
8 FEET
SATISFACTION 100% GUARANTEED

OFFER DETAILS:

With Tree Tomato you can grow up to 60 lbs of tomatoes from just 1 single plant! For only $10 and $5.95 processing and handling you can grow more tomatoes than most plants produce an entire season. Order now through this special early bird offer and we'll send you not one, not two, but 3 tree tomato nursery packs. And you'll also receive the **FREE Bonus** 3 pack of Big Early Tomatoes just pays $5.95 processing and handling. It's a Tomato lover's dream!

51.2.3 Graphic Design

Finally, let us look at some examples of graphic design, starting with the website of a well-known and very successful vendor of gourmet coffee: Starbuck's (http://www.starbucks.com/). Figure 51.10 shows the Starbuck's home page.

The graphic design on this page seems unlikely to invoke any positive emotions or associations. It is boring, pedestrian, and uninspired. It fails to exploit the possibility of creating a positive, appealing coffee shop "ambiance"—the dominant imagery does not even include coffee or a coffee shop. Instead, it is very businesslike and likely leaves visitors cold. Internal pages on the site do no better, the design is very perfunctory.

By contrast, consider the home page of a competitor's website: New England Coffee (http://www.newenglandcoffee.com/), shown in Figures 51.11 and 51.12.

The imagery on this home page immediately conjures up the delights of good coffee in a way that is even season-specific (the screen shot was taken in mid-winter). The photographs create images in the mind and evoke smells, tastes, and even the pleasurable sensation of heat. The brown and cream color palette—more apparent on internal pages such as that shown in Figure 51.12—help to evoke the experience of good coffee. Reputation, usability, and persuasion aside, the New England Coffee site is simply much more enjoyable to visit than the Starbuck's site and more effective at invoking an appetite for good coffee.

51.3 MEASURING THE IMPACT OF THE USER EXPERIENCE

The impact of the quality of eCommerce website *usability* on the bottom line is well established. *Cost Justifying Usability—An Update for the Internet Age* (Bias and Mayhew 2005) provides many examples. Several impressive anecdotes are reported in one chapter (Rohn 2005). According to the first, Dell Computer applied usability principles to an eCommerce site, which resulted in sales increasing from $1 million to $34 million per day within 6 months. In a second, Skechers (a shoe vendor) moved its product selection closer to the home page, resulting in a sales increase of over 400%. And in a third, IBM invested in a site redesign, resulting in a 400% sales increase and an 84% decrease in use of the Help button.

There is also ample research to support the importance of *persuasion* and *graphic design* principles as well, although not much of it was conducted specifically in the context of eCommerce website design. While we do not have research that teases out the impact of each of these three qualities on eCommerce conversion rates, it seems likely that they are somewhat cumulative, that is, that adding in optimized

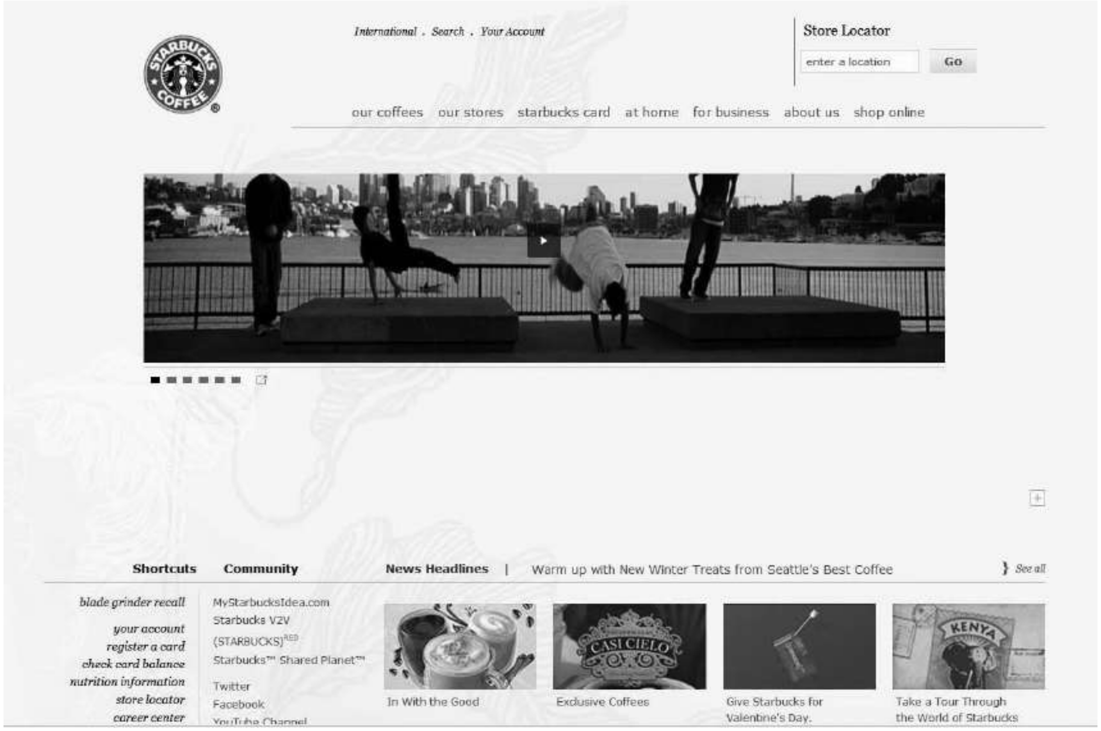

FIGURE 51.10 Graphic design: ambiance. http://www.starbucks.com/.

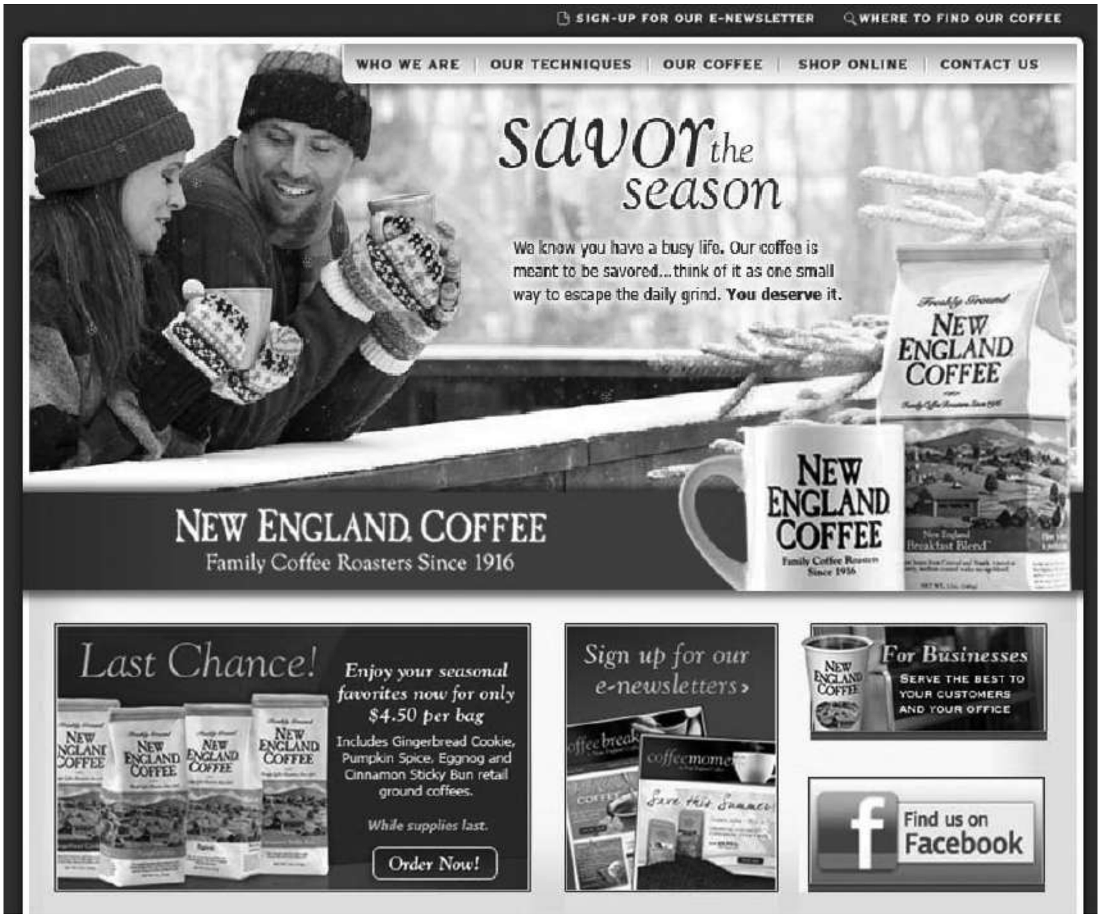

We know you have a busy life. Our coffee is meant to be savored...think of it as one small way to escape the daily grind. **You deserve it.**

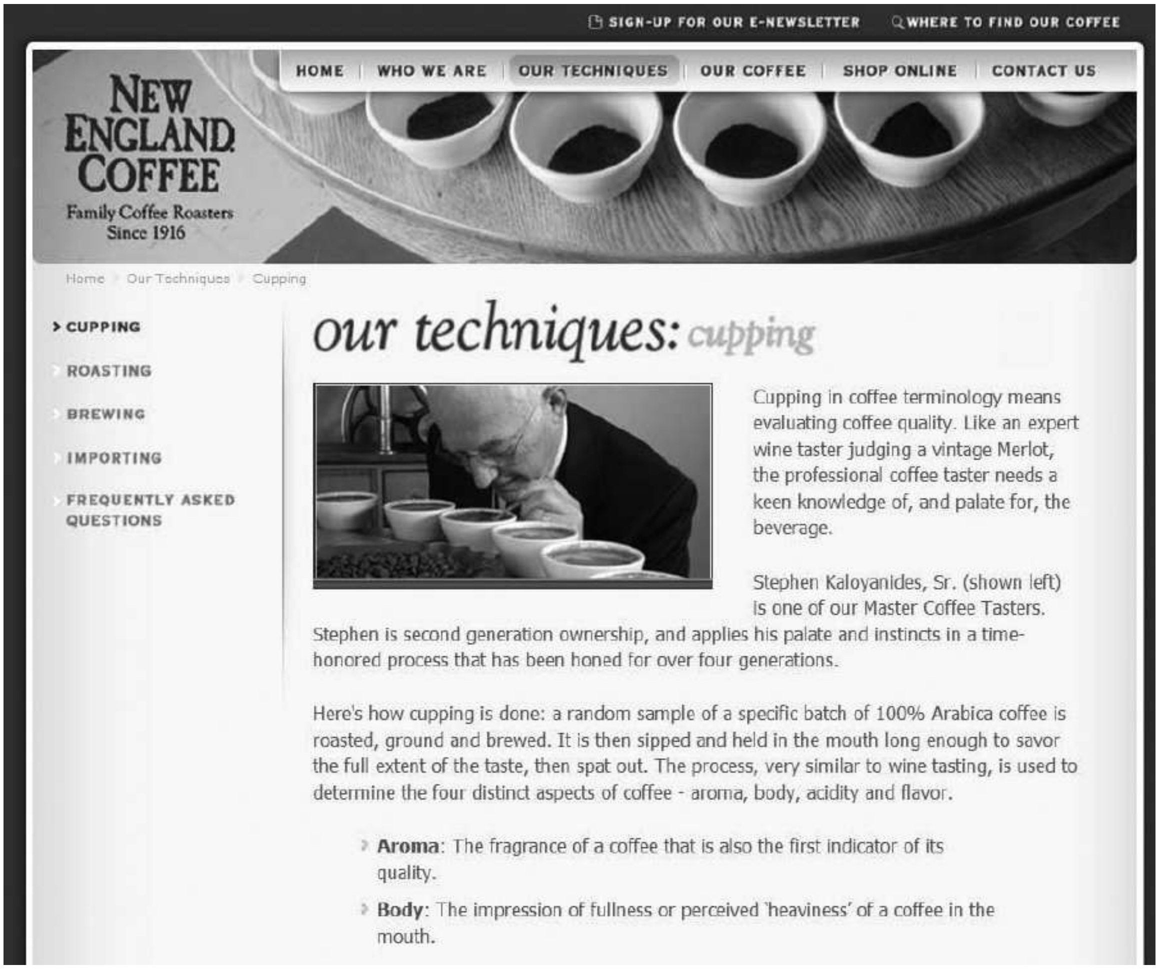
While supplies last.

FIGURE 51.11 Graphic design: ambiance. http://www.newenglandcoffee.com/.



our techniques: cupping

Cupping in coffee terminology means evaluating coffee quality. Like an expert wine taster judging a vintage Merlot, the professional coffee taster needs a keen knowledge of, and palate for, the beverage.

Stephen Kaloyanides, Sr. (shown left) is one of our Master Coffee Tasters. Stephen is second generation ownership, and applies his palate and instincts in a time-honored process that has been honed for over four generations.

Here's how cupping is done: a random sample of a specific batch of 100% Arabica coffee is roasted, ground and brewed. It is then sipped and held in the mouth long enough to savor the full extent of the taste, then spat out. The process, very similar to wine tasting, is used to determine the four distinct aspects of coffee - aroma, body, acidity and flavor.

- **Aroma**: The fragrance of a coffee that is also the first indicator of its quality.
- **Body**: The impression of fullness or perceived 'heaviness' of a coffee in the mouth.

FIGURE 51.12 Graphic design: ambiance. http://www.newenglandcoffee.com/techniques/cupping/index.asp.

persuasion and graphic design could improve conversions even more than optimizing usability alone.

In an example completely justified by research and experience (see Bias and Mayhew 2005), suppose an eCommerce website for a small business currently has the following:

- 1500 monthly visitors (a very small business)
- A 2% conversion rate
- An average $50 in revenue per online order

Annual revenue from this site is thus on average 1,500 × 0.02 × $50 × 12, or $18,000.

A very modest prediction would be that improving the *usability* of the site could increase the conversion rate from 2% to 3%, which would result in an annual revenue of 1,500 × 0.03 × $50 × 12, or $27,000, an increase of $9,000 in revenues. It seems likely that optimizing *persuasiveness* and *graphic design* as well could bump this conversion rate up even higher, increasing conversions and revenues even more.

What we do know is that statistically speaking, there is a great deal of opportunity to improve conversion rates on eCommerce websites. According to http://index.fireclick.com, the average eCommerce conversion rate in March 2009 was 1.87%. That is, more than 98% of visitors left eCommerce websites without buying. Similarly, the same source cites the shopping cart abandonment rate as 40%, meaning that 40% of visitors left sites even after putting items in their shopping cart. While some of these conversion failures will be due to things like unqualified leads coming to the site (i.e., lack of *utility* to incoming traffic) or lack of *functional integrity*, surely some significant percent are due to suboptimal usability, persuasiveness, and/or graphic design.

51.4 DEFINING A PROCESS FOR GREAT eCOMMERCE USER EXPERIENCE DESIGN

Over 10 years of experience with website developers suggests that in many organizations, sites typically evolve the quality of their user experience over releases, in a particular order represented in the pyramid in Figure 51.13.

Often a business starts with a plan for products or services and a target market, which may or may not be supported by research or already established in a bricks and mortar business. Then they may focus on getting up a functioning eCommerce website as soon as possible. If the business already exists, often the website is created directly from brochures and other traditional marketing material and catalogs, with

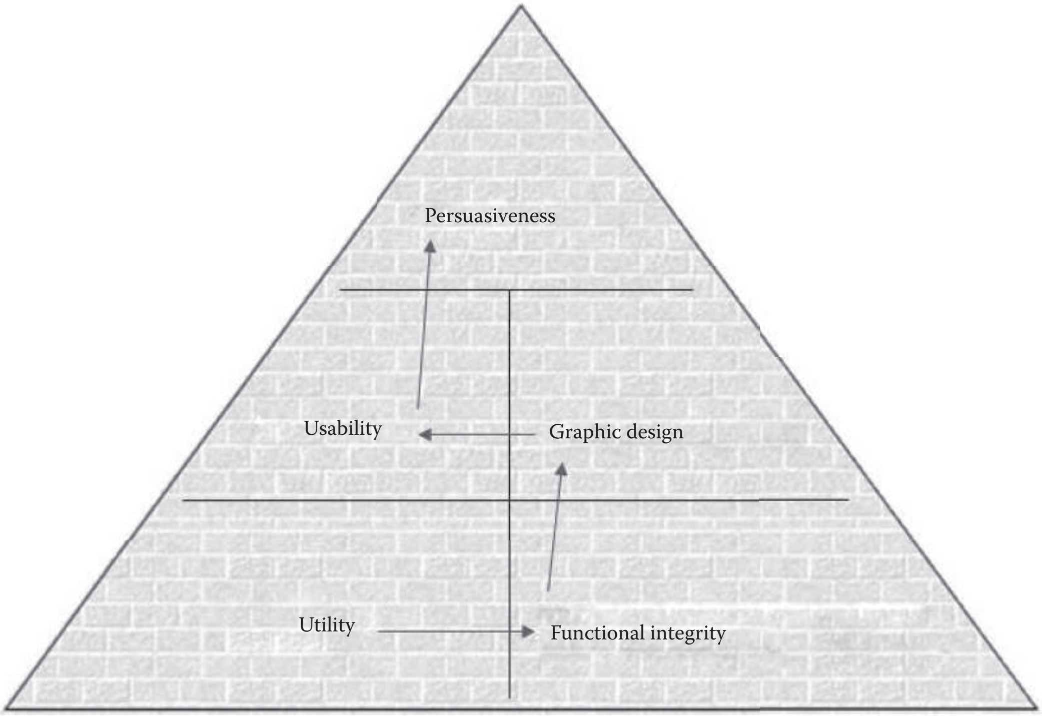


FIGURE 51.13 Typical website user experience design evolution.

little attention paid to the online user experience. That is, they start with the basics of *utility* and *functional integrity*, and launch.

Of the three remaining qualities of user experience, the one most familiar to web developers is *graphic design*, so often this is the first thing addressed in enhancements once a site is launched. Bricks and mortar businesses in particular are already familiar with the importance of good graphic design from their hardcopy marketing materials designers, and so this is a natural next step. It may take a business a while to figure out that what works on hardcopy does not necessarily work as a part of an online user experience, but at least as an organization they may be familiar with the value of graphic design and have the graphic design skill set already in house.

Less familiar to web developers and their organizations is the quality and discipline of *usability*. Usually this quality is not pursued until and unless there is some sort of "pain," such as an inordinate amount of website customer support calls or high bounce rates and low conversion rates.

Finally, in spite of the fact that established business organizations usually use marketing and sales professionals, *persuasiveness* is the least familiar user experience design quality to web developers, and even graphic design and usability experts may be unaware of this field and the importance of this quality to user experience design. Thus, this quality is often the last addressed or never addressed at all.

Evolving a website's user experience in the typical order described above and in Figure 51.13 is inefficient and expensive. It is more efficient and effective as well as less expensive to use a design process that addresses all the user experience qualities right from the start and in a logical order. The optimal order in which to address the five user experience qualities is illustrated in Figure 51.14. As the figure implies, designing and building a house provides a good metaphor for designing and building a website.

Utility does make sense as a first step. Every house building project starts with a "blueprint," which captures the basic needs and desires of the future occupants, such as the need for a certain number of bedrooms and the desire for a dining room large enough to accommodate a certain number of people.

Similarly, every business—traditional or web-based—should have a clear and well researched business plan that defines products or services, intended market, competition, competitive edge, and so on.

In homebuilding, an early next step involves designing a foundation, which will support the framework of the house, given the blueprint. No choices of building materials or interior decoration are necessary at this point. Similarly in web design and development, *usability* requirements are incorporated into an information architecture "wireframe," which is the foundation of a user experience design. No persuasive elements or graphic design are specified at this point. Without basic usability, they will not be very effective.

Next, the outside of the house is designed—shingles or brick, roofing color and material, doors and windows. These are all designed to make a home appealing from the outside, you might say to make it attract entry. Similarly in eCommerce website design, *persuasive* design elements are laid

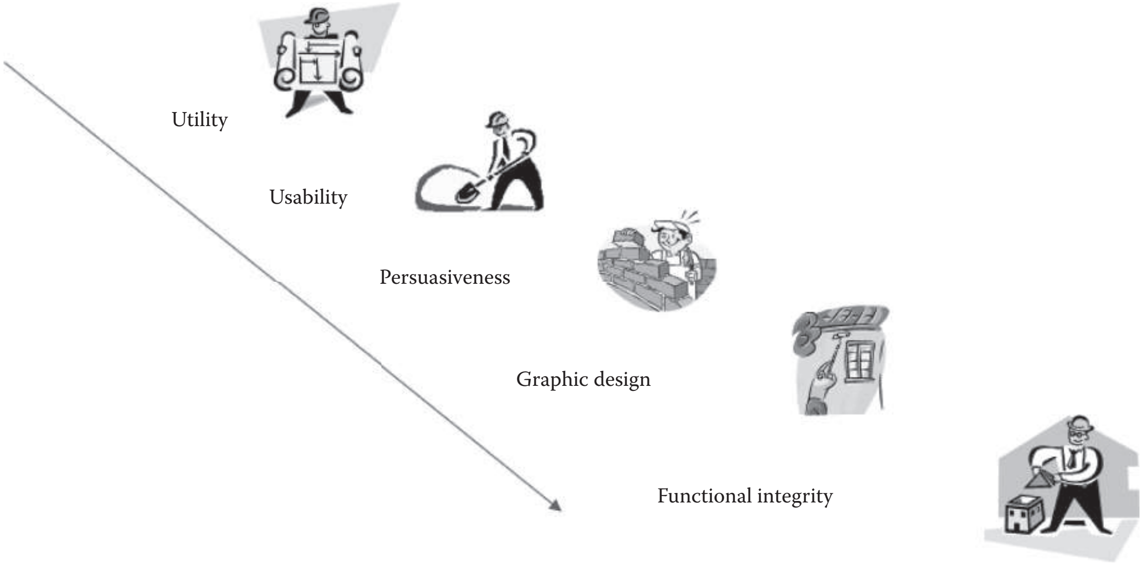

FIGURE 51.14 Recommended user experience design process.

over the information architecture design. Certain persuasive design elements appear on a site "home" page, where their purpose is to motivate engagement and encourage entry into the internal pages of the site. As illustrated earlier, persuasive elements that create trust and encourage engagement—such as credible recognitions and awards, company history, a physical business address, testimonials and the like—go beyond usability, but are more fundamental than the graphic design of those elements.

Once the framework, foundation, and exterior of a house are designed, decoration of the interior is planned to appeal to the tastes of the future occupants. Curtains, furniture, lighting, rugs, and the like move the house beyond adequate and usable, to homey, appealing, and an expression of personality and taste. Likewise, the *graphic design* of a website is the dressing over the framework of usability and persuasiveness. It makes the difference between a functional "house" and an emotionally satisfying "home."

Finally, the house—or website—is built. This is where *functional integrity* comes into the process. Just as the house is fully designed before it is built, it is premature and potentially disastrous to build a website before it has been thoroughly and well designed. You do not want to be well into decorating your bedrooms before discovering that you do not have enough for your family or build your dining room only to find that a table for 12 simply would not fit in it. Similarly, you do not want to be doing graphic design and building your eCommerce website before you are sure it will serve the needs of your visitors (usability) and engage them and encourage conversions (persuasiveness).

Getting the detailed design right before implementation is invariably more cost-effective than redesigning after launch. Adding a bedroom or enlarging the dining room is a lot cheaper and faster on paper than it is after the house is already built. In the case of eCommerce websites, if stakeholders rush to launch with little investment in the user experience and then redesign and relaunch later with an improved user experience, not only will it be more expensive, but in addition, visitors who had a bad experience with your first launch may simply never return.

51.5 SUMMARY

To summarize, while the term "user interface" is heavily associated with the specific quality of usability, the term "user experience" is more useful to eCommerce web designers and developers because it encompasses all the elements that impact a visitor's experience using a website, and in particular that impact the likelihood of a conversion. This chapter offered an optimal process (at a high level) for designing great user experiences and identified the set of skills that will increase the likelihood of success. In addition, it offered the insight that an eCommerce website development project team needs not only to be an interdisciplinary team, but also to be a team of members who all know how to work collaboratively with very different disciplines to achieve the common goal of a great user experience.

52 Human–Computer Interaction and Software Engineering for User Interface Plasticity

Joëlle Coutaz and Gaëlle Calvary

CONTENTS

52.1 INTRODUCTION

Human–computer interaction (HCI) and software engineering (SE) are like two old friends with different backgrounds: they share values but use them differently. Both domains address the design and development of useful and usable systems and are concerned with “requirements analysis,” “incremental and iterative design,” as well as “quality assurance.” However, they address these problems with different development processes, different notations, and different priorities. For HCI, human is the first-class entity in all phases of the development. For SE, the final objective is a running system developed at minimal cost and delivered in time, while satisfying contractual specifications. The user is involved, at best, at the very beginning of the process and hopefully at the very end of the project for summative evaluation. However, to avoid or correct wrong design decisions, this is too little and too late. Even in the early stages of development, functional requirements and quality goals are rarely the result of a close collaboration between HCI and SE specialists.

There are many reasons for the lack of collaboration between HCI and SE scientists and practitioners: mutual ignorance resulting from educational background, and from there, economic consideration. HCI methods such as contextual design, scenario-based approaches (Rosson and Carroll 2002), and task analysis are perceived as too demanding in terms of time and competence to inform system requirements in a formal and timely manner. On the other hand, Unified Modeling Language (UML) use cases, which express the functions that the system should support with a scenario-based flavor, are pale attempts to factor out user-centered concerns. They do not result from a human-centered requirements analysis nor do they have the expressive power of task models. Task-modeling techniques such as Concur Task Tree (Paternò 2003) or User Action Notation (Hartson, Siochi, and Hix 1990), which use notations familiar to computer scientists (i.e., Language of Temporal Ordering Specification operators and logic), are not used in SE. On the other hand, task models are not well suited for expressing what can go wrong, whereas the SE KAOS goal-oriented modeling approach supports the explicit expression of "goal obstacles" (van Lamsweerde 2009). Similarly, domain-dependent concepts referenced in task models are ill defined, whereas UML class diagrams would improve task specifications significantly.

In summary, HCI and SE pursue the same goal, using development processes and notations that sometimes overlap and complement each other. In this chapter, we present one way to exploit both fields for the development of plastic user interfaces (UIs) using the notion of model as the keystone between these two disciplines. This chapter is structured as follows: First, we define the concept of UI plasticity and develop the problem space for this concept. Exemplars of plastic interactive systems will illustrate aspects of this problem space. We then introduce the key objectives and principles of model-driven engineering (MDE) (http://planetmde.org) and analyze the contributions and limitations of MDE to address the problem of UI plasticity. Drawing from our experience with MDE applied to UI plasticity, we show how to address these limitations and conclude with recommendations for a research agenda.

52.2 USER INTERFACE PLASTICITY: DEFINITION

The term "plasticity" is inspired from the capacity of biological tissues such as plants and brain to undergo continuous deformation to rebuild themselves and to adapt to external constraints to preserve function without rupture. Applied to interactive systems, UI plasticity is the capacity of UIs to adapt to the context of use while preserving usability (Thevenin and Coutaz 1999) or human values (Calvary et al. 2003; Cockton 2004).* In the following sections, we define context of use, usability and the notion of human values in more detail.

52.2.1 Context and Context of Use

Since the early 1960s, the notion of context has been modeled and exploited in many areas of informatics. The scientific community has debated definitions and uses for many years without reaching a clear consensus (Dourish 2001; Dey 2001). Nonetheless, it is commonly agreed that context is about evolving, structured, and shared information spaces (Winograd 2001) and that such spaces are designed to serve a particular purpose (Coutaz et al. 2005). In UI plasticity, the purpose is to support the adaptation process of the UI to preserve use. Thus, there is no such thing as "the" context, but there is a context qualified by the process it serves. This is why we use the term "context of use" and not simply the word "context." A context change could be defined as the modification of the value of any element of the contextual information spaces. This definition would lead to an explosion of contexts. The following ontological foundation provides some structure to master this explosion.

52.2.1.1 Ontological Foundation for Context

As shown in Figure 52.1, a contextual information space is modeled as a directed graph where a node denotes a context and an edge denotes a condition to move between two contexts. In turn, a context is a directed graph of situations where a node denotes a situation and an edge denotes a condition to move between two situations. Thus, a contextual information space is a two-level data structure, that is, a graph of contexts where each context is in turn a graph of situations. If more structure is needed, situations may in turn be refined into "sub-situations," and so on. We now need to specify the domain of definition of contexts and situations.

A context is defined over a set E of *entities*, a set Ro of *roles* (i.e., functions) that these entities may satisfy, and a set Rel of *relations* between entities. Entities, roles, and relations are modeled as expressions of *observables* that are captured and/or inferred by the system. For example, in a conference room, E denotes the participants, Ro denotes the roles of a speaker and a listener, and Rel denotes some spatial relations between entities such as "entity e1 (who plays the role of a speaker) stands in front

* The cloud computing community uses the term "elasticity" for systems where "capabilities can be rapidly and elastically provisioned, in some cases automatically, to quickly scale out and rapidly released to scale in. To the consumer, the capabilities available for provisioning often appear to be unlimited and can be purchased in any quantity at any time" (NIST's definition—http://csrc.nist.gov/groups/SNS/cloud-computing/). Indeed, elasticity has the property of returning to an initial form (or state) following strain, which is not necessarily the case for plasticity. An elastic matter can break whereas a plastic entity aims at preserving survival. For these reasons, we consider that plasticity is a more general and demanding property than elasticity. We must admit however, that they are very similar in spirit. (In economics, elasticity measures the incidence of the variation of one variable on that of another variable. cf. Wikipedia.)

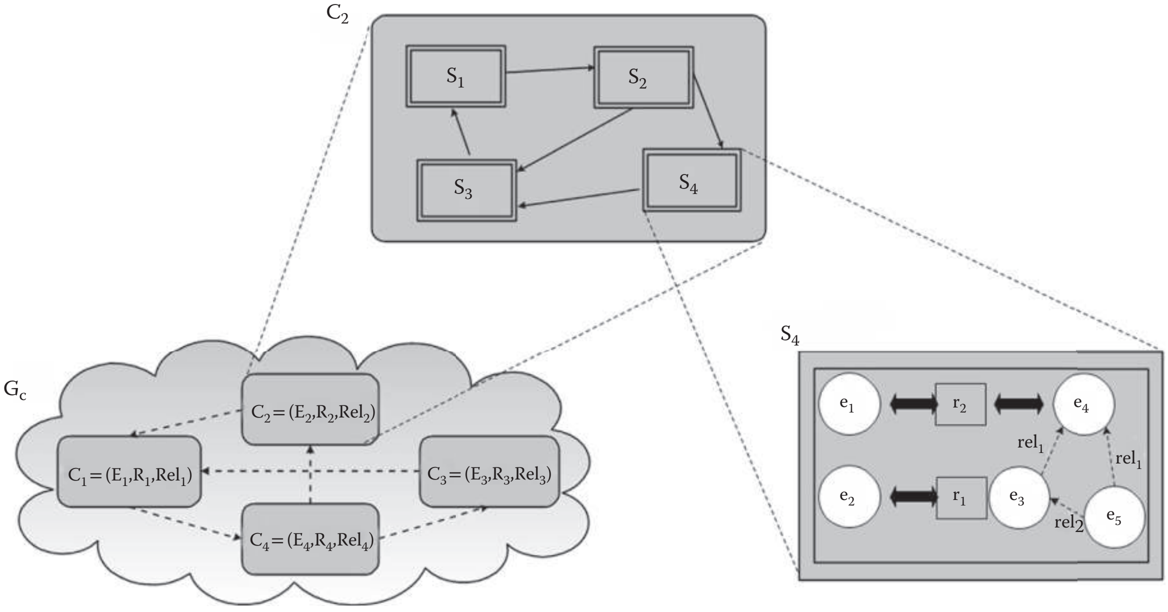

FIGURE 52.1 The graph of contexts G_C is composed of four contexts C_1, C_2, C_3, and C_4 defined on their own sets of entities, roles, and relations. In turn, Context C_2 is composed of four situations S_1, S_2, S_3, and S_4. By definition, these situations share the same sets of entities, roles, and relations. In S_4, entities e_1 and e_4 (elements of E_2) play the role r_2 (element of R_2), whereas role r_1 is played by entity e_2; e_3 and e_4 satisfy relation rel_1, e_5 and e_3 satisfy rel_2, and e_5 and e_4 are related by rel_1 (rel_1, rel_2, and rel_3 are elements of Rel_2).

of entity e_2 (who plays the role of a listener)." The situations that pertain to the same context share the same sets E, Ro, and Rel.

The condition to move between two contexts is one of the following: E is replaced by a different set (e.g., the set E of participants is now replaced with the set E' of family members), Ro has changed (e.g., the roles of the speaker and the listener are replaced with that of parent), or Rel has changed (e.g., in addition to spatial relationships, temporal relationships between entities may now matter).

The condition to move between two situations is one of the following:

- The cardinality of the set E has changed. For example, two persons enter the room and are recognized by the system as participants (their observables match the characteristics and behavior of participants). The system may provide the two latecomers with a summary of the current talk. If the latecomers are recognized as the organizers of the conference, then the system would detect a context change (not a situation change), because a new role (i.e., that of an organizer) is coming into play.
- A role assignment to an entity has changed (e.g., participant e switches from speaker to listener).
- A relation between two entities has changed (e.g., participant e was in front of e'. Now, e' is in front of e).

The ontology does not specify the nature of the entities, roles, relations, and observables. These are abstract classes from which a domain-dependent model can be specified. Using expressions of observables, designers identify the set of entities, roles, and relations that are relevant to the case at hand. Reignier et al. (2007) use this ontology and these principles for moving between situations and contexts for the development of smart environments. For UI plasticity, the observables of a context of use are organized into three information spaces that model the user, the environment, and the computing platform.

52.2.1.2 Observables of the Context of Use

The observables of a context of use define three information spaces: (1) the user model, (2) the environment model, and (3) the platform model.

1. The user model denotes the attributes and functions that describe the archetypal person who is intended to use, or is actually using, the interactive system. This ranges from basic user preferences as provided by most interactive systems, to more sophisticated descriptions such as profiles, idiosyncrasies, and current activities inferred from the repetitive use of services, of commands sequences and current tasks.
2. The environment model includes attributes and functions that characterize the physical places and times where the interaction will take place or is actually taking place. As for the user model, the number of candidate dimensions is quite large. It includes numeric locations (e.g., GPS coordinates) and/or symbolic locations (e.g., at home, in a public space, on the move in the street, a train or a car), numeric and symbolic temporal characteristics (e.g., 4th of January vs. winter), social rules and activities, as well as physical human perceivable conditions such as light, heat, and sound (using numeric and/or symbolic representations).

3. The platform model describes the computing, sensing, networking, and interaction resources that bind together the physical environment with the digital world. In the conventional GUI paradigm, the platform is limited to a single computing device, typically a workstation or a smart phone, connected to a network, and equipped with a fixed set of interaction resources such as a screen, keyboard, and stylus. Technological advances have enabled individuals to assemble and mould their own interactive spaces from public hot spots and private devices to access services within the global computing fabric. Interactive spaces will soon take the form of autonomous computing islands, or ecosystems, whose horizon will evolve, split, and merge under human control. Resources will be coupled opportunistically to amplify human activities where any real-world object has the potential to play the role of an interaction resource. Among many others, the Siftables (Merrill, Kalanithi, and Maes 2007), the History Tablecloth (Gaver 2006), as well as Skinput (Harrison, Desney, and Morris 2010) illustrate this trend. As a result, the platform must be modeled as a dynamic cluster of heterogeneous resources, rather than as a conventional mono-computing static device.

52.2.2 Usability

The term "usability" is interpreted in different ways by authors, even within the same scientific community. Usability has been identified with ease of use and learning, while excluding utility (Shackel 1984; Nielsen 1993). In other cases, usability is used to denote ease of use and utility, while ignoring learning. In SE, usability is considered an intrinsic property of the software product, whereas in HCI, usability is contextual: a system is not intrinsically usable or unusable. Instead, usability arises relatively to the context of use.

The contextual nature of usability has been recently recognized by the International Organization for Standardization/International Electrotechnical Commission (ISO/IEC) 9126 standards developed in the software community with the overarching notion of "quality in use." Quality in use is "the capability of the software product to enable specified users to achieve specified goals with effectiveness, productivity, safety, and satisfaction in specified contexts of use." Unfortunately, as shown in Figure 52.2, usability is viewed as one independent contribution to quality in use. Thus, the temptation is high for software people to assimilate usability to cosmetic issues limited to the UI component of a software product, forgetting that system latency, reliability, missing functions, and inappropriate sequencing of functions have a strong impact on the system "useworthiness."

Useworthiness is central to Cockton's argument for the development of systems that have value in the real world (Cockton 2004, 2005). In value-centered approaches, software design should start from the explicit expression of an intentional creation of value for a selected set of target contexts of use. Intended value for target contexts are then translated into evaluation criteria. Evaluation criteria are not necessarily elicited from generic intrinsic features such as time for task completion but are contextualized. They are monitored and measured in real usage to assess the achieved value.

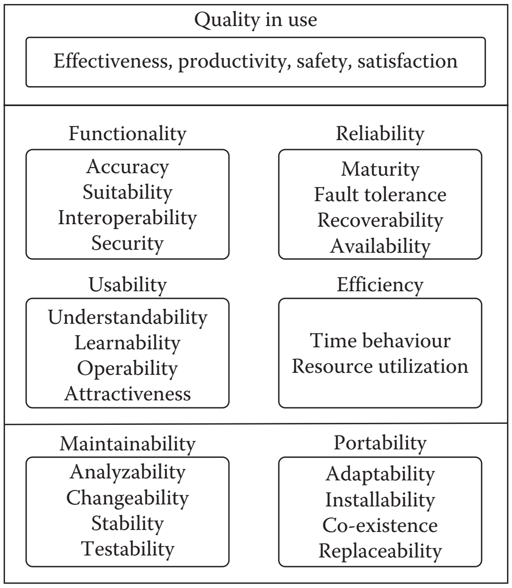

FIGURE 52.2 The usability model from ISO/IEC 9126-1.

Building on Cockton's approach, we suppose that for each of the target contexts of use C_i of a system, an intended value V_i has been defined and that V_i has been translated into the set of triples $\{(c_{i1}, d_{i1}, w_{i1}), \ldots, (c_{ij}, d_{ij}, w_{ij}), \ldots (c_{\text{in}}, d_{\text{in}}, w_{\text{in}})\}$, where c_{ij} is an evaluation criteria, and d_{ij} and w_{ij}, the expected domain of values and relative importance (the weight) of c_{ij} in C_i. As just discussed, c_{ij} may be a generic measurable feature or a customized measure that depends on the intended value in C_i. Usability U_i of the system for context C_i is evaluated against a combining function F_i on the set $\{(c_{i1}, d_{i1}, w_{i1}), \ldots, (c_{ij}, d_{ij}, w_{ij}), \ldots (c_{\text{in}}, d_{\text{in}}, w_{\text{in}})\}$ whose result is intended to lie within a domain of values D_i.

Coming back to the notion of plasticity, *an interactive system S is plastic from a source context of use C_i to a target context of use C_j* if the following two conditions are satisfied:

1. Adaptation, if needed, is supported when switching from C_i to C_j.
2. Usability (value) is preserved in C_j by the adaptation process. In other words, the usability function F_j defined for C_j lies within its intended domain D_j.

The domain of plasticity of a system is the set C of contexts of use C_i for which usability is achieved. We have defined usability by reasoning at the context level. If needed, a finer grain of reasoning can be applied at the situation level: intended value is defined for each situation of each context and then translated into evaluation criteria. Preserving usability is then evaluated on situation changes.

These definitions provide a theoretical framework where value comes first and is defined on a per-context (or situation) of use basis. For each of the intended target contexts (or situations), value is operationalized into a mix of generic and customized metrics. The difficulty is the identification of the relevant contexts of use and situations as well as the appropriate translation of value into significant metrics. We have no answer for operationalizing value, except to use generic measures when applicable, to instrument the system appropriately using sound software development techniques, such as aspect-oriented programming (Elrad, Filman, and Bader 2001), and to apply a healthy dose of common sense. However, our ontological framework on context and its associated method (Rey 2005) can be used to define the boundaries of contexts and situations of use as well as their relationships. For our notion of context of use, the fundamental entities are the user(s), environment, and platform, each of them being characterized by observables monitored by the system. Section 52.7 shows how to integrate the monitoring of observables within the software architecture of an interactive system.

52.3 PROBLEM SPACE OF USER INTERFACE PLASTICITY

Figure 52.3 captures the problem space of UI plasticity, where each branch denotes an issue along with the possible options for resolution. This problem space is characterized by (but not limited to) the following dimensions: the means used for adaptation (i.e., remolding and redistribution); the smallest UI units that can be adapted by the way of these means (from the whole UI considered a single piece of code to the finest grain: the interactor); the granularity of state recovery after adaptation has occurred (from the session level to the user's last action); the UI deployment (static or dynamic) as a way to characterize how much adaptation has been predefined at design time versus computed at runtime; the context coverage to denote the causes for adaptation with which the system is able to cope; the coverage of the technological spaces (TSs) as a way to characterize the degree of technical heterogeneity that the system supports; and the existence of a meta-UI to allow users to control and evaluate the adaptation process. A subset of these dimensions is now developed in detail.

52.3.1 Adaptation Means: UI Remolding and UI Redistribution

52.3.1.1 UI Remolding

UI remolding consists in changing the "shape" of the UI by applying one or several transformations on all, or parts, of the UI. These transformations include suppression of the UI components that become irrelevant in the new situation/context; insertion of new UI components to provide access to new services relevant in the new situation/context; substitution of UI components when UI components are replaced with new ones (substitution can be viewed as a combination of suppression and insertion); and reorganization of UI components by revisiting their spatial layout and/or their temporal dependency.

Remolding a UI from a source to a target UI may imply changes in the set of the available modalities. UI remolding is *intramodal* when the source UI components that need to be changed are retargeted within the same modality. Note that if the source UI is multimodal, then the target UI is multimodal as well: intramodal remolding does not provoke any loss in the set of modalities. Remolding is *intermodal* when the source UI components that need to be changed are retargeted into a different modality. Intermodal retargeting may engender a modality loss or a modality gain. Thus, a source multimodal UI may be retargeted into a monomodal UI, and conversely, a monomodal UI may be transformed into a multimodal UI. Remolding is *multimodal* when it uses a combination of intra- and intermodal transformations. For example, TERESA supports multimodal remolding between graphics and vocal modalities (Berti and Paternò 2005).

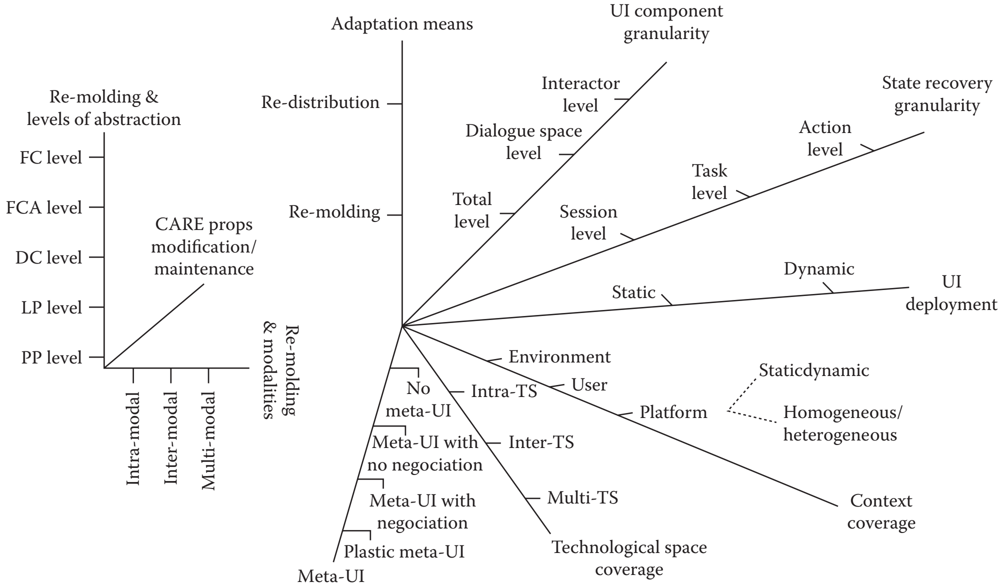

FIGURE 52.3 Problem space of user interface plasticity.

Remolding a UI may also change the way the CARE properties (Coutaz et al. 1995) are supported by the target UI (*complementarity*—several modalities must be combined to produce a semantically valid expression whether it be for input or output; *assignment*—only one modality can be used to produce a semantically valid input or output expression; *redundancy*—several equivalent modalities are used simultaneously to produce a semantically valid input or output expression; *equivalence*—several modalities are available to produce semantically equivalent expressions, but only one can be used at a time). Typically, because of a lack of computing power in the new situation, redundancy may be replaced with equivalence. Or, a synergistic complementarity (as in the "put-that-there" vocal sentence produced in parallel with two deictic gestures to denote "that" and "there") may be transformed into an alternate complementarity (as in the sequence: vocal "put that"; deictic gesture "that"; vocal "there"; and deictic gesture "there").

Transformations are performed at multiple levels of abstraction from cosmetic arrangements to deep software reconfiguration:

- At the physical presentation (PP) level, physical interactors (widgets) used for representing domain-dependent functions and concepts are kept unchanged, but their rendering and behavior may change. For example, if a concept is rendered as a button class, this concept is still represented as a button in the target UI. However, the look and feel of the button or its location in the workspace may vary. This type of adaptation is used in Tk as well as in Java/AWT with the notion of peers.
- At the logical presentation (LP) level, adaptation consists of changing the representation of domain-dependent functions and concepts. For example, the concept of month can be rendered as a Label1Textfield, or as a Label1Combobox, or as a dedicated physical interactor. In an LP adaptation, physical interactors can replace one another provided that their representational and interactional capabilities are equivalent. The implementation of an LP-level adaptation can usefully rely on the distinction between Abstract Interactive Objects and Concrete Interactive Objects as presented by Vanderdonckt and Bodart (1993). Changes at the LP level imply changes at the PP level.
- At the dialog component (DC) level, the tasks that can be executed with the system are kept unchanged, but their organization is modified. As a result, the structure of the dialog structure is changed. AVANTI's polymorphic tasks (Stephanidis and Savidis 2001) are an example of a DC-level adaptation. Changes at the DC level imply changes at the LP and PP levels.
- At the functional core adaptor (FCA) level, the nature of the entities as well as the functions exported by the functional core (which implements the domain-dependent concepts and functions) are changed. Changes at the FCA level imply changes at the DC, LP, and PP levels.

UI adaptation is often assimilated to UI remolding. This is true as long as we live in a closed world where the interaction resources are limited to that of a single computer at a time. In ubiquitous computing, the platform may be a dynamic cluster composed of multiple interconnected computing devices. In this kind of situation, instead of being *centralized*, the UI may be *distributed* across the interaction resources of the cluster.

52.3.1.2 UI Redistribution

UI redistribution denotes the reallocation of the UI components of the system to different interaction resources. The granularity of UI redistribution may vary from application level to pixel level:

- At the application level, the UI is fully replicated on each computing device. When the redistribution is dynamic, the whole UI of the application *migrates* to a new computing device, which in turn may trigger remolding.
- At the workspace level, the unit for distribution is the workspace. A workspace is a logical space that supports the execution of a set of logically connected tasks. This concept is similar to the notion of focus area used in contextual design for expressing the user-environment design. PebblesDraw (Myers 2001) and Rekimoto's Pick and Drop (Rekimoto 1997) are examples of UI distribution at the workspace level.
- The interactor level distribution is a special case of the workspace level in which the unit for distribution is an elementary interactor.
- At the pixel level, any UI component can be partitioned across multiple resources. For example, in the seminal smart room DynaWall (Streitz et al. 1999), a window may simultaneously lie over two contiguous white boards as if these were managed by a single computer.

52.3.2 State Recovery

The granularity of state recovery characterizes the effort users must apply to carry on their activity after adaptation has occurred. State recovery can be performed at the session, task, and physical action levels:

- When the system state is saved at the session level, users have to restart the interactive system from scratch. They rely on the state saved by the functional core before adaptation is taking place.
- At the task level, the user can pursue the job from the beginning of the current interrupted task (provided that the task is attainable in the retargeted system).

- At the physical action level, the user is able to carry on the current task at the exact point within the current task (provided that the task is attainable in the retargeted system).

52.3.3 Coverage of Technological Spaces

"A technological space is a working context with a set of associated concepts, body of knowledge, tools, required skills, and possibilities" (Kurtev 2002). Examples of technological spaces (TS) include documentware concerned with digital documents expressed in XML, dataware related to database systems, ontologyware, and so on. Most UIs are implemented within a single TS, such as Tcl/Tk, Swing, html. This homogeneity does not hold anymore for plastic UIs because redistribution to different computing devices may require crossing TSs. For example, a Java-based UI must be transformed into WML when migrating from a personal digital assistant (PDA) to a WAP-enabled mobile phone.

TS coverage denotes the capacity of the underlying infrastructure to support UI plasticity across TSs: *Intra-TS* corresponds to UIs that are implemented and adapted within a single TS. *Inter-TS* corresponds to the situation where the source UI, which is expressed in a single TS, is transformed into a single distinct target TS. *Multi-TS* is the flexible situation where the source and/or the target UIs are expressed in distinct TSs as supported by the Comet toolkit (Demeure, Calvary, and Koninx 2008).

52.3.4 Existence of a Meta-UI (or Supra-UI)

A meta-UI (or a Supra-UI) is a special kind of end-user development environment whose set of functions is necessary and sufficient to control and evaluate the state of an interactive ambient space (Coutaz 2006). This set is *meta* (or *supra*) because it serves as an umbrella *beyond* the domain-dependent services that support human activities in this space. It is *UI*-oriented because its role is to allow users to control and evaluate the state of the ambient interactive space. By analogy, a meta-UI is to ambient computing what desktops and shells are to conventional workstations.

A *meta-UI without negotiation* makes observable the state of the adaptation process but does not allow the user to intervene. A *meta-UI incorporates negotiation* when, for example, it cannot make sound decisions between multiple forms of adaptation, or when the user must fully control the outcome of the process.

The balance between system autonomy and too many negotiation steps is an open question. Another issue is the *plasticity of the meta-UI* itself. Thus, the recursive dimension of the meta-UI calls for the definition of a *native bootstrap meta-UI* capable of instantiating the appropriate meta-UI as the system is launched. This is yet another research issue.

The following examples illustrate the problem space of plastic UIs.

52.4 Case Studies

CamNote and Sedan-Bouillon are two examples of plastic interactive systems developed according to the MDE approach presented next. The services they provide are accessible from different types of computing devices including workstations, PDAs, and mobile phones. The UI components of these systems can be dynamically distributed and migrated across the interaction resources currently available in the interactive space. CamNote and Sedan-Bouillon differ in the TSs used for implementation: CamNote is Java centric, whereas Sedan-Bouillon uses PHP-MySQL Internet solutions. Whereas CamNote and Sedan-Bouillon offer a WIMP UI, the UI of our third example, Photo-Browser, includes a post-WIMP UI component. Photo-Browser has been developed to show how runtime adaptation can combine MDE with a code-centric approach.

52.4.1 CamNote

CamNote (for CAMELEON Note) is a slides viewer that runs on a dynamic heterogeneous platform. This platform may range from a single PC to a cluster composed of a PC and a PDA. Its UI is structured into four workspaces: (1) a slides viewer, (2) a note editor for associating comments to the slides, (3) a video viewer, also known as "mirror pixels," that shows a live video of the speaker, and (4) a control panel to browse the slides and to setup the level of transparency of the mirror. Speakers can point at items on the slide using their finger. This means of pointing is far more compelling and engaging than the conventional mouse pointer that no one can see. (Technically, the mirror is combined with the slides viewer using alpha-blending. See http://iihm.imag.fr/demos/CamNote/camnote_short.mov for a short movie demo.)

Figure 52.4a shows a configuration in which the graphical UI is distributed across the screens of a PC and PDA. The slide viewer is displayed in a rotative canvas so that it can be oriented appropriately when projected onto a horizontal surface. If the PDA disappears, the control panel automatically migrates to the PC screen. Because different resources are now available, the control panel includes different widgets and also a miniature representation of the speaker's video is now available. During the adaptation process, users

can see the control panel emerging progressively from the slides viewer, so that they can evaluate the progress of the adaptation process. The UI, which was distributed on a PC and a PDA, is now centralized on the PC (Figure 52.4b). Conversely, if the PDA reenters the interactive space, the UI automatically switches to the configuration of Figure 52.4a, and the control panel disappears from the PC screen by weaving itself into the slides viewer before reappearing on the PDA.

In this exemplar, context of use is limited to the platform. Transitions between situations occur at the arrival or departure of a computing device. Adaptation is based on redistribution of UI components at the workspace level. In turn, this redistribution triggers an intramodal GUI remolding at the dialog controller level: when the control panel resides on the PDA, the note-editing task is no longer available. Adaptation is automatic: the user has no control over the adaptation process, but a minimum of meta-UI exists (i.e., the weaving effect) to express the transition between two situations. State recovery is performed at the physical action level: the slides show is not disturbed by adaptation.

52.4.2 Sedan-Bouillon Website

Sedan-Bouillon is a website that aims at promoting tourism in the regions of Sedan (France) and Bouillon (Belgium) (http://www.bouillon-sedan.com/). It provides tourists with information for visiting and sojourning in these regions including a selection of hotels, camping, and restaurants. Figure 52.5a shows a simplified version of this website when a user is logged in from a PC workstation.

Preparing a trip for vacation is an exciting experience when shared by a group of people. However, one single PC screen does not necessarily favor collaborative exploration. By dynamically logging to the same website with a PDA, users are informed on the PDA that they can distribute the UI components of the site across the interaction resources currently available. In Figure 52.5b, the user asks for the following configuration: the title must appear on the PDA and the PC (the title slots are ticked for the two browsers available), whereas the content should stay on the PC and the navigation bar should migrate to the PDA. Figure 52.6 shows the resulting UI. At any time, the user can ask for a reconfiguration of the UI by selecting the "meta-UI" link in the navigation bar. The UI will be reconfigured accordingly.

Within the problem space of UI plasticity, the Sedan-Bouillon website is very similar to CamNote: same model of context of use, adaptation based on redistribution at the workspace level, with GUI intramodal remolding at the workspace level. Contrary to CamNote, remolding is performed at the LP level (no task is suppressed or restructured), and state recovery is supported at the task level: if adaptation occurs as the user is filling a form, the content of the form is lost by the adaptation process. Contrary to CamNote, the user has full control over the reconfiguration of the UI using the control panel provided by the meta-UI.

52.4.3 Photo-Browser

Photo-Browser supports photo browsing in a centralized or distributed way depending on the availability of a dynamic set of heterogeneous devices. These include a DiamondTouch interactive table, a wall, and a smart phone running Windows, MacOS X, and Android. The UI of Photo-Browser is dynamically composed of the following:

- A Tcl-Tk component running on the multipoint interactive surface (Figure 52.7a)
- A Java component that shows a list of the image names (Figure 52.7b)

ASSOCIATION DES PAYS DE SEDAN & BOUILLON

Entrez dans la légende des pays de Sedan et Bouillon !

BIENVENUE

Entre Meuse et Semois, de part et d'autre de la frontière franco-belge, les Pays de Sedan et de Bouillon sont d'abord un résumé des charmes et des mystères de la nature ardennaise, faite de hauts plateaux couverts de forêts profondes, de vallées sinueuses aux méandres encaissés, de panoramas superbes dominant des sites de légende, d'une faune et d'une flore d'une richesse insoupçonnée.

L'Office du tourisme du Pays Sedanais et le Syndicat d'initiative de Bouillon vous invite à découvrir et visiter leurs pays, leurs châteaux et leurs légendes. Afin de préparer au mieux votre séjour, nous essayons de rassembler sur ce nouveau site web l'ensemble des informations nécessaires : Agenda, Hôtels, Restaurants, Camping, Gîtes, Musées, ... Vous pouvez également recevoir de la documentation, pour cela utilisez notre formulaire de contact.
A très bientôt ......

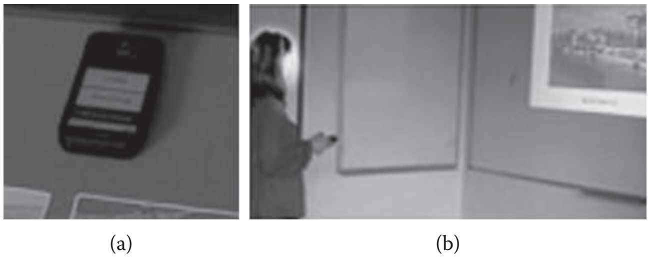

FIGURE 52.8 (a) Connecting a gPhone to the interactive space by laying it down on the interactive table. (b) Using the gPhone as a remote-controller to browse photos displayed by the HTML UI component of Figure 52.7c and video-projected on the wall.

- An HTML-based browser to navigate through the images set (Figure 52.7c)
- A Java component running on the gPhone to navigate sequentially through the photos using Next and Previous buttons (Figure 52.8)

The gPhone is dynamically connected to the interactive space by laying it down on the interactive table (Figure 52.8, left). As part of the platform, the gPhone can be used as a remote controller to browse photos displayed by the HTML UI component of Figure 52.7c and video-projected on the wall.

Within the problem space of UI plasticity, the context of use covered by Photo-Browser is a dynamic heterogeneous platform, and adaptation is multi-TS based on redistribution at the interactor level (i.e., photos) with no remolding. In its current implementation, the meta-UI is simulated using the Wizard of Oz technique. This meta-UI includes the recognition of three gestures: (1) a "wipe" gesture that allows the user to command the migration of the current selected photo from the table to the wall, (2) a "wipe" gesture that commands the system to shut down the table, and (3) the contact of the gPhone with the DiamondTouch.

Having characterized three exemplars in the problem space of UI plasticity, we now consider the method and mechanisms necessary to support UI plasticity. Although we advocate a MDE approach, we will analyze its limitations and suggest improvements.

52.5 MODEL-DRIVEN ENGINEERING

The motivation for MDE is the integration of knowledge and techniques developed in SE using the notions of model, model transformation, and mapping as the key concepts. In the early days of computer science, software systems were simple programs written in assembly languages. In those days, a code-centric approach to software development was good enough, not to say unavoidable, to ensure a fine control over the use of computing resources. Over the years, the field has evolved into the development of distinct paradigms and application domains, leading to the emergence of multiple TSs. Today, TSs can no longer evolve in autarky. Most of them share challenges of increasing complexity, such as adaptation, to which they can only offer partial solutions. Thus, we are in a situation where concepts, approaches, skills, and solutions need to be combined to address common problems. This is where MDE comes into play. MDE aims at achieving integration by defining gateways between TSs using a model-based approach. The hypothesis is that models, meta-models, model transformations, and mappings are everything.

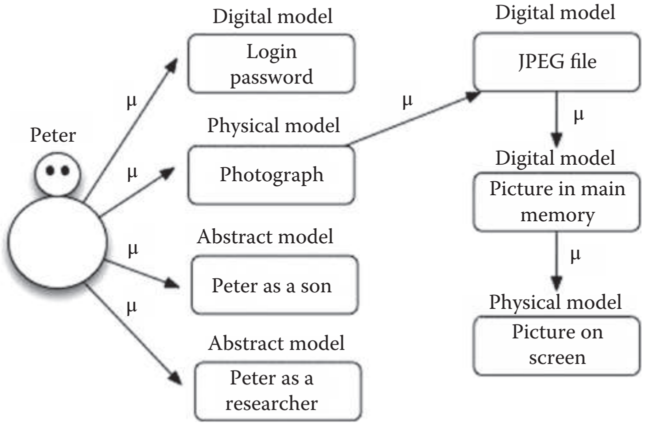

FIGURE 52.9 Models organized as oriented μ graphs (μ = "is represented by").

52.5.1 Models

A *model is a representation of a thing* (e.g., a system), *with a specific purpose*. It is "able to answer specific questions in place of the actual thing under study" (Bézivin 2004). Thus, a model, built to address one specific aspect of a problem, is by definition a simplification of the actual thing under study. For example, a task model is a simplified representation of some human activities (the actual thing under study), but it provides answers about how "representative users" proceed to reach specific goals.

A model may be *physical* (a tangible entity in the real world), *abstract* (an entity in the human mind), or *digital* (an entity within computers) (Favre 2004a,b). As illustrated in Figure 52.9, a printed photograph of a young man named Peter is a physical representation of Peter that his mother (for example) uses for a specific purpose. Peter's mother has mental representations of him as a good son or as a brilliant researcher (multiple abstract models about Peter). The authentication system that runs on Peter's computer knows him as a login name and password (digital model). If Peter's portrait is digitized as a JPEG picture, then the JPEG file is a digital model of a physical model. When displayed on the screen, the JPEG file is transformed into yet another digital graphics model in the system's main memory before being projected on the screen as an image (yet another physical model that Peter's mother can observe). As this example shows, models form oriented graphs (μ graphs) whose edges denote the μ relation "is represented by." In other words, a model can represent another model, and a model can be represented by several models.

Models may be *contemplative* (not able to be processed automatically by computers) or *productive* (able to be processed by computers). Typically, scenarios developed in

HCI (Rosson and Carroll 2002) are contemplative models of human experience in a specified setting. To be processed (by humans and/or by computers), a model must comply with some shared syntactic and semantic conventions: it must be a well-formed expression of a language. This is true for both productive and contemplative models; most contemplative models developed in HCI use a mix of drawings and natural language. A language is the set of all well-formed expressions that comply with a grammar (along with semantics). In turn, a grammar is a model from which we can produce well-formed expressions (or models). Because a grammar is a model of a set of models, it is called a "meta-model."

52.5.2 Meta-Model

A *meta-model is a model of a set of models that comply with it*. It sets the rules for producing models. It does not represent models. Models and meta-models form a tree: a model complies with a single meta-model, whereas a meta-model may have multiple compliant models.

As an example, suppose that the authentication system mentioned above is a Java program J. J is a digital model that represents Peter and that complies with the Java grammar G_J. G_J does not represent J, but defines the compliance of J with Java. G_J is one possible meta-model, but not the only one. The authentication system could also be implemented in C (yet another digital model of Peter). It would then be compliant with the C grammar G_C. Grammars G_C and G_J could be, in turn, produced from the same grammar such as Extended Backus-Naur Form (EBNF). EBNF, defined as the ISO/IEC 14977:1996 standard, is an example of a meta-meta-model, which is a model of a set of meta-models that are compliant with it. It does not represent meta-models, but sets the rules for producing distinct meta-models. As shown in Figure 52.10, the OMG model-driven architecture (MDA) initiative has introduced a four-layer modeling stack as a way to express the integration of a large diversity of standards using meta-object facility (MOF) as the unique meta-meta-model. MDA is a specific MDE deployment effort around industrial standards including MOF, UML, CWM, QVT. EBNF, G_J and G_C, and the Java and C programs are models that belong to the programming TS. Within the MDA TS, the java source code of our authentication system becomes a UML Java model compliant with the UML meta-model. In the XML Technological Space, the Java source code could be represented as a JavaML document compliant with a JavaML document type definition (DTD). (In the XML Technological Space, a DTD defines the legal building blocks of an XML document.)

As shown in Figure 52.10, the relation ("complies with") makes explicit the multiplicity of existing TSs and their systematic structure into three levels of modeling spaces (the so-called M1, M2, and M3 levels of MDA) plus the M0 level that corresponds to a system, or parts of a system. The μ and χ relations, however, do not tell how models are produced within a TS or how they relate to each other across distinct TSs. The notions of transformation and mapping are the MDE answer to this issue.

52.5.3 Transformations and Mappings

In the context of MDE, *a transformation is the production of a set of target models from a set of source models, according to a transformation definition*. A *transformation definition is a set of transformation rules* that together describe how source models are transformed into target models (Mens, Czarnecki, and VanGorp 2005). Source and target models are related by the τ relation "is transformed into." Note that a set of transformation rules is a model (a transformation model) that complies with a transformation meta-model.

Relation τ expresses an overall dependency between the source and target models. However, experience shows that finer grain of correspondence needs to be expressed. Typically, the incremental modification of one source element should be propagated easily into the corresponding target element(s) and vice versa. The need for traceability between the source and target models is expressed as mappings between source and target elements of these models. For example, as demonstrated in Section 52.6, the correspondence between a source task (and concepts) and its target workspace, window and widgets, is maintained as a mapping function.

Transformations can be characterized within a four-dimensional space:

- The *transformation may be automated* (it can be performed by a computer autonomously), semi-automated (requiring some human intervention), or manually performed by a human. For example, given our

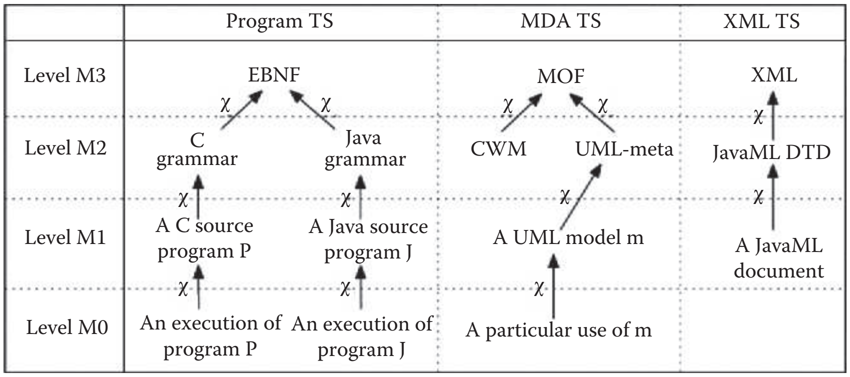

FIGURE 52.10 The OMG model-driven architecture four-layer stack.

current level of knowledge, the transformation of a "value-centered model" into a "usability model" can only be performed manually. On the other hand, UI generators such as CTTE (Mori, Paternò, and Santoro 2002, 2004) produce UIs automatically from a task model.

- A *transformation is vertical* when the source and target models reside at different levels of abstraction. UI generation is a vertical top-down transformation from high-level descriptions (such as a task model) to code generation. Reverse engineering is also a vertical transformation, but it proceeds bottom up, typically from executable code to some high-level representation by way of abstraction. A *transformation is horizontal* when the source and target models reside at the same level of abstraction. For example, translating a Java source code into C code preserves the original level of abstraction.
- Transformations are *endogenous* when the source and target models are expressed in the same language. They are *exogenous* when sources and targets are expressed in different languages while belonging to the same TS. For example, the transformation of a Java source code program into a C program is exogenous (cf. Figure 52.10).
- When *crossing TSs* (e.g., transforming a Java source code into a JavaML document), then additional tools (exporters or importers) are needed to bridge the gap between the spaces. Intertechnological transformations are key to knowledge and technical integration. This is the quest of MDE.

In Section 52.6, we show how the MDE principles have been applied to the development of plastic interactive systems by bringing together HCI practice and mainstream SE.

52.6 CONTRIBUTIONS OF MDE TO HCI AND PLASTIC USER INTERFACES

The HCI community has a long experience with models and meta-models, long before MDE existed as a field. In the 1980s, grammars (meta-models) were the formal basis for generating textual and graphical UIs (Hayes, Szekely, and Lerner 1985; Schulert, Rogers, and Hamilton 1985). MDE has helped the HCI community to define a shared vocabulary that expresses different perspectives on interactive systems as well as a reference framework for structuring the development process of plastic UIs.

52.6.1 Meta-Models as Different Perspectives on an Interactive System

Figure 52.11 shows an example of M2-level models that illustrate the principles of MDE applied to UI plasticity. These meta-models (and their relations) are intended to specify the canonic structures of the "important" concepts of the problem space of UI plasticity. These include, but are not limited to the following:

- M2-Tasks and M2-Concepts, respectively, define the notions of task and domain-dependent concepts. For example, in Figure 52.11, a task has a name and pre- and post-conditions. It may be composed of subtasks by the way of a binary operator (such as the AND, OR, SEQ operators) or decorated with a unary operator (such as Optionality, Criticity, and Default option).
- M2-Abstract UI (AUI) is a canonical expression of the rendering and manipulation of the domain-dependent concepts in a way that is independent of the concrete interactors (widgets) available on the target platform. It is expressed in terms of workspaces (as in Mara [Sottet, Calvary, and Favre 2006]), or in terms of Presentation Units (as in SEGUIA [Vanderdonckt and Bodart 1993; Vanderdonckt and Berquin 1999]), or in terms of Presentations (as in TERESA [Paternò 1999]). Workspaces, Presentation Units, and Presentations are synonyms to denote the same requirement: platform independence and absence of detailed UI design decisions.
- M2-Concrete UI (CUI) is an interactor-dependent expression of the UI. An interactor (e.g., a widget provided by an interaction toolkit such as Swing) is an entity of the UI that users can perceive (e.g., text, image, animation) and/or manipulate (e.g., a push button, a list box, a check box). A CUI expresses detailed UI design decisions.
- M2-Final UI (FUI) is the effective UI as perceived and is manipulated by the user at runtime. Typically, the same CUI Java code may behave differently depending on the Java virtual machine used at runtime.
- M2-Context of use is defined as a specialization of the ontology presented in "Context and Context of Use" where users, platforms, and physical environments are first-class entities.
- M2-Transformation supports the description of transformations that can be automated. Figure 52.12 shows an example of M1-level transformation using ATL as a meta-model to express the transformation of M2-Task compliant models into M2-Workspace compliant abstract UIs. Figure 52.13 illustrates the principles of this transformation graphically.

Considering the relations between the M2-level models of Figure 52.11, the BinaryOperators of M2-Task are related to navigation interactors to move between workspaces in the CUI. A task manipulates concepts (denoted by the "ConceptTask" relation). In turn, a concept is a class composed of a set of attributes. This class may inherit from other classes and may serve different purposes. A concept is represented as interactor(s)

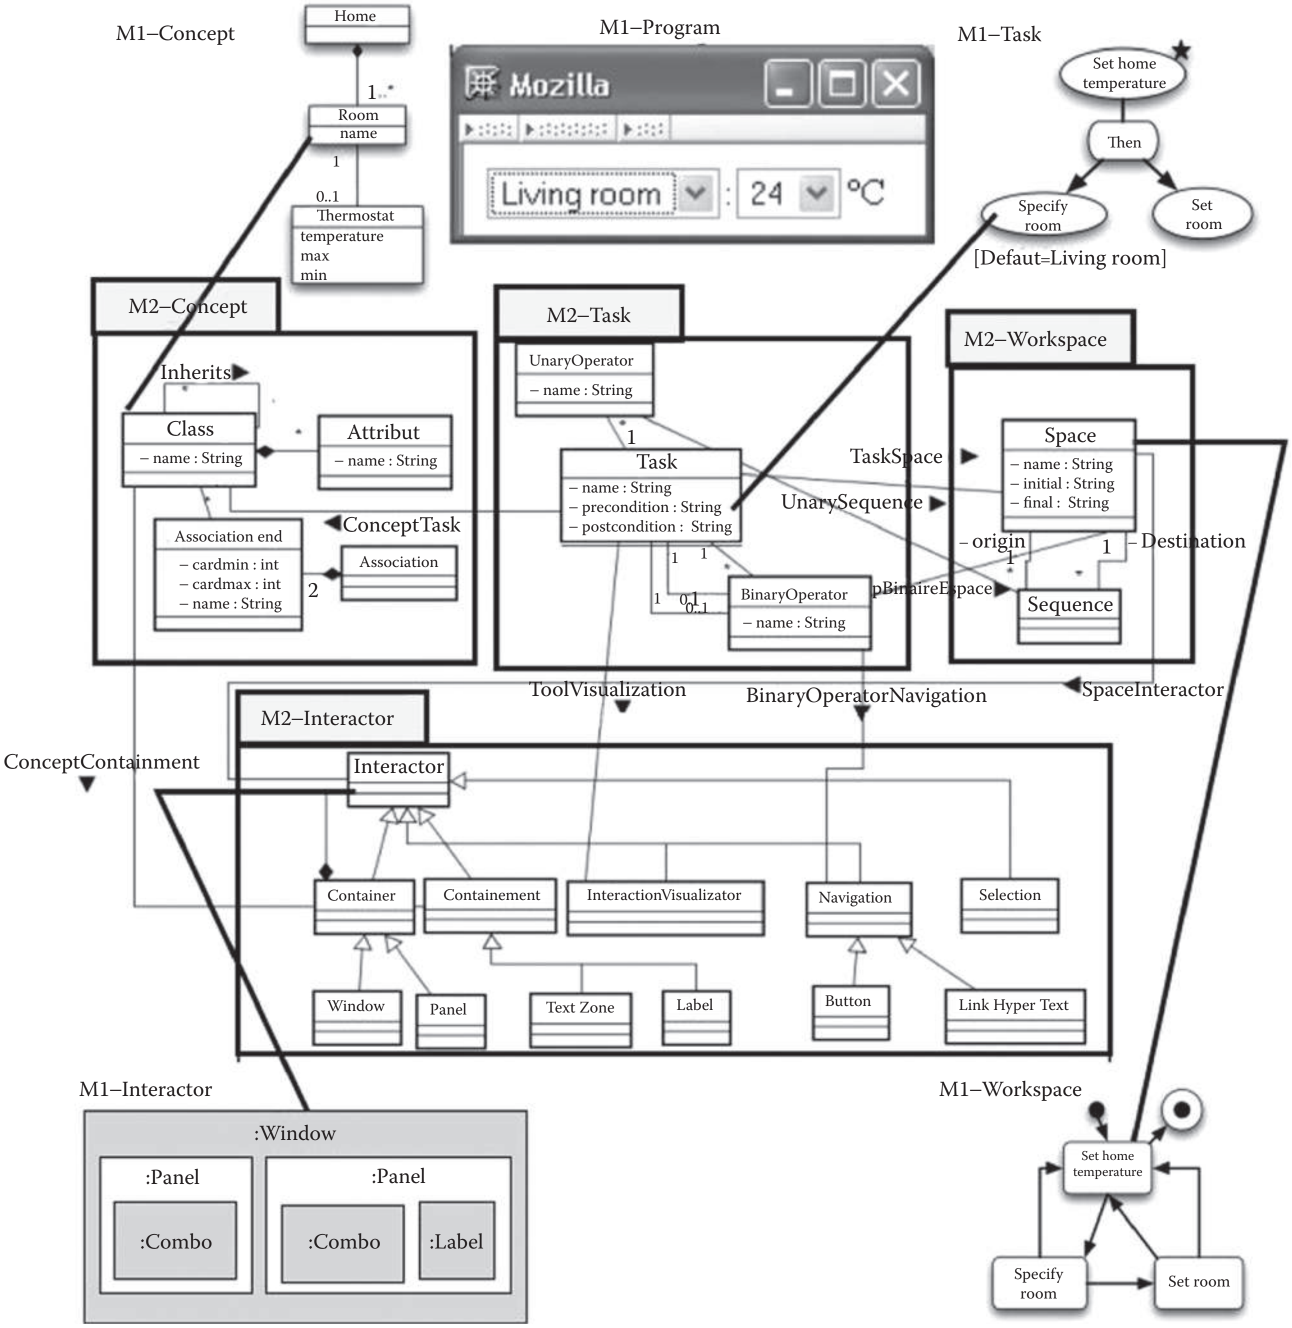

FIGURE 52.11 A home heating control system from an MDE perspective. A subset of the M1-level models and their mapping with their respective M2-level models. (For simplification purpose, only a subset of the mappings are represented.) (Adapted from Sottet, J.-S. 2008. *Méga-IHM: Malléabilité des Interfaces Homme-Machine Dirigée par les Modèles.* PhD Thesis, Université Joseph Fourier, Grenoble.)

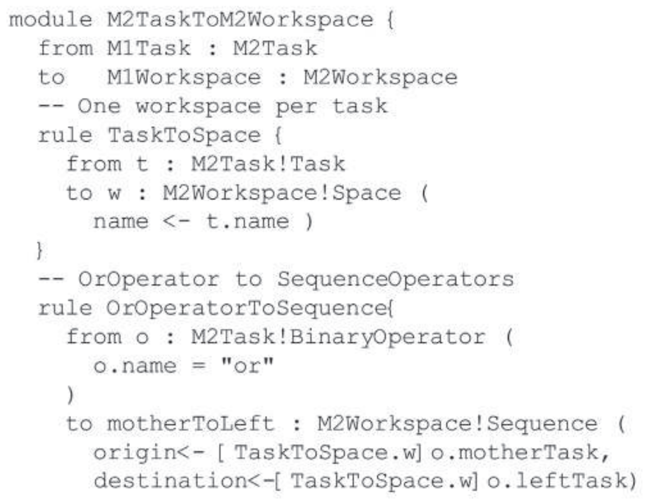
in the CUI by the way of the ConceptContainment relation. The TaskSpace relation shows how a task relates to a workspace. M2-Workspace structures the task space at an abstract level, and M2-Interactor describes the interactors that will populate workspaces in the CUI. As shown by the definition of M2-Workspace, workspaces are chained with one another depending on the binary operator of the source tasks. A workspace is mapped into the CUI as a container class interactor. This container interactor, which, in the GUI modality, may be a panel or a window, is populated with interactors that render concepts and binary operations (navigation operators).

In addition to the examples of M2-level models, Figure 52.11 shows the M1-level models instantiated for a simple example: a home heating control system. At the top of Figure 52.11, M1-Task (which is compliant with M2-Task) has a name (“Set home temperature”), is repetitive (denoted by *), and is composed of two subtasks (“Specify room” and “Set Room”) that must be executed in sequence. By default, if “Specify room” is not executed, then the selected room is the living room. M1-Workspace (at the bottom right of Figure 52.11) is the AUI that corresponds to M1-Task. M1-Workspace is comprised of three workspaces (one per



```
module M2TaskToM2Workspace {
  from M1Task : M2Task
  to   M1Workspace : M2Workspace
  -- One workspace per task
  rule TaskToSpace {
    from t : M2Task!Task
    to w : M2Workspace!Space (
      name <- t.name )
  }
  -- OrOperator to SequenceOperators
  rule OrOperatorToSequence{
    from o : M2Task!BinaryOperator (
      o.name = "or"
    )
    to motherToLeft : M2Workspace!Sequence (
      origin<- [ TaskToSpace.w] o.motherTask,
      destination<-[ TaskToSpace.w] o.leftTask)
```

FIGURE 52.12 An ATL transformation description based on the meta-models shown in Figure 52.11. The rule *TaskToSpace* creates one workspace *w* per source task *t* where *w* takes the name of *t*; The rule *OrOperatorToSequence* transforms all OR operators *o* between two tasks (*o.leftTask* and *o.rightTask*) into two sequence operators (from *o.motherTask* to *o.leftTask*, and *o.leftTask* to *o.rightTask*).

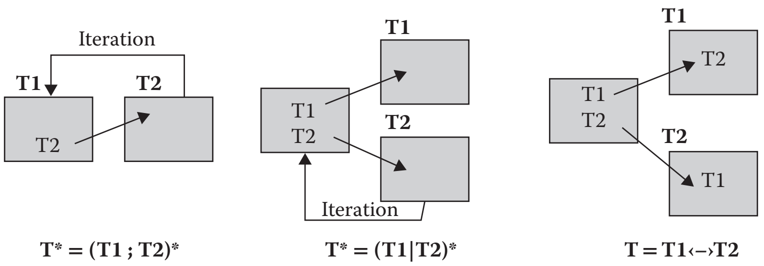


FIGURE 52.13 Typical transformation patterns between task models (expressed with UAN operators) and workspaces.

task) whose relations (denoted by arrows) express the navigation scheme between the workspaces. M1-Workspace is then populated with interactors to obtain a CUI. As shown at the bottom left of Figure 52.11, the "Set home temperature" workspace is mapped into a window, and the two others "Specify room" and "Set Room" become panels, populated with Combobox and Combobox with Label, respectively. At the top center of Figure 52.11, M1-Program represents the FUI of the home heating control system. All these M1-level models have been derived automatically by way of transformations.

Until recently, transformation rules were implemented as code within UI generators offering very little to no control over the resulting UI (Hayes, Szekely, and Lerner 1985; Schulert, Rogers, and Hamilton 1985). In addition, mappings were limited to the expression of correspondence (bindings) between elements of the UI with the API of the functional core (i.e., the business code). *MDE has helped the HCI community to promote transformation rules as models.* "Transformations as models" has three notable advantages—which, so far, have not been fully exploited by the HCI community: (1) It opens the way to knowledge capitalization and reuse: frequent transformations can serve as patterns in libraries, which in turn provide handles for intra- and inter-UI consistency. (2) Comparative evaluations of UIs can be performed in a controlled way, and UIs can be (re)targeted for different contexts of use using different transformations. (3) Most notably, transformations can be transformed, offering a powerful formal recursive mechanism for supporting UI plasticity. To our best knowledge, no research has been conducted on transforming transformations for UI plasticity. On the other hand, patterns are emerging (Taleb, Seffah, and Abran 2009), and early work has been initiated on UIs generated with different sets of transformation rules to support different usability criteria (Gajos, Wobbrock, and Weld 2008; Sottet et al. 2007).

The set of meta-models presented in Figure 52.11 is only one example among a plethora of proposals. Whereas there are a multiplicity of meta-models for task modeling (e.g., TeresaXML), the CUI level, on the other hand, is a very active area of research with no clear integrated vision. This is primarily due to the inherent diversity of interaction modalities and of interaction paradigms developed in HCI and also the diversity of TSs and of the competition among software vendors. To name just a few, the W3C recommendations include VoiceXML for voice integration, InkML for digital ink input representation with electronic pen, Extensible Multimodal Annotation Markup Language (EMMA) for multimodal input, not to mention 3D Markup Language (3DML) and Virtual Human Markup Language (VHML). Software vendors offer Macromedia Flex Markup Language (MXML), OpenLaszlo, XUL, XAML, and many other UI description languages (UIDL). As an answer to this plethora, the European ITEA2 UsiXML research project aims at covering the problem space of UI plasticity into a unified, systematic, and structured way with a clear motivation for standardization (http://usixml.org, http://itea.defimedia.be/usixml). The framework presented in Section 52.6.2 will serve as a basis for structuring the development process along with the appropriate tool support.

52.6.2 Reference Framework for a Structured Development Process

Over the years, the CAMELEON framework has progressively come to serve as a generic canonical structure for exploiting MDE to address the problem of UI plasticity (Calvary et al. 2003). In particular, the notion of transformation is used to cover many forms of the development process (see Figure 52.14). Typically in a forward engineering process, an AUI is derived from the domain-dependent concepts and task models. In turn, the AUI is transformed into a CUI, followed by the final executable UI. At the opposite, a reverse engineering process infers abstract models from more concrete ones using vertical bottom-up transformations. Translations may also be applied to transform a source model into a new model adapted for a different context of use.

Unlike the process initiated in the 1980s, which contained one entry point only at a high level of abstraction, the CAMELEON framework authorizes entry points at any level of abstraction from which any combination of horizontal and vertical bottom-up and top-down transformations can be applied. This theoretical flexibility means that the stakeholders involved in the development of an interactive system can use the development process that best suits their practice or the case at hand. In other words, the CAMELEON framework can be put in actions in many ways.

Seminal work in forward engineering for UI plasticity includes UIML (Phanariou 2000) and XIML (Puerta and Eisenstein 2001) that transform M1-level models into M0 level programs to support LP-level adaptation for centralized GUI. Tools for retargeting UIs such as Vaquita (Bouillon and Vanderdonckt 2002) and WebRevenge (Paganelli and Paternò 2003) correspond to a combination of bottom-up vertical, horizontal, and top-down vertical transformations. They lie within the same meta-meta level (the XML Technological Space), but they use distinct M2 meta-models. Vaquita and WebRevenge work offline. On the other hand, Digymes (Coninx et al. 2003) and Icrafter (Ponnekanti et al. 2001) generate CUI at runtime where a renderer dynamically computes a CUI from a workspace-level model expressed in XML. Websplitter (Han, Perret, and Naghshineh 2000) supports the distribution of web

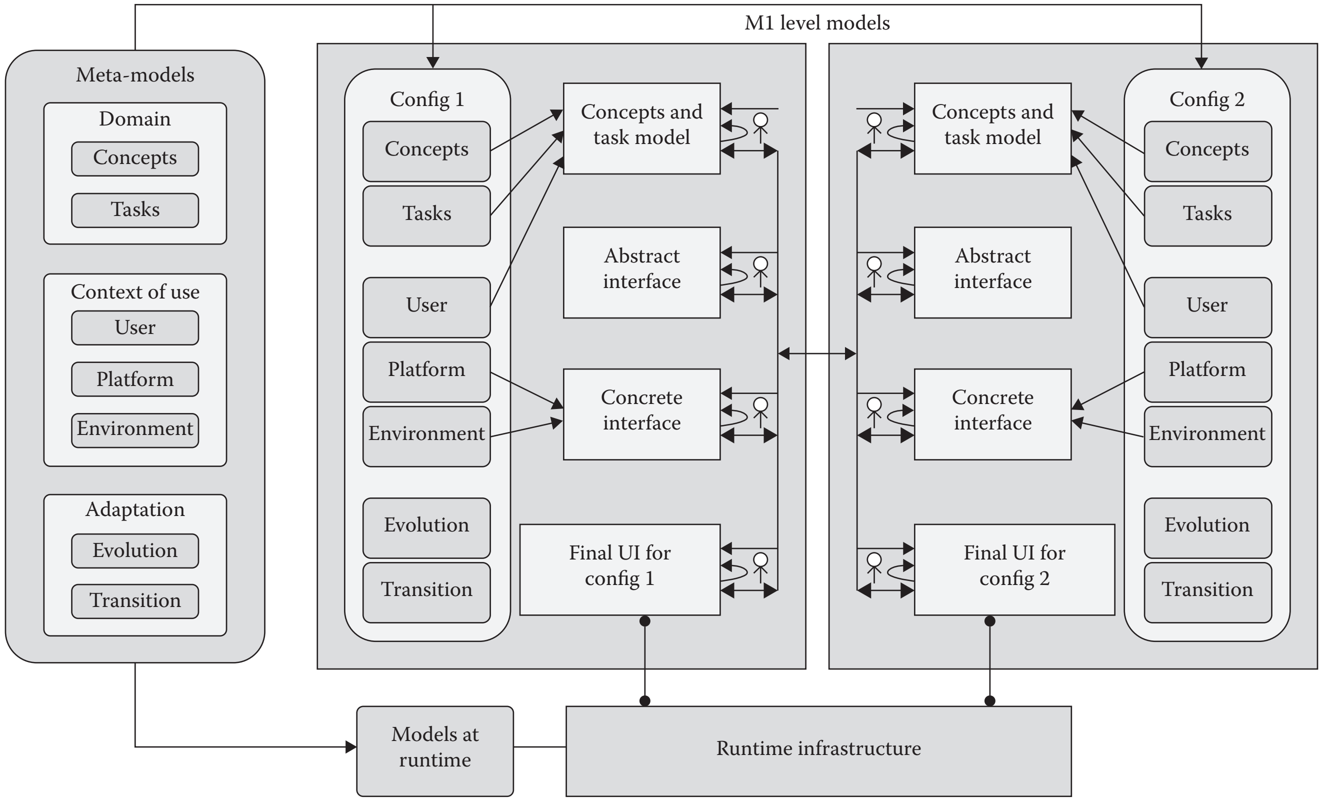

FIGURE 52.14 The CAMELEON reference framework for the development of plastic user interfaces.

pages content at the interactor level across the interaction resources of heterogeneous clusters, but distribution is statically specified in an XML policy file. As proof of concepts, small-size exemplars have been developed for different TSs.

To summarize, the CAMELEON reference framework is an MDE-compliant generic structuring conceptual tool for the development of plastic UIs:

- As a structuring reference framework, it federates the HCI community around a consensus.
- As a conceptual generic tool, it sets a vast agenda for technical research.
- As an MDE-compliant framework, it is still unclear in practice that formal modeling is the only way to go in HCI. This issue is discussed next.

52.6.3 Limits of MDE

The CAMELEON reference framework brings together the "right models," but the HCI community is far from having the "models right." As discussed above, the profusion of initiatives related to UIDL is symptomatic of the need and difficulty to define a coherent set of nonambiguous and easy to understand meta-models capable of covering the problem space of plastic UIs. In our opinion, two meta-models (at least) are key to the success of MDE for addressing UI plasticity: transformations and CUIs.

Transformations offer an elegant mechanism for full flexibility and technical integration. However, *transformations are hard to express*: QVT and ATL (Bézivin et al. 2003) are not languages for naive developers. In addition, usability rules (Sottet et al. 2007) are even harder to convey formally. More importantly, *inverse transformations cannot be automatically derived* for any source transformations. This is a fundamental flaw that may result in inconsistent models as transformations are performed up and down iteratively during the lifecycle of a system, breaking down the flexibility of the solution space envisioned by the CAMELEON reference framework. TransformiXML of the UsiXML (Limbourg 2004; Limbourg et al. 2004) meta-level environment, which is based on graphs transformations, is certainly a promising way.

At the CUI level, meta-modeling not only lags behind innovation but also bridles creativity. UIDLs for the expression of concrete UIs are technology driven instead of leaving rooms for new forms of interaction techniques. Although the CARE properties (Coutaz et al. 1995) have been devised 15 years ago, CUI languages have hardly scratched the surface of multimodal interaction. We are still unable to generate the paradigmatic "put-that-there" multimodal UI introduced more than 25 years ago (Bolt 1980). However, we do generate simplistic multimodal UIs based on XHTML+VoiceXML but with very limited microdialogs for interaction repair (Berti and Paternò 2005). Actually, CUI-level UIDLs are still struggling with the description of conventional GUIs for desktop computing. Meanwhile

- New forms of "constructable" computers such as the MIT siftables* and the CMU toy blocks† are put on the market.
- Novel interaction techniques are proliferating whether it be for supporting mobility (e.g., SixthSense [Mistry and Maes 2009]), for 3D interaction (where gesture and 3D screens are becoming predominant), or even for graphical tabletops and multisurface interaction (Balakrishnan and Baudisch 2009).
- New requirements are emerging: design is switching from the development of useful and usable systems for people with precise goals to engaging and inspired interaction spaces whose users can easily switch from consumers to creators.

In short, CUI meta-models need to capture the unbound vibrant convergence of physicality with "digitality." Perhaps, meta-modeling is, by essence, the wrong approach to CUIs: a model, which represents a thing, is necessarily a simplification, therefore a reduction, of the real thing. In these conditions, the subtle aspects of interaction, which make all the differences between constrained and inspired design, are better expressed using code directly in place of an abstraction of this code. However, this assertion should be mitigated by the following findings: designers excel at sketching pictures to specify concrete rendering. On the other hand, they find it difficult to express the dynamics, forcing them to use natural language (Myers et al. 2008). One way to fill the gap between designers' practice and productive models is to revive work à-la-Peridot (Myers 1990) such as SketchiXML (Coyette et al. 2004; Kieffer, Coyette, and Vanderdonckt 2010) where drawings are retro-engineered into machine-computable rendering. As for inferring behavior from examples, the promising "Watch What I Do" paradigm initiated in the late 1970s (cf. Dave Smith's Pygmalion system [Smith 1993]) is still an opened question.

In addition to impeding creativity, MDE, as a software development methodology, has favored the dichotomy between the design stages and the runtime phase, resulting in three major drawbacks:

1. Over time, models may get out of sync with the running code.
2. Design tools are intended for software professionals not for "the people." As a result, end users are doomed to consume what software designers have decided to be good for their hypothetic target users.
3. Runtime adaptation is limited to the changes of context identified as a key by the developers. Again, the envelope for end users' activities is constrained by design.

* http://sifteo.com/.

† http://www.modrobotics.com/.

Applied to UI development, the dichotomy between design and runtime phases means that UI generation from a task model cannot cope with ambient computing where task arrangement may be highly opportunistic and unpredictable. On the other hand, because the task model is not available at runtime, the links between the FUI and its original task model are lost. It is then difficult, not to say impossible, to articulate runtime adaptation based on semantically rich design-time descriptions. As a result, a FUI cannot be remolded beyond its cosmetic surface as supported by the CSS (Cascading Style Sheets).

Blurring the distinction between the design stage and the runtime phase is a promising approach. This idea is emerging in mainstream middleware (Ferry et al. 2009) as well as in HCI. The middleware community, however, does not necessarily address the concerns of the end user. Typically, a "sloppy" dynamic reconfiguration at the middleware level is good enough if it preserves system autonomy. It is not "observable" to the end user, whereas UI remolding and UI redistribution are! Thus, UI plasticity puts additional constraints on the developers and on the tools to support them. In particular, it becomes necessary to make explicit the transition between the source and the target UIs so that, in Norman's terms, end users can evaluate the new state. We need to pay attention to transition UIs in generic terms, not on a case-by-case basis.

In Section 52.7, we show how MDE can be reconciled with a code-centric approach at runtime.

52.7 MODELS AT RUNTIME

The combination of MDE with "code centricity" relies on three principles:

1. Principle 1: Cooperation between closed adaptiveness and open adaptiveness.
2. Principle 2: Runtime availability of high-level models.
3. Principle 3: Balance between the importance of Principles 1 and 2. The application of this principle is illustrated with Photo-Browser.

52.7.1 Principle 1: Cooperation between Closed Adaptiveness and Open Adaptiveness

"A system is open-adaptive if new application behaviors and adaptation plans can be introduced during runtime. A system is closed adaptive if it is self-contained and not able to support the addition of new behaviors" (Oreizy et al. 1999, page 55). By design, an interactive system has an "innate domain of plasticity": it is closed adaptive for the set of contexts of use for which this system/component can adapt on its own. For unplanned contexts of use, the system is forced to go beyond its domain of plasticity. It must be open adaptive so that a tier infrastructure (i.e., a middleware) can take over the adaptation process. The CAMELEON runtime conceptual architecture (CAMELEON-RT) shows how closed adaptiveness and open adaptiveness can be combined harmoniously (Balme et al. 2004). CAMELEON-RT shown in Figure 52.15 is a refinement of the box "Runtime infrastructure" at the bottom of Figure 52.14.

At the bottom of Figure 52.15, "Hardware" denotes a wide variety of physical entities: computing and communication facilities, interaction resources such as displays, mice, and stylus, as well as sensors and actuators. "Operating Systems" includes legacy OS such as Linux, MacOS, and Android; virtual machines such as the JVM; and modality interpreters such as speech and gesture recognition. Together, "Hardware" and "Operating Systems" constitute the ground basis of the interactive space, that is, the platform as defined in Section 52.2.

The top of Figure 52.15 shows the interactive systems (e.g., CamNote and Photo-Browser) that users are currently running in the interactive space. The meta-UI is one of them. A flower-like shape, ✿, denotes open adaptive components of these interactive systems. Components are open adaptative if they provide the world with management mechanisms. Management mechanisms include self-descriptive metadata (such as the current state and the services it supports and requires), and the methods to control its behavior such as start/stop and get/set-state. Software reflexivity coupled with a component model is a good approach to achieve open adaptiveness. The miniature adaptation-manager shape, ⊞⊡, denotes facilities embedded in the interactive system to support closed adaptiveness to observe the world, to detect situations that require adaptation, to compute a reaction that satisfies the new situation, and to perform adaptation. This functional decomposition is similar to that of the tier infrastructure shown in the center of Figure 52.15.

The tier infrastructure that supports open adaptiveness is structured in the following way:

- The context infrastructure builds and maintains a model of the context of use (Reignier et al. 2007). In turn, this infrastructure can be refined into multiple levels of abstraction, typically: raw data acquisition as numeric observables, transformation of raw data at the appropriate level of abstraction (e.g., as symbolic observables), which then feeds into situation management.
- The situation synthesizer computes the situation and possibly informs the evolution engine of the occurrence of a new situation. (This layer is in general considered as a part of the context infrastructure.)
- The evolution engine elaborates a reaction in response to the new situation.
- The adaptation producer implements the adaptation plan produced by the evolution engine. This is where the following dimensions of the problem space of UI plasticity come in play: granularity of UI remolding and/or redistribution, granularity of state recovery, coverage of TSs, and presence of a meta-UI.

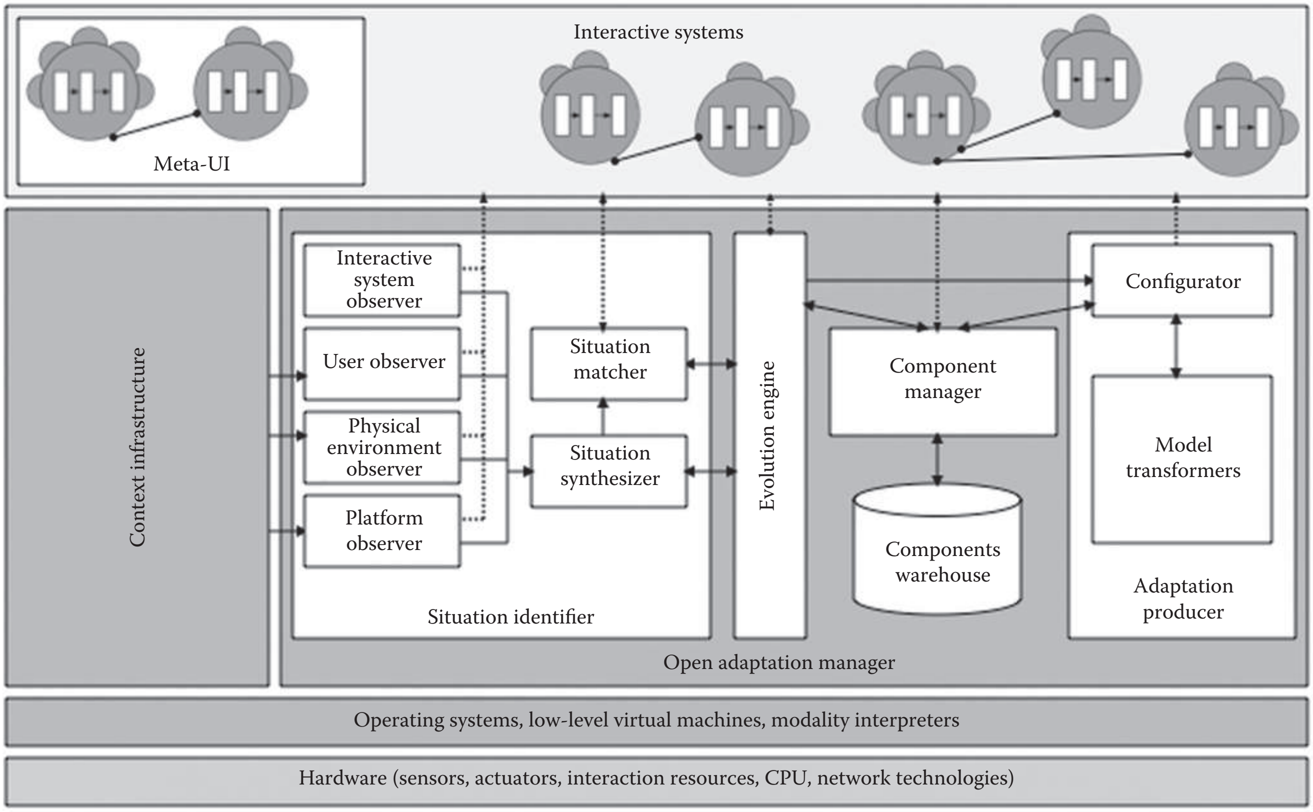

FIGURE 52.15 CAMELEON RT: a functional decomposition for supporting a mix of closed-adaptiveness and open-adaptiveness at runtime.

Such a functional decomposition is commonly used for the development of autonomic systems. To adapt this decomposition to plastic UIs, we propose the following improvements:

- The end user is kept in the loop: the reaction to a new situation may be a mix of specifications provided by developers or learned by the evolution engine based on observations of and reasoning on human and environmental behavior. In addition, the evolution engine as well as the adaptation producer may call upon end users' advice by the way of the meta-UI.
- The components referred to in the action plan do not necessarily exist as executable code. This is where Principle 2 comes into play.

52.7.2 Principle 2: Runtime Availability of High Level of Abstraction Models

At runtime, an interactive system is a set of graphs of models that express different aspects of the system at multiple levels of abstraction. As advocated by the CAMELEON framework, these models are related by mappings and transformations. As a result, an interactive system is not limited to a set of linked pieces of code. Models developed at design time, which convey high-level design decision, are still available at runtime for performing rational adaptation beyond cosmetic changes. When a component retrieved by the component manager is a high-level description such as a task model, the configurator relies on reificators to produce executable code as in Digymes (Coninx et al. 2003) and iCrafter (Ponnekanti et al. 2001). A retrieved component may be executable but may not fit the requirements. Ideally, it can be reversed engineered through abstractors, then transformed by translators and reified again into executable code (Bouillon and Vanderdonckt 2002).

52.7.3 Principle 3: Balance between Principles 1 and 2

By analogy with the slinky meta-model of the Arch model (Bass et al. 1992), the software developer can play with Principles 1 and 2. At one extreme, the interactive system may exist as one single-task model linked to one single AUI graph, linked to a single CUI graph, and so on (see Figure 52.16). This application of Principle 1 does not indeed leave much flexibility to cope with unpredictable situations unless it relies completely on the tier middleware infrastructure that can modify any of these models on the fly, then triggers the appropriate transformations to update the FUI. This approach works well for interactive systems for which conventional WIMP UIs are "good enough."

At the other extreme, the various perspectives of the system (task models, AUI, FUI, context model, etc.) as well as the adaptation mechanisms of the tier infrastructure are distributed across distinct UI service-oriented components,

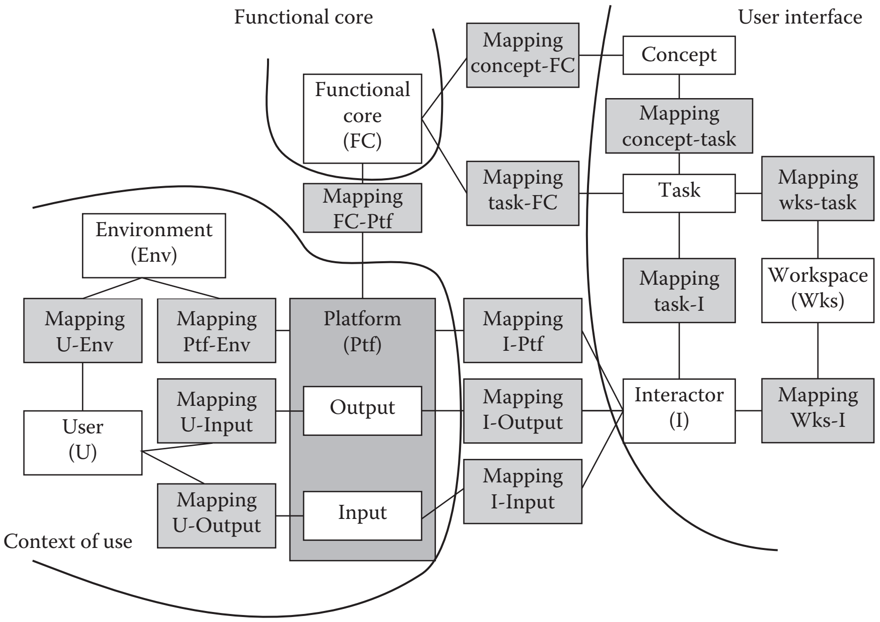

FIGURE 52.16 An interactive system as a graph of models available at runtime. These models are related by mappings and transformations.

each one covering a small-task grain that can be run in different contexts of use. This approach has been applied in the Comet toolkit (Demeure, Calvary, and Koninx 2008).

Basically, a comet is a plastic microinteractive system whose architecture pushes forward the separation of concerns advocated by PAC (Coutaz 1987) and MVC (Krasner and Pope 1988). The functional coverage of a comet is left open (from a plastic widget such as a control panel, to a complete system such as a powerpoint-like slide viewer). Each comet embeds its own task model, its own adaptation algorithm, as well as multiple CUIs and FUIs, each one adapted to a particular context of use. FUIs are hand coded possibly using different toolkits to satisfy our requirements for fine-grained personalization and heterogeneity. From the infrastructure point of view, a comet is a service that can be discovered, deployed, and integrated dynamically into the configuration that constitutes an interactive environment. The COTS (Bourguin, Lewandowski, and Tarby 2007), whose executable UI code is meta-described with the task they support, are based on similar ideas.

Figures 52.7 and 52.8 show another application of Principles 1 and 2 for the implementation of Photo-Browser. The FUI of Photo-Browser is dynamically composed of the following:

- A Tcl-Tk component running on a multipoint interactive surface (Figure 52.7a)
- A Java component that shows a list of the image names (Figure 52.7b)
- An HTML-based browser to navigate through the images set (Figure 52.7c)

Photo-Browser is implemented on top of a tier middleware infrastructure (called Ethylene) that covers the evolution engine, the component manager, and the adaptation producer of Figure 52.15. Ethylene is a distributed system composed of ethylene factories, each one running on possibly different processors (IP devices). The role of an ethylene factory is to manage the lifecycle of a set of components that reside on the same IP device as this factory and that have been registered to this factory. When residing on storage space, a component is meta-described using EthylenXML, an extension of the W3C standard WSDL (Web Service Definition Language). This meta-description includes the human task that the component supports, the resources it requires, and whether it is executable code or transformable code. In the latter case, it may be a task model, an AUI, a CUI, or even a graph of these models. For example, the HTML-based component (Fig 52.7c) is a CUI expressed in a variation of HTML. It must be transformed on the fly to be interpreted by an HTML renderer. The Tcl-Tk multipoint UI and the Java list are executable code. Their EthyleneXML meta-description specifies that they support image browsing and image selection tasks, that they need such and such interaction resources (e.g., a Tcl-Tk interpreter and a DiamondTouch interactive table) for proper execution, and that they require such communication protocol to be interconnected with other components. The gPhone UI component is an executable gPhone app that supports the next-previous browsing tasks (Figure 52.8). Interconnection between the components is initiated by the factories.

As shown by the examples above as well as by other works (Blumendorf, Leehmann, and S. Albayrak 2010; Clerckx, Vandervelpen, and Coninx 2007; Duarte and Carriço 2006; Savidis and Stephanidis 2010), the engineering community of HCI has focused its attention on runtime adaptation of the UI portion of an interactive system, not on the dynamic adaptation of the interactive system as a whole. The SE community is developing several approaches to enable dynamic bindings for service-oriented architectures. For example, Canfora et al. (2009) propose the dynamic composition of web services based on BPEL4People (that expresses a task-like model) as well as an extension of WSDL to meta-describe the services and using these two descriptions to generate the corresponding UI. Although bindings can be performed at runtime, users are confined within the workflow designed by the software developers. In addition, the generated UIs are limited to conventional WIMP UIs.

One promising approach to support flexibility at runtime is to consider the functional core components as well as UI components as services. In Ethylene, UI components adhere to this philosophy. They can be implemented in very different technologies, they can be discovered and recruited on the fly based on their meta-description, and they can be transformed on the fly. On the other hand, the business logic side of interactive systems is left opened. CRUISe (Pietschmann, Voigt, and MeiBner 2009) aims at supporting both sides in a uniform way but applies to the dynamic composition of web services and UI composition for the web (Yu et al. 2007).

52.8 CONCLUSION

An MDE has provided the HCI community with useful concepts for framing its own research agenda. Additional research is required for the definition of meta-models, transformations, and mappings provided that high-level descriptions can take full advantage of the latest innovations at the FUI level. Models at design time should not disappear at runtime but should be available to go beyond cosmetic adaptation. Design phase and runtime phase equal "même combat!"

Maximum flexibility and quality should be attainable by modeling the business logic as well as the UI as services with their own domain of plasticity. UI components should not be pure executable code. They have to be meta-described to express their exact nature and contracts with a human-centered perspective. They can be retrieved, transformed, and recomposed on the fly thanks to a tier middleware infrastructure. This middleware, which supports context, dynamic discovery, as well as the dynamic (re)composition of business logic and of transformable UI components, will permit interactive systems to go beyond their domain of plasticity. However, we must be careful at keeping the user in the loop while being able to produce transition UIs automatically.

The risk is that this wonderful apparatus will be designed for the specialists. We need to put the power in the people's hands and explore the potential from social programming. The success of the Apple App Store is a good indication for this. Mash-up tools have also started this trend for composing web-based applications (e.g., Google Gadgets or Yahoo! Widgets). More collaboration should be developed with the "cloud computing crowd." After all, an interactive space is a minicloud. If interaction resources were virtualized as memory, and network and computing resources are currently envisioned by the "systemers," then this would simplify enormously the development of UIs.

In short, MDE is an important tool for adaptation as long as it does not block creativity.

ACKNOWLEDGMENTS

This work is the result of research supported by the CAMELEON European project (IST-2000-28323) and by the Framework VI Network of Excellence SIMILAR. We thank the ANR CONTINUUM project (ANR-08-VERS-005) as well as the ITEA 08026 UsiXML project for supporting this research. We also thank Gaëtan Rey for the development of the contextor infrastructure, Lionel Balme and Alexandre Demeure for the implementation of CamNote, and the Sedan-Bouillon website as well as for the development of the first version of the runtime infrastructure for plastic UIs. Thanks to Jean-Marie Favre and Jean-Sébastien Sottet for their insights into MDE principles.

Part VI

The Development Process

Section C: Testing, Evaluation, and Technology Transfer

53 Usability Testing

Joseph S. Dumas and Jean E. Fox

CONTENTS

53.1 INTRODUCTION

At the turn of the millennium, a survey of usability professionals showed that they rated usability testing as the most influential method for having a strategic impact on organizations (Rosenbaum, Rohn, and Humburg 2000). At that time, testing frequently was recommended as a key to stimulating product development organizations to integrate user-centered design into the development process. It had strong face validity: it appeared to evaluate usability fairly, and tests always produced a list of usability problems to be addressed.

Testing's face validity and its value as a tool to influence developers delayed the profession's examination of the details of the method, its reliability, and more importantly its forms of validity. In the past decade, books and research studies have looked at both the strengths and limitations of the large variety of practices that are now part of the umbrella term "usability testing." In this chapter, we discuss those new materials. There are two themes that appear throughout: (1) the widespread use of Agile and other streamlined development practices has increased the pressure to test faster and cheaper and to strip testing of some of its essentials and (2) the lack of consensus about the criteria for what constitutes a valid usability test has made it vulnerable to attacks on what were assumed to be its basic foundations.

In a previous edition of this handbook, we focused primarily on the basic concepts of testing practice that were established over the period of its emergence and growth (Dumas and Fox 2007). In this edition, we focus on the body of research and opinion that has emerged during the past decade.

53.2 TYPES OF TESTS

The fact that the term "usability testing" refers to a wide variety of methods becomes apparent when one tries to categorize them. There are at least five dimensions to describe a particular test:

1. Purpose of the test—explore the usability of early design concepts, diagnose usability problems, fix usability problems, validate usability, measure baseline usability, or compare usability of products
2. Scope of the product tested—the whole product, part of it, and/or selected task flows
3. Location of sessions—local or remote
4. Presence of a test moderator—moderated or unmoderated
5. The level of functionality of the product—paper prototype, static screens, interactive prototype, or live code

We are not aware of any empirical data about the frequency of test types. We believe that the most common test, at this time, is a moderated diagnostic test on a subset of a product conducted locally in the middle of development. While the stated desire of many in the usability profession is to test earlier, it is not clear that early tests are most common, though testing has moved from the late stage method it was 20 years ago.

Alternative protocols are gaining in popularity. As we see in this chapter, remote and unmoderated online tests are more common. The rapid iterative test and evaluation (RITE) method is an example of a local, moderated test of a whole or part of a product, conducted early in development, with the purpose of fixing rather than finding problems.

In addition to this classification of types of usability tests, there are other terms that are used in the literature and in practice to describe tests: qualitative, quantitative, formal, and informal. What these terms denote is not always clear. They add to the ambiguity about what a usability test is.

53.3 TRADITIONAL DIAGNOSTIC USABILITY TEST

Over the past 20 years, the basic characteristics of a moderated, diagnostic usability test have been established:

- The focus is on usability. The traditional usability test is intended to uncover usability issues both positive and negative.
- The participants are end users or potential end users. Most usability professionals would agree that to have a valid diagnostic usability test, the participants must be part of the target market for the product. The key to finding people who are potential candidates for the test is a user profile (Branaghan 1997) or a persona (Pruitt and Adlin 2005). A user profile captures two types of characteristics: (1) those that the users share and (2) those that might make a difference among users. The test team must also determine how many participants per user group to include in the test. Five to eight users has become a common sample size.
- The participants perform tasks with a product or prototype, usually while thinking aloud. One of the essential requirements of every usability test is that the test participants attempt tasks that users of the product will perform. When a product of even modest complexity is tested, however, there are more tasks than there is time available to test them, so it is necessary to sample tasks. While not often recognized as a limitation of testing, the sample of tasks is a limitation to the scope of a test. Those components of a design that are not touched by the tasks the participants perform are not evaluated. Almost without exception, testers present the tasks that participants do in the form of a task scenario. For example, consider the following:

> You have just bought a new combination telephone and answering machine. The box is on the table. Take the

product out of the box and set it up so that you can make and receive calls.

- Before the test session starts, the administrator instructs the participant how the test will proceed and informs the participant that the test probes the usability of the product, not the participant's skills or experience. In most diagnostic usability tests, participants are asked to think aloud.
- The data are recorded and analyzed. In a usability test, there will be both quantitative and qualitative data. Quantitative data include measures of efficiency (e.g., task times), effectiveness (success rates), and satisfaction (ease-of-use ratings). Qualitative data include participant comments and tester observations. The data can be collected and recorded in a variety of ways. In the early days of usability testing, the test administrators recorded all data by hand with stopwatches and clipboards. Over the years, numerous tools have become available to automatically record video and data. Many of these tools also conduct basic data analysis, such as calculating average task times and success rates. Much of the data analysis involves building a case for a usability problem by combining several measures—a process that has been called "triangulation." In addition, problems are usually categorized by their severity.
- The results of the test are communicated to appropriate audiences. Test reporting began with lengthy written reports and highlight tapes, but reporting has become less formal.

53.4 UPDATING USABILITY TESTING BASICS

While many usability tests still are consistent with the traditional basics, the variations on what are still called "usability tests" have grown. In this section, we discuss how testing evolved.

53.4.1 From Usability to User Experience

Beginning about the year 2000, there was a concern that the "traditional" view of usability was limiting. These efforts have led the professional to ask whether task effectiveness, efficiency, and satisfaction are only part of the story. For example, Quesenbery (2004, 2005) broadened the ISO definition by adding e*ngaging:* "how pleasant, satisfying, or interesting an interface is to use" (Quesenbery 2004, p. 5). Others have advocated looking beyond traditional views of the scope of the profession to consider "user experience," shaped not only by usability, but by aesthetic, emotional, social, and business factors (Jordan 2002; Teague and Whitney 2002; Karat 2003; Hancock, Pepe, and Murphy 2005). Many industry groups have changed their name from "usability" to "user experience" groups.

This broadened view of what it takes for a product to be successful has had two important implications for usability practice. First, traditional usability measures are being adapted to assess the broader notions of user experience. Second, new methods are being used to supplement the more traditional ones (e.g., Karat 2003; Pagulayan et al. 2003; Murphy, Stanney, and Hancock 2003). Usability practitioners are supplementing traditional measures with value-based metrics and methods drawn from the marketing, anthropology, and psychology disciplines. Questions such as "Is it fun?," "Is it motivating?," and "Does it provide enough variety (as opposed to consistency)?" are a few examples of what usability practitioners are asking today in addition to "Is it usable?"

As a result of these changes, usability testers are including more subjective measures into tests, and testing is often paired with marketing methods such as online surveys to broaden the scope of the evaluation beyond usability issues.

53.4.2 Are Five Still Enough?

Part of the popularity of usability testing has come from its ability to find usability problems with only a few participants. Anyone who watches multiple test sessions with the same set of tasks perceives that the same issues begin to repeat, and that somewhere in the five-to-eight test participant range, with the same user population, it begins to seem unproductive to test more participants. So it was with great joy that testers greeted the research studies by Virzi (1990, 1992), showing that 80% of the total number of usability problems that will be uncovered by as many as 20 participants will be found by as few as five. Virzi also found that those five participants will uncover most of the problems judged by experts to be severe. This finding has been confirmed several times (Faulkner 2003; Law and Vanderheiden 2000). Practitioners conducting diagnostic, moderated tests continue to select small numbers of participants, confident that they are finding most of the problems that they could find.

Those findings lead to a popular rule of thumb for diagnostic tests that "five is enough." But the interpretation of the rule is not as simple as it appears. Among others, the rule has been attributed to Nielsen (2000). But Nielsen placed the rule into an iterative testing context in which he proposed that three iterative tests of the same product each with five participants are better than one test with 15 participants.

In Section 53.12, we discuss some recent studies showing that a single usability test only finds a small fraction of the total number that multiple independent tests will find. How do we reconcile that finding with the studies of sample size? All the studies that have looked at sample size and the number of problems found have done so with a single test by one test team. Apparently, there is a limitation in how many problems a single test team can find. At this point in time, we do not know why test teams have this limitation.

Furthermore, all the sample size studies, except Lewis (1994), tested very simple applications. As Redish (2007) points out, we know very little about the optimal usability testing process with complex systems. So the rule of thumb would be more accurate if it said that five participants will uncover about 80% of the problems that one team can find with a small application. That fact also means that adding more participants may not find more problems as long as the test team does not change.

There also have been a few challenges to the generality of the “five is enough” rule of thumb, most notably by Lewis (1994, 2001) and Turner, Lewis, and Nielsen (2006). Their challenge makes the reasonable case that tests differ in the probability of problem detection. A moderately complicated product being tested for the first time might indeed yield many of its problems with five to eight participants. Those authors have looked at problem detection over a large sample of tests and found that the average probability of detection is about 30%.

But what about a product that is being retested after most of its problems have been fixed? One might expect that it might take more participants because it is harder to detect the problems. It also may take more participants if the user population is very heterogeneous, such as with elderly and disabled users (Grossnickle 2004; ITTATC 2004; Swierenga and Guy 2003). Turner, Lewis, and Nielsen (2006) created and verified a formula for determining how many participants are needed in a variety of testing situations.

Finally, the pressure coming from organizations using an Agile development approach is to test with even fewer than five participants (see Section 53.7). Krug (2010) suggests monthly tests with three participants each. He argues that each test will find more than enough problems to keep the team busy for the next month. Again, Krug is saying that his rule needs to be viewed in an iterative testing context.

53.4.2.1 Sample Sizes with Other Testing Types

Most of the dialog about minimum sample size and all the research have been done in the context of diagnostic test with a moderator. The minimum sample size for comparison and baseline tests is much larger because of the need to measure usability not just to find problems. Minimum sample sizes for those types of tests are similar to those for cognitive science research studies, about 12–15 per group.

One of the strengths of online unmoderated testing is that much larger samples are easier to obtain. These larger samples can make the results of online tests more credible. By adding survey questions in addition to tasks, such tests can gather market research as well as usability data (Albert, Tullis, and Tedesco 2010).

53.4.3 Are “Real” Users Necessary?

The first books on testing procedures stressed that it is necessary to recruit test participants who are part of the target market for the product (Rubin 1994; Dumas and Redish 1993). The rationale was that all the problems that the target market will have would not be uncovered if a different population is tested. This rationale was based on a logical analysis and anecdotal evidence.

The methods for identifying the qualifications of participants were asking marketing experts in the organization, developing a user profile, or more recently, using personas (Pruitt and Adlin 2005). However, these methods result in ranges of qualifications that are difficult to cover with a small sample. For example, if one of the qualifications is knowledge of a software operating system, do you select participants with a little or a lot of experience? The advice is to make sure you have a range, some with a little and some with a lot. This strategy may mean that two subgroups are combined into one. Furthermore, as participants are recruited, compromises in the details of the qualifications are often made. Consequently, the final sample only approximates the profile or persona.

For usability testing, as with other types of research, it is nearly impossible to draw a random sample of the population. You may be limited by issues such as geography (e.g., those close enough to come to your lab), availability (e.g., who can participate during business hours), or willingness (e.g., who wants to participate). To some extent, every usability test sample is at least partly a sample of convenience. The challenge for testers is to determine which characteristics might affect the participants’ experiences with a product.

One of the consistent results of tests is that they always yield lists of problems, often long ones. It has seldom been necessary to question whether a different sample would have yielded a different list. But the pressure from Agile development and from startups to get websites to market faster has led to a practice called “hallway” testing (Spolsky 2000), in which “you grab the next person that passes by in the hallway and force them to try to use the code you just wrote. If you do this to five people, you will learn 95% of what there is to learn about usability problems in your code.” Krug (2010, p. 42) makes a similar point, “But there are many things you can learn by watching almost anyone use it (a website).”

Until a research study shows that a sample of “real” users, that is people who are part of the target market, yields the highest quality list of problems, some practitioners will continue to see value in recruiting a more convenient sample. As long as such samples uncover usability problems, it will be difficult to argue that the sample invalidates the test.

53.4.4 Does Task Selection Matter?

An essential component of any usability test is that participants attempt tasks. The measures taken during and after tasks provide the empirical data on which the product design is evaluated.

The selection of tasks is a function of the purpose and scope of the test. Testers must also consider the order of the tasks. In some cases, the tasks must be completed in a particular order, such as when a later task relies on the results of an earlier task or when there is a natural task order. In other tests, the order of tasks is randomized or varied in some way to balance any order or start up effects.

Task selection has been identified as one source of the lack of agreement in independent tests. Molich et al. (1998)

concluded that differences in usability test results across four teams were at least partially explained by fact that the teams use different tasks. However, Molich and Dumas (2008) found that even when teams used almost the same tasks, the problems they listed did not appear to have any more agreement than for teams with quite different task sets. This may have occurred because the task statement is only the starting point for the task. Participants can go down very different paths from the same starting point, thereby exposing different flaws.

In addition to the types of tasks to include, it is also important to consider the number of tasks. Lindgaard and Chattratichart (2007), using the same data as Molich and Dumas, found that the number of tasks used by teams was significantly correlated with the number of problems found, while the number of test participants recruited was not. Interestingly, they also found that the number of participants was not significantly correlated with either measure or the number of problems found. In this case, the number of tasks had greater influence on the number of problems found than on the number of participants.

Most of the advice about task selection and wording has been given in the context of moderated tests. The challenges of creating tasks for unmoderated online tests are quite a bit different (Albert, Tullis, and Tedesco 2010). Task statements for unmoderated tests must be clear and unambiguous because there is no moderator to clarify them. Careful piloting of wording is essential. "Easy to understand" is not the same as "easy to guess," as the participant may guess rather than perform the task. The best tasks are ones whose successful completion is obvious, such as an answer to a question that can be found on a web page. It may be necessary to constrain the participant in the path they use to complete a task to be sure the test is probing the product design appropriately. Finally, sometimes the participant must indicate whether they believe that they completed the task successfully. In such cases, an analysis of their path through the task may be needed to supplement their belief in their success.

53.4.5 Incorporating Thinking Aloud into Usability Testing

One of the early differences between a usability test and a research study was that the test participants typically thought aloud in a usability test. While concurrent thinking aloud is normally done as part of a diagnostic usability test, it is really a method of its own. It has been used in psychological research since the turn of the twentieth century, but it is best known as a cognitive psychology method for studying short-term memory (Ericsson and Simon 1993). Retrospective thinking aloud, that is thinking aloud while watching a video recording of task performance, is also used, especially in situations in which concurrent thinking aloud cannot or should not be done.

Concurrent thinking aloud provides usability testing with most of its drama. Without thinking aloud, it is unlikely that usability testing would have become the most influential usability method. It is the think aloud protocol that grabs the attention of first-time visitors to a usability test and gives a test session the appearance of a science-based method.

When usability testing was first being codified, thinking aloud was borrowed from cognitive psychology without much reflection. It was not until shortly after 2000 that usability specialists began to look at it more closely. Independently, Boren and Ramey (2000), Dumas (2001) and, more recently, Nielsen, Clemmensen, and Yssing (2002) went back to look more closely at what Ericsson and Simon (1993) had described and whether testing practitioners were really following that method. Those reviews showed that the descriptions of how to use the think aloud method that had been provided to usability testing practitioners by Dumas and Redish (1999) and Rubin (1994) were in direct contradiction to the instructions used in cognitive psychology research in which participants are discouraged from reporting feelings or expectations or to make any verbal diversions over and above the content of their actions. In usability testing, participants are encouraged to report on their feelings and expectations and on additional relevant issues.

Only a few research studies have been done on the think aloud method in a usability testing context. Krahmer and Ummelen (2004) compared typical usability testing think aloud instructions to the instructions used by Ericsson and Simon and found that the research instructions do not work well in a testing context. Ebling and John (2000) traced each usability problem found in a usability test back to its source in the test measures. They found that over half of the problems identified in their test came from the think aloud protocol alone. Their study supplements an earlier one by Virzi, Source, and Herbert (1993), who showed that fewer problems are identified when the participants do not think aloud. Eger et al. (2007) found that concurrent and retrospective think aloud protocols found approximately the same number of usability problems. However, when they included eye movements in the retrospective cue, they uncovered significantly more usability problems than in the traditional think aloud condition.

Two interesting questions about thinking aloud are "can everyone think aloud while performing another task?" and "should thinking aloud be done in all tests?" There are now a number of studies and demonstrations that suggest that many user populations cannot perform tasks and think aloud at the same time, including the following:

- Teen and preteen children (Als, Jensen, and Skov 2005)
- Low-literacy populations (Birru et al. 2004)
- People for whom English is not their first language (Evers 2004)
- People from some non-English speaking cultures (Evers 2004)

Evers (2004) conducted think aloud tests and post-test interviews with a sample of 130 high school students from England, North America, the Netherlands, and Japan.

The moderator was English. The Japanese students had the most difficulty with the think-aloud sessions. They felt uncomfortable speaking out loud about their thoughts and seemed to feel insecure because they could not confer with others to reach a common opinion. The English also needed reassurance before feeling comfortable with thinking out loud.

Concurrent thinking aloud also is to be avoided in tests of voice response system, tests using eye trackers (Bojko 2005), and tests that include complex tasks or complex environments (Redish and Scholtz 2007). van den Haak, de Jong, and Schellens (2003) found that participants performing complex tasks exposed fewer problems using concurrent thinking aloud than with retrospective thinking aloud.

Some authors have proposed alternatives to concurrent thinking aloud. Redish and Scholtz suggest using retrospective thinking aloud for testing complex and open-ended tasks. Als et al. used a technique with children called constructive interaction, in which children work in pairs on tasks. The pairs who used constructive interaction exposed more usability problems than the children who used thinking aloud. Strain, Shaikh, and Boardman (2007) conducted concurrent think aloud tests with blind participants and found the audio from the screen reader interfered with the conversation. Although the method worked when participants were familiar enough with the screen reader to pause and restart the audio easily, the authors suggest considering retrospective think aloud or what they call "Modified Stimulated Retrospective Think-Aloud." With this method, the participant walks through the application after completing the task.

Frøkjær and Hornbæk (2005) proposed a technique called "Cooperative Usability Testing" as a way to deal with the difficulties participants sometimes have with concurrent thinking aloud. In their technique, there are two parts to a test session. In the first part of the session, interaction, a test participant performs tasks while thinking aloud in the presence of an evaluator. The session is videotaped and the participant is allowed to ask questions of the evaluator, who takes a more active role than is typical. In the second part of the session, interpretation, the participant and one or more evaluators discuss the video of the interaction session with the goal of clarifying the usability problems. In their study, Frokjaer and Hornbaek report that evaluators and participants liked the cooperative technique and that it uncovered more problems. In addition, participants who just did a traditional think aloud session made negative comments about thinking aloud, including that it was hard to think aloud and perform difficult tasks or read text and that thinking aloud felt like "asocial" monolog. Participants also reported that what they were saying out loud was only a fraction of what they were thinking internally. Similarly, Eger et al. (2007) found that participants rated concurrent think aloud sessions as significantly more unpleasant and unnatural than a retrospective think aloud session. These studies are among the few to record comments about thinking aloud from the participant's point of view. We need more studies that provide data on what the thinking aloud experience is really like for test participants.

Studies of how thinking aloud instructions are actually given and how test moderators prompt participants to think aloud show that moderators are inconsistent (Boren and Ramey 2000; Norgaard and Hornbaek 2006). The think aloud method described in the books on testing techniques and in this section of the chapter is simply not followed in practice.

53.4.6 New Research on Testing Measures

Some recent studies have begun to clarify the relationships among the measures that are taken during tests. Testers have assumed that the measures should correlate. Usability problems often are identified through their impact on multiple measures. For example, a structural problem with the organization of a website might cause task failures, longer task times, errors, the need for assistance, and the participants rating tasks or the product as hard to use.

On the other hand, if the measures were highly correlated, testers would not need so many of them. Frøkjær, Hertzum, and Hornbæk (2000, p. 345) argued that, "Unless domain specific studies suggest otherwise, effectiveness, efficiency, and satisfaction should be considered independent aspects of usability and all be included in usability testing." Supporting that point, Hornbæk and Law (2007) reported weak correlations among efficiency, effectiveness, and satisfaction, with an average Pearson-product moment correlation (*r*) of about +0.2. The correlations were equally weak among time-on-task, completion rates, error rates, and user satisfaction. But many of the studies they analyzed were not usability tests.

Sauro and Lewis (2009) conducted an analysis of data from 90 summative usability tests conducted in industry settings. The pattern of correlations added some complexity to the discussion of whether measures do or do not correlate. They found that correlations among the performance measures were all significant and in the medium range, around or slightly higher than +0.5. The correlations between the performance measures and post-task ratings were slightly lower. Lowest of all, around +0.2, were correlations between post-test ratings and performance measures. Sauro and Lewis then performed a factor analysis on the correlations, which produced two factors: the first is heavily loaded with the three performance measures while the second is heavily loaded with the subjective measures. They argue that this pattern provides support for a construct of usability with a performance and subjective component and that using multiple measures increases the reliability of testing data.

53.4.6.1 Subjective Measures

Recent studies have begun to clarify several issues about subjective measures in usability testing. One of the issues is the format of rating scales. Tedesco and Tullis (2006) compared five different rating scale formats used for post-task ratings. They found that a simple five level Likert scale from very difficult to very easy was the most reliable. But none of the formats had acceptable reliabilities below sample sizes of

8–10 participants. Sauro and Dumas (2009) confirmed those findings and also found that a simple subjective mental effort scale performed as well as the Likert scale.

Tullis and Stetson (2004) conducted a similar study of post-test questionnaires, such as the System Usability Scale (SUS). They found that the 10-question SUS was the most reliable and that none of the questionnaires was reliable with sample sizes below 10 participants.

As discussed earlier, several studies have shown that correlations between post-test questionnaires and other measures are among the weakest. Sauro and Lewis (2009, p. 1617) notes: “It is reasonable to speculate that responses to post-test satisfaction questions elicit reactions to aspects beyond the immediate usability test (past usage, brand perception, customer support).”

For the practitioner, this research means that simple subjective measures are to be preferred, that none of these measures are reliable with the sample sizes typically used in diagnostic testing, and that post-test subjective questionnaires are tapping into factors beyond what happens during the test session.

53.4.6.2 Online Testing Measures

Online tests provide the potential for additional measures. Click stream data can show pages visited, page transitions, and how much time users spend on pages or key areas of pages (Albert, Tullis, and Tedesco 2010). For example, looking at pages visited during failed tasks can provide additional clues about design flaws. The larger sample sizes with online tests also make it possible to break the total population of participants into smaller segments, which is usually impossible with the small samples used in moderated tests.

53.4.7 New Ways of Reporting Test Results

In the early days of user testing, the test team almost always created a formal report and a highlight video tape. Testers needed those deliverables to communicate what they did, what they found, and to justify the testing method itself. Now, it is more common for the results to be communicated more informally, such as by scheduling a meeting soon after the last test session to discuss the results and/or creating a slide presentation for a briefing that may also contain sections of video from the sessions. Collaboration tools such as Wiki workspaces are also used to create “living” documentation to which subsequent design recommendations and user-interface concepts are added (Luef and Cunningham 2001).

53.5 TESTING STEPS OUT OF THE LABORATORY

With remote usability testing, the test administrator and participant are in different locations. Hartson and Castillo and colleagues began exploring remote usability testing as early as 1996 (Hartson et al. 1996; Castillo, Hartson, and Hix 1998). Tools to conduct remote usability testing were becoming available, and they saw the benefits of remote testing. Since then, technologies have improved and become less expensive, making it easier to conduct the tests. As a result, user experience professionals have continued to develop and explore methods of remote usability testing.

There are a number of advantages to remote testing:

- You can reach a worldwide population of participants because you are not limited to the local testing area. This may be especially helpful when there are not many users, and they are geographically dispersed.
- It is easier to get participants to volunteer because they do not have to travel.
- Participants work at their desks in their work environments, which may make them more comfortable and the testing more realistic. This can be especially helpful in recruiting disabled participants, who may find it difficult to travel or who use specific assistive technologies when they use the computer.
- You do not need a usability lab.

In the past, the technology to conduct such sessions was not good enough to allow usability specialists to get the information they need (Dumas 2003). That is no longer true because of several factors:

- The Internet has made it possible for usability specialists and participants to work together without installing special hardware or complex software on both the tester’s and the participant’s computers.
- There are tools available for instrumenting websites to collect usability measures automatically and to insert questions and ratings as the participants work.
- Collaboration software that works over the Internet makes it possible to share desktops and control the cursor.
- Recording software makes it possible to store good quality video and sound in files that are not large by today’s standards, often less than 50M for a 2-hour session.
- PC processors and RAM are fast enough to run both recording software and the application you are testing simultaneously. In addition, participants often have broadband or high-speed transmissions, so they are not limited by slow modem connections.

Remote testing takes two forms: (1) synchronous, in which the moderator and the participant work together, communicating over the phone or through their computer, and (2) asynchronous, in which the participants work on their own without the direct guidance of a moderator. Each has its strengths and weaknesses.

53.5.1 Synchronous Remote Testing

Synchronous remote testing is similar to a traditional usability laboratory test, except that the participant and tester are in different locations. The two methods tend to use similar protocols and similar methods of analysis. As a result, synchronous remote tests generally also involve the small numbers of participants.

With synchronous remote testing, the participant and moderator will use screen sharing software so that the moderator and other team members can observe what the participant is doing.

Typically, the administrator cannot see the participant (a webcam can be used, but usually is not). We do not yet know what the impact of not seeing the participant is, but one laboratory study indicates that usability specialists judge usability problems as less severe when they cannot see the participant's face (Lesaigle and Biers 2000).

Some remote testing configurations may present security problems. For example, participants could obtain screen shots without the knowledge of the moderator. In addition, allowing participants to share applications on computers inside your organization's firewall may be prohibited. Some organizations may be able to address this with a nondisclosure agreement, while others may require a special computer outside their firewalls.

53.5.2 Asynchronous Remote Testing

With asynchronous remote testing, participants complete the tasks on their own, and the test team reviews the session results later. Recently, the first book length discussion of this type of testing has appeared (Albert, Tullis, and Tedesco 2010). These are unmoderated tests. Asynchronous remote testing can be conducted by providing the participant with two browsers (one for the product or prototype and one for instructions). The instruction browser includes the tasks to be attempted, buttons to click at the beginning and end of a task, a free-form comment area, and questions or ratings to answer during or after each task. Asynchronous remote tests can also be conducted with tools specifically designed for that type of testing. Whichever arrangement is used, participants must be able to start and complete the entire test session on their own.

The primary advantage of asynchronous over synchronous testing is a larger sample size, because the number of participants is not limited by time requirements of the moderator. In addition, participants can complete the study at their convenience. For example, Tullis et al. (2002) tested 88 participants in a short period of time.

The disadvantage is that you cannot see or interact directly with the participants. However, in the Tullis et al. (2002) study, the participants provided an unexpectedly large volume of feedback in the free form comment field. These comments provided insight into the usability problems with the product.

53.5.3 Comparing Laboratory and Remote Testing

There have been just a few studies comparing results of usability tests conducted in a laboratory and remotely, and the results are not always consistent. Relating to performance measures, Tullis et al. (2002) reported no substantial difference between asynchronous testing and laboratory testing in terms of performance measures. However, West and Lehman (2006) found that asynchronous remote participants completed the tasks faster and were more likely to abandon a task than participants in a laboratory, but they showed similar success rates. Further, Thompson, Rozanski, and Haake (2004) also reported that asynchronous remote participants were faster. They also reported that these participants made fewer errors.

Regarding the number of problems identified, both Tullis et al. (asynchronous) and Thompson et al. (synchronous) found no difference with laboratory testing. However, in a study with blind participants, those in the asynchronous remote condition found fewer problems per website than those in the laboratory condition (each participant completed 2 tasks on each of 10 websites) (Petrie et al. 2006).

Clearly, we need to better understand the benefits and challenges of each method. As a result, research on this topic continues and is expanding into new domains such as remote testing with mobile devices.

53.5.4 Testing Mobile Devices

Conducting usability tests with mobile requires that testers be able to see both the screen of the device and the participants' hands. Early efforts used a computer-based emulator or a single camera pointed at a mobile device mounted on the table. These configurations captured the participants' interactions with the devices, but the experience was not realistic. Testers then developed creative solutions to capture the screen and the participants' hands. For example, both Catani (2003) and Schusteritsch, Wei, and LaRosa (2007) attached two small cameras to mobile devices, one to capture the screen (since many mobile devices have no "video out") and one to capture the participants' hands.

Another challenge is that mobile devices are intended to be used "on the go," not in the quiet office setting typically simulated in a usability test. Factors such as weather, signal strength, and background noise can all impact the users' experiences. In addition, mobile device users are often preoccupied by other tasks.

Several studies have evaluated the differences in the results from both laboratory and field usability tests, but there is little consistency in the findings. Kaikkaner et al. (2005) found exactly the same problems in both a laboratory and a field setting. Betiol and Cybis (2005) found more usability problems with a phone mounted to a desk than with a computer-based emulator or with a camera mounted on a mobile device used in the field. Duh, Tan, and Chen (2006) found more critical problems in the field than in the laboratory. On the other hand, Kjeldskov and Stage (2004) found more usability problems in the laboratory than in the field. However, the differences appear to be primarily in problems classified as "cosmetic," not in problems classified as "critical" or "serious." The great variety in the research results suggests that we need to continue to study this issue to better understand the methods of testing mobile devices.

53.6 ROLE OF THE TEST ADMINISTRATOR

Most usability specialists learn the skills of moderating tests through apprenticeship. They watch a few sessions, then moderate a few sessions under supervision. Quite quickly they move into a journeymen status during which they almost never receive feedback on their interaction skills unless they request it. In the first book published on the topic, Dumas and Loring (2008) have provided a systematic rationale for how to moderate a test session. They describe 10 rules for interacting with participants that put the first stake in the ground on the topic. The rules attempt to cover the common situations that moderators encounter rather than unusual incidents.

Dumas and Loring propose that moderators play three separate but overlapping roles:

1. The gracious host, who is responsible for making participants feel welcome from the moment they arrive to the moment they leave and who attends to their physical comfort, ensuring that the session goes smoothly and that they have a positive experience overall
2. The leader, who respects participants but who is clearly in charge of the direction and pacing of the session
3. The neutral observer, who is unbiased and objective and who keeps interactions to a minimum while providing support and encouragement to the participant when needed

Balancing those roles is one of the skills new moderators learn.

53.6.1 Training and Education of Moderators

Some of the early books on testing had chapters describing the skills needed and how to deal with selected situations. In the past 10 years, there have been a few Master's degree programs teaching moderating skills. But most usability professionals still learn on the job from more experienced moderators (Dumas 2007).

The usability profession has not established any educational or training qualification to become a moderator. Dumas and Loring (2008, p. 7) list the following qualifications:

- Understanding the basics of usability testing
- Interacting well with test participants (using our 10 rules)
- Ability to establish and maintain rapport with participants
- Lots of practice

Krug (2010) believes that all that is needed to be a competent moderator is a few hours of training in a workshop. He restricts his view to diagnostic testing. He says that he has never seen a bad moderator. He has challenged his readers to bring him a case in which a moderator has made a product less usable as a result of user testing. He believes that encouraging more moderators to run more tests is a path to making technology work better for its users. Clearly, we need more research on what makes a successful moderator.

53.7 FITTING TESTING INTO AN AGILE PROCESS

One of the important forces from outside of the user experience community that has had a major impact on its practices is Agile development (Frishberg 2010). Agile development methodology grew out the frustrations that the software industry has had managing the development process. After more than 25 years of trying, software was still released later than planned, over budget, and filled with bugs. Previous to Agile, the most common approach to development was the "waterfall" method, a sequential software development process in which progress is seen as flowing steadily downwards (like a waterfall) through the phases of conception, initiation, analysis, design, construction, testing, and maintenance. Starting about 2001, Agile development was a reaction against the waterfall model. The term "Agile" refers to a family of processes that share some common characteristics. Product requirements are addressed in a series of 2–4 week cycles by a dedicated team that is co-located. Each cycle ends with tested, working code. While code is documented, paper documents such as specifications are not part of the process.

While Agile development has begun to grow in popularity, it is unclear how traditional user experience methods, especially usability testing, can be integrated into it. Over the past few years, user experience professionals have been changing the way they work to remain players in these fast moving Agile cycles. Some of the important changes have been the following:

- Practicing iterative design and evaluation. The concept of iterative evaluation has been touted for decades, but the traditional waterfall model with traditional testing made iteration expensive and hard to justify (why are we testing again?). Iteration was, perhaps, the least practiced principle of user-centered design. Because iteration is at the foundation of the Agile model, user experience professionals have had to find a way to implement it. One approach is for the user experience team to be on a separate track from the coders, a track that is one cycle ahead (Lu, Rauch, and Miller 2010). While the user experience team is on Cycle 2, the coders are on Cycle 1. The user experience team does its user research and design concepts for Cycle 3 while conducting usability testing on the Cycle 1 user interface. The testing that is done is usually with very small samples and sometimes with internal staff rather than target users. Quantitative measures typically are not taken.

- Integration into the development team. The friction between user experience professionals and developers using the waterfall model kept user experience professionals on the outside looking in. Testing was often performed too late to impact design, and developers often viewed testers as people good at finding fault rather than fixing problems. The Agile method requires all members of the team to be co-located and to be engaged full-time. This face-to-face contact seems to create more cooperation and respect than was typical with the waterfall model.

Fitting testing into an Agile model was been facilitated by a new approach to testing (Medlock et al. 2005). Known as the RITE Method, it focuses on fixing designs rather than just finding problems. In outline, the method consists of the following:

- Key decision makers for the product participate in the study with the usability specialists.
- The team selects the tasks to be run and attends all sessions. As with traditional usability testing, users who are part of the target market for the product are recruited and sessions use the think aloud method.
- After each session, the usability specialist identifies problems and their severity. The team then decides whether they have enough data to verify each problem and how to refine the design to address the problem.
- The design team refines the design and tests it with the next participants.
- Problems are identified again, including whether the refinements have mitigated previous problems. If not, new refinements are created.
- The team decides which problems they can fix and which need to be examined in more detail or require resources that are not currently available.
- Additional participants are run until the major problems have been fixed or there are no more resources to continue.

With its emphasis on iteration and an integrated team, the RITE method fits nicely into the requirements of the Agile model (Douglass and Hylton 2010). Both Agile and RITE have the potential to change the way testing is performed and perceived. Those methods put pressure on testers to conduct tests quickly, to focus on fixing problems, and to require that developers be present during sessions.

As this chapter shows, since the early days of testing, there has been an emphasis on a faster process, scaled-down reporting, and getting modifications into the product. The traditional laboratory test with 5–8 participants, taking 2–4 weeks, with a report following some days later fit well into the waterfall model but not into the Agile model. The new approaches have some advantages in that they are more integrated into development and provide for iteration. But they also have the potential to make it convenient to test very small samples and to not use target users. It remains to be seen as testers move farther from the tradition testing basics whether diagnostic testing will remain as the most influential evaluation method. We desperately need some research to evaluate how effective testing is with these new models.

53.8 WEBSITE TESTING TOOLS

53.8.1 Eye Tracking

Eye tracking has slowly become more prevalent in usability testing. The technology has advanced to a point where it is noninvasive and almost unnoticeable to participants. Further, the software available to analyze the data also has improved. Although the equipment is still expensive, the prices are more affordable than in the past. Testers can even rent eye tracking equipment for short-term use at an even lower cost. These factors have led to an increase in the use of eye tracking in usability testing.

Eye trackers indicate where a participant is looking throughout a task or a whole test session. Eye trackers emit a pattern of infrared light (invisible to humans) and track the reflection of these patterns on the participants' eyes with special cameras. Participants no longer need to wear bulky head devices or stabilize their head when using an eye tracker. (Some eye trackers that can be used outside the laboratory are head-mounted but they are not as cumbersome as earlier models.)

Eye trackers can generate huge data files but vendors have developed sophisticated software that has greatly simplified the analysis process. This has been essential to the growing popularity of eye trackers, as they can sample data up to 120 times per second. Testers can now quickly determine the number or length of fixations on any particular area of a stimulus (such as a web page).

Testers can use eye tracking data in several ways. Eye trackers can be set up to allow observers to follow the participant's gaze during the test session. The test moderator can then tailor post-test debriefing questions based on patterns observed during the test. For example, if the participant spent a lot of time looking at a feature, the test moderator can ask what the participant thought of that feature.

Testers can also use the quantitative data generated by the eye tracker in post-test analyses. These eye tracking results can provide additional insights into participants' behaviors. The data can answer questions such as "Which areas of the page did participants look at most?" and "Were there areas they did not see it all?" For example, Albert and Tedesco (2010) used eye tracking measures to determine if self-reported awareness of items on a screen are reliable.

Running a usability test with eye tracking is not difficult but does require some additional planning. For example, testers will have to adjust their screening process slightly. Eye trackers may have difficulty tracking certain people, such as those who wear some styles of the bifocals. Also, the screeners should inform potential participants about the eye tracking and encourage them to bring whatever vision correction they need to see the screen easily. Participants who do not bring proper vision correction often sit too close or too far from the screen, where the equipment cannot track them.

In running a usability test with eye tracking, there are certain issues to consider:

- The informed consent should mention the eye tracking.
- The test protocol will have to include about 5–10 minutes at the beginning of each test session to calibrate the eye tracker to the participant.
- Scenarios for eye tracking tasks should not use a think aloud protocol. Participants look at the screen differently when they are thinking aloud (Bojko 2005). The tester may use eye tracking with some scenarios but not others to get a variety of information.

The analysis software for eye trackers can display the data in a variety of ways. Testers should understand the types of data they will be collecting and determine which are the most appropriate to address their issues (Bojko 2009; Poole and Ball 2005). Testers who want to use quantitative data should be sure to have enough participants to warrant statistical analyses (Goldberg and Wichansky 2002).

Eye tracking also has some disadvantages. It is difficult to conduct eye tracking studies with dynamic content, which includes not just video, but also objects such as cascading menus or pop-up message windows. The analysis software may present the results as if all the activity occurred on the original stimulus page.

Testing can be expensive, not just in terms of equipment, but also in terms of additional time to recruit participants, calibrate them during the test session, and analyze the results afterwards. In addition, because some participants cannot be tracked, the pool of possible participants becomes more limited. Testers may have to plan for additional participants in case some participants cannot be tracked (Schnipke and Todd 2000).

Despite these costs and challenges, eye tracking data can be very helpful in understanding participants' behavior. The data can help testers identify areas of confusion or point out objects participants missed entirely. Thus, although eye tracking is not standard usability laboratory equipment now, given the benefits of eye tracking, along with advancements in the technology, it is likely that the use of eye tracking will increase in the future.

53.8.2 FirstClick Testing

FirstClick usability testing is a method for evaluating the structure of a website. Wolfson et al. (2008) developed FirstClick testing as a way to conduct card sorting within the context of the actual website. They felt that the standard form of card sorting, using only labels and possibly brief descriptions for each "card," did not provide the same context as the website itself. They used it as a closed card sort, after designing wireframe options based on a more traditional open card sort.

In FirstClick testing, participants are given a task to complete. However, the scenario ends after they click on their first link. Researchers record the link selected and the time required in making a selection. Wolfson et al. also suggest having the participants rate their confidence after each selection. By aggregating data across participants, researchers can determine where users expect to start specific tasks. Researchers can see whether participants correctly selected the first link and whether the expectations were consistent.

To conduct a FirstClick test, researchers will need at least a somewhat functional wireframe of the homepage. The links must be active, but the second-level pages can just have a "task complete" message. With just a wireframe, researchers can conduct FirstClick testing fairly early in the development process, before the organization of the site has been established.

53.9 BASELINE AND COMPARISON TESTS

Some tests have a measurement focus, either for benchmarking a product's usability or comparing the usability of different products or versions. These performance-based tests tend to be summative and more like research experiments than a typical diagnostic test.

At present, the usability specialist's interpretation of summative usability test data plays a large role in evaluating the product's usability. Experienced usability professionals believe that they can make a relatively accurate and reliable assessment of a product's usability when considering the following:

- The product is stable.
- The number of participants is sufficiently large (larger than for most diagnostic tests).
- Participants are discouraged from making lengthy comments or evaluative statements in their think aloud protocol.
- The test administrator makes minimal interruptions to the flow of tasks.

The primary objective of a baseline test is to establish a standard against which other products or future versions of the product tested can be compared. By testing with the same set of tasks, a company can measure whether a new design has improved the usability of the product.

An important variation on the benchmark test is one focused primarily on comparing usability. Here the intention is to measure how usable a product is relative to some other product or to an earlier version of itself.

There are two variations:

- A diagnostic comparison test focused on finding as much as possible about a product's usability relative to a comparison product

- A summative comparison test intended to produce results that measure comparative usability and/or to find the winner

In both these tests, there are two important considerations:

- The test design must provide a valid comparison between the products.
- The selection of test participants, the tasks, and the way the test administrator interacts with participants must not favor any of the products.

As soon as the purpose of the test moves from diagnosis to comparison, the test design moves toward becoming more like a research experiment. In considering the design for the comparison, there are two important decisions:

- Will each participant use all the products, some of the products, or only one product?
- How many participants are enough to detect a statistically significant difference?

In the research methods literature, a design in which participants use all the products is called a "within-subjects" design, while in a "between-subjects" design, each participant uses only one product. If one uses a between-subjects design, one avoids having any contamination from product to product, but one needs to make sure that the groups who use each product are equivalent in important ways, and the sample size must increase. Because it is difficult to match groups on all the relevant variables, between-subject designs need to have enough participants in each group to wash out any minor differences. An important concern to beware of in the between-subjects design is the situation in which one of the participants in a group is especially good or bad at performing tasks; Gray and Salzman (1998) called this the "wildcard effect." If the group sizes are small, one superstar or dud could dramatically affect the comparison. With larger numbers of participants in a group, the wildcard has a smaller impact on the overall results. This phenomenon is one of the reasons that summative tests have larger sample sizes than diagnostic tests. The exact number of participants depends on the design and the variability in the data. Sample sizes in summative tests are closer to 20 in a group than the 5–8 that is common in diagnostic tests.

If one uses a within-subjects design in which each participant uses all the products, it eliminates the effect of groups not being equivalent and can have a smaller sample. However, one then has to worry about other problems, the most important being order and sequence effects and the length of the test session. (See Dumas (1998) for rules on counterbalancing.) One also has to be concerned about the test session becoming so long that participants get tired.

Perhaps the most important factor in the fairness of the comparison is the selection of tasks. The participants must perform the same tasks with the products. Anyone familiar with the products being compared is capable of selecting a sample of tasks that would favor one product. Consequently, some third party, perhaps an industry expert, who is not familiar with the details of the products but is familiar with the typical tasks users perform may be asked to select the tasks. Or a company conducting an internal comparison might ask a team independent of the test team to select the tasks.

The focus of the data analysis in a baseline or comparison task is usually on measures of performance and standardized subjective ratings rather than on qualitative measures that point to usability flaws.

53.10 TESTING WITH SPECIAL POPULATIONS

There is a growing literature about testing with special populations, including the following:

- International participants
- People with physical disabilities
- The elderly
- Children

This literature has been summarized by Dumas and Loring (2008). This section presents a brief summary of findings relevant to usability testing.

53.10.1 International Participants

Many manufacturers look for new customers across the globe. However, preparing a product for a new market may involve more than simply translating the language. Cultural differences can also impact appropriate design decisions such as color selections and the use of images. These differences can also impact the appropriate structure for web applications. Because of the significant differences across cultures, it is important to conduct usability testing with participants from all the target cultures.

International usability testing follows the principles and theories of generic usability testing. However, there are a variety of challenges with testing participants in other cultures that generally do not apply when testing in one's own culture. The challenges of communication and cultural differences are described below.

53.10.1.1 Communication

One of the most significant challenges with international usability tests is communication. Often, there are different languages. Sometimes the testers are bilingual, but often the tester must have helped recruiting participants, preparing test materials, conducting the test, analyzing the results, and writing the report. Nielsen (1996) and Vatrapu and Pérez-Quinones (2004) offer several suggestions including the following:

- Use employees of the company who live and work in that country. This may require training the employees to facilitate a usability test.

- Conduct the test in the participant's language using an interpreter.
- Hire a local usability firm.
- Run the test remotely.
- As a last resort, conduct the test yourself in your language, though this method is likely to be unnatural for the participant.

Tests that are conducted in the participant's language must be translated. Some testers prefer to have the translator work real-time during the test. The translator can either serve as a liaison between the tester and the participant (adding significant time to the test) or between the test administrator and participant (who are both speaking the same language) and the observers. The tester may also have to make arrangements to provide the test report in more than one language.

53.10.1.2 Cultural Differences

Other cultural differences may also impact a usability test. As noted earlier, Evers (2004) conducted think aloud tests and post-test interviews with a sample of 130 high school students from England, North America, the Netherlands, and Japan. There were several key differences including the finding that participants from Japan and the United Kingdom were uncomfortable thinking out loud. There may be gestures considered natural or friendly in one culture, but offensive in another. Vatrapu and Pérez-Quinones (2004) report that when both the participant and the test administrator were from the same culture, the participants engaged in more think aloud behavior and the usability tests revealed more problems.

53.10.2 Disabled Participants

Usability tests with disabled participants require careful planning. Testers must understand the participants' disabilities and adjust their procedures accordingly. Several researchers have published "lessons learned" from their experience with disabled participants (Coyne 2005; Grossnickle 2004; the Information Technology Technical Assistance and Training Center (ITTATC) 2004; Lepistö and Ovaska 2004; and Swierenga and Guy 2003). Some of these lessons include the following:

- Recruiting disabled participants is more time consuming than recruiting general population participants. Local organizations and support groups may be willing to help.
- Disabled participants may need assistance getting to the usability lab.
- Consent forms must be accessible to all participants.
- Blind participants may require electronic or Braille versions.
- Participants with learning or cognitive disabilities may require special consideration to ensure they understand the test and their rights.
- Deaf participants may require a sign language interpreter, who needs to be informed about the goals of the study.
- Participants with disabilities may require extra assistance understanding the tasks and may have trouble thinking aloud. Strain, Shaikh, and Boardman (2007) conducted concurrent think aloud tests with blind participants and found the audio from the screen reader interfered with the conversation.
- Participants with physical disabilities may require adaptive technology to interact with the computer. Be sure the devices are working before participants arrive.
- Because of the great variability in disabilities, it may take more participants than typical usability tests.
- It can be especially difficult to observe participants who use Braille readers, as there is currently no good way to follow what the participant is reading.

Overall, tests with disabled participants may take longer than expected; testers should schedule enough time so that participants are not rushed. Further, participation may be more taxing than for general population users, and so the test should limit the number of tasks evaluated (Coyne 2005). Finally, testers should ask participants before the test whether they need any special accommodations.

53.10.3 Elderly Participants

As the population ages, manufacturers are looking to expand their market to this growing population. Seniors are more active than ever. As a result, many manufacturers are working to ensure that their products are usable by their older users.

As people age, the diversity in their abilities increases. They may also have disabilities, such as those mentioned in the previous section. Many of the concerns and issues mentioned earlier also apply with elderly participants. In general, testers should be prepared for each participant, leaving plenty of time for each person.

There may also be generational issues. Testers should be aware of what their participants expect regarding social interaction and courtesy. Chisnell, Lee, and Redish (2005), Coyne (2005), and Tedesco, McNulty, and Tullis (2005) provide some guidance based on their experiences running usability test with older participants.

53.10.4 Children as Participants

When designing a product for children, usability tests must target children. Although the process is generally the same as with adult participants, there are a few important differences.

Recruiting children actually involves recruiting their parents. Patel and Paulsen (2002) suggest several good sources for recruiting. They recommend building rapport with organization leaders and parents. It is important to pay attention to the needs of both the parents and the child. Sometimes it is necessary to have the parents in the room during the test, especially for very young children. Investigators should be sure that the parents do not unnecessarily interfere with the test. However, investigators should be flexible, as each family will be different.

Investigators may want to alter the usability laboratory itself to be a better environment for children. Most usability laboratories use a standard office layout and décor. Although this is fine for testing adults, it is not the most welcoming to children. Making the room more "child friendly" can make children more comfortable and willing to participate.

The tasks should accommodate the abilities of children in the target age group. Investigators should consider (1) the wording of the instructions to be sure they are at an appropriate grade level and (2) whether the participants are old enough to complete the tasks. For example, children may not be able to perform a task and think aloud simultaneously. As mentioned earlier, Als, Jensen, and Skov (2005) used a technique with children called constructive interaction, in which children work in pairs on tasks. The pairs who used constructive interaction exposed more usability problems than the children who used thinking aloud.

Finally, what motivates adults does not always motivate children. Hanna, Risden, and Alexander (1997) suggest age-appropriate approaches for motivating young participants to continue. Most likely, the best approach for a preschooler is very different from that for a teenager.

Children can be unpredictable, so one or more members of the test team must understand the skills, abilities, and expectations of the children in the target user population. This will help testers to respond appropriately to unexpected situations.

53.11 HOW TESTS ARE ACTUALLY CONDUCTED

While there are many books and articles that describe how usability testing ought to be practiced, there have been few studies of how tests actually are conducted. The Comparative Usability Evaluations (CUE), especially the first two, inspected test reports from commercial usability laboratories (Molich et al. 1998; Molich et al. 2004). By reviewing the reports, the study authors saw the procedures used as well as the quality of the reports. There have been two other studies in which test sessions at commercial laboratories were observed and recorded (Boren and Ramey 2000; Norgaard and Hornbaek 2006). The results of these studies taken together are not encouraging. There is a large discrepancy between what testers actually do and what didactic texts say they should be doing.

The CUE studies looked at test reports from 13 organizations. No two reports were alike. They described tests from 4 to 50 participants with widely varying sets of tasks for the same product tested, leading or poorly designed task scenarios, different measures taken, and reports with few descriptions of the profiles of participants or procedures used.

Norgaard and Hornbaek watched and recorded 14 test sessions from seven different companies. They also recorded many discussions, analyses, and informal conversations among the usability evaluators before and after the sessions. They found that evaluators asked questions that were leading, questions asking participants to predict future outcomes, and questions that put words into the participants' mouths, such as "So … you feel more secure now … or?" (p. 215) There were two additional findings that are cause for concern. First, there was no systematic analysis while the results of a session were still fresh in evaluators' minds. Evaluators did not discuss findings during or directly after the sessions. Second, the behavior of evaluators indicated that they were confirming usability problems that they had found by inspecting the design themselves before the test started. Their tasks, questions, and probes were designed to support their own preconceived opinions about what the problems were. When participants' ratings disagreed with the evaluator's opinions, they were dismissed without further analysis.

While the Boren and Ramey and Noorgaard and Horbaek studies did not make other measures of participant's performance, a recent study has (Olmsted-Hawala et al. 2010). In that study, participants were assigned to various think-allowed conditions, ranging from "silent," with no think allowed or interaction with the test administrator, to "coaching," where the test administrator asked direct questions about the participant's thoughts and behaviors, which is what moderator's typically do in diagnostic testing. The results showed that when moderators are free to probe and ask questions, participants complete significantly more tasks and rate the product as more usable. That study is the first evidence that the moderator's behavior can change participants' behavior as well as the participants' perception of the product.

These studies suggest that usability testing as actually practiced is another important source of variability in usability measurement.

53.12 RELIABILITY OF USABILITY TESTING

Prior to about 1998, practitioners assumed that two equally competent teams conducting independent tests on the same product would have a large degree of overlap in the problems they detected, especially for problems judged to be severe. Jacobsen, Hertzum, and John (1998) were the first to study the reliability of testing in a laboratory experiment. They looked at how evaluators differ when analyzing the same usability test sessions. Four usability testers independently analyzed the same set of videotapes of four usability test sessions. Each session involved a user thinking aloud while solving tasks. Forty six percent of the problems were uniquely reported by single evaluators and all four evaluators agreed on only 20% of the problems. Furthermore, none of the top 10 most severe problems appeared on all four evaluators' lists.

In that same year, the first of the CUE studies appeared (Molich et al. 1998). It reported that of 141 unique problems found by four professional testing teams, only one problem appeared on all four lists. Subsequent CUE studies have also reported low levels of agreement (Molich et al. 2004; Molich and Dumas 2008).

Hertzum and Jacobsen (2001) conducted the first meta-analysis of reliability studies and termed the lack of agreement on problems "the evaluator effect." They also clarified the metric of agreement, recommending the any-2 agreement method. Any-2 agreement is the average of $|P_i \cap P_j| / |P_i \cup P_j|$ for all ½ $n(n - 1)$ pairs of evaluators—the total problems found in common divided by total problems found between two evaluators. Any-2 agreement has become the most commonly reported metric of reliability in assessments of usability evaluation. Using that metric, Hertzum and Jacobsen (2001) found only a 11% agreement among independent evaluators of a usability test.

To date, there have been more than two dozen papers with data on the reliability of testing, and they all show relatively low agreement rates. Several factors have been proposed to explain the low agreement:

- Evaluators use different tasks and task scenarios.
- Users explore different parts of the product.
- Participants are chosen based on different qualifications.
- Evaluators have different skills, experience, and training.
- Evaluators bring different biases to the test.
- There are no objective problem criteria.
- There is no metric for determining when two problems are the same or different.

53.12.1 Severe, Serious, or Just "Show Stoppers"

Several practitioners have proposed scheme for rating the severity of usability problems: Dumas and Redish (1999), Nielsen (1992), Rubin (1994), and Wilson and Coyne (2001). The schemes differ on a number of dimensions. In addition, many organizations have created their own scales. The reliability of severity scales has been questioned by several studies. Jacobsen, Hertzum, and John (1998) asked four experienced usability testers to watch tapes of the same usability test and then identify problems, including the Top 10 problems in terms of severity. None of the Top 10 severe problems appeared on all four evaluators' lists. Lesaigle and Biers (2000) reported a disappointing correlation coefficient (+0.16) among professional testers' ratings of the severity of the same usability problems in a usability test. Molich and Dumas (2008) found that 25% of the problems reported in common by two or more evaluation teams were classified into different severity categories.

The results of these studies strike a blow at one of the most often mentioned strengths of usability testing—its ability to uncover the most severe usability problems. At this point in time, we do not know whether the inconsistencies in severity judgments are the result of the poorly designed scales, the differing perceptions of usability specialists, the lack of training in how to make severity judgments, or all three.

53.12.2 Testing Is No Longer a Gold Standard

Several authors have proposed that usability testing be used as a gold standard against which to compare other evaluation methods (Andre, Williges and Hartson 2003; Sears 1997; Bailey, Allan, and Raiello 1992; Desurvire, Kondziela, and Atwood 1992). Their argument is that only problems identified by testing are true problems or hits. When other evaluation methods identify problems not found by testing, those problems are by that very fact not considered to be true problems. They are considered to be false positives, sometimes called false alarms. Those papers have been particularly harsh in their criticism of inspection by experts, such as heuristic evaluation.

There are two reasons to reject testing as a standard. First, as we have just described, independent tests find different subsets of problems. Second, Molich and Dumas (2008, p. 263) compared problem detection with testing and with expert inspection. They reported, "…there was no practical difference between the results obtained from usability testing and expert reviews for the issues identified. It was not possible to prove the existence of either missed problems or false alarms in expert reviews."

An issue not discussed in the literature comparing evaluation method is whether one should expect experts in usability evaluation to agree. There is a large body of literature on expertise showing that agreement among experts in most fields is low. It may be that disagreement among usability specialists is not any worse than it is among experts in medicine, biological, and social science disciplines (Shanteau 2001; Aboraya et al. 2006).

53.13 VALIDITY OF A USABILITY TEST

While there has been a good deal of research and analysis about the reliability of testing, there has been almost nothing written about its validity. Validity always has to do with whether a method does what it is supposed to do. There has never been a published study questioning whether testing finds problems. Perhaps the validity of usability testing has been ignored because, no matter how they are designed, tests always find strengths and weaknesses in a product. It has strong face validity. Testers believe when they have finished a test that they have uncovered the most important design flaws. But is finding problems enough?

To truly assess the validity of usability testing, we must first agree on what a usability test is supposed to do. Prior to the mid-1990s, the usability community used diagnostic tests primarily to uncover usability problems. The more problems found, the better and, of course, the tests should find the most severe ones. Because testing has never been viewed as the only usability evaluation method to apply during development and because, ideally, there are iterative tests performed, it was not essential or expected that one test would find all the problems.

The RITE method, discussed earlier, suggests two additional possibilities for goals:

1. A test should provide the data for and confirm the usability of an improved design.
2. A test should increase the commitment of a development team to user-centered design and its willingness to pursue it for future projects.

Fifteen years ago, Sawyer, Flanders, and Wixon (1996) proposed that the measure of validity for usability inspections should be how many of the problems that it identifies are actually fixed in the design. That criterion also could be applied to usability testing.

Until we sort out the importance of these goals (finding problems, creating an improved design, team building, and problems fixed in the design), we cannot fully understand the validity of what is arguably our most powerful usability assessment tool.

53.14 TESTING ETHICS

Informed consent is a method testers used to ensure that usability test participants have the information they need to decide whether to participate in the session. Millett, Friedman, and Felten (2001) state that “informed” requires the tester to be disclosing the necessary information in a manner that the participant can comprehend. They define “consent” to be the voluntary agreement to participate, made by someone competent to make such a decision.

Participants complete informed consent forms at the beginning of the test session. The forms themselves vary widely across organizations, but are generally expected to include the following information (Burmeister 2001):

- A brief description of what the participant will be expected to do
- A statement that participation is voluntary and that the participant can withdraw at any time without penalty
- Any potential risks the participant will be exposed to
- A description of any benefits either to the participant directly (including incentives) or to the population at large
- The name and contact information for the person responsible for the test
- How the test will handle all records from the test session (i.e., the extent to which data will be kept confidential), including the following:
    - Measures resulting from the test
    - Direct quotes from the participant
    - Video and/or audio recordings of the session (including whether the video will show the participant’s face)
    - Eye tracking data

Sometimes, testers use forms that allow participants to choose whether or not they will allow the testers to release video, quotes, and so on.

Completing the informed consent form usually only requires a participant to read and sign the form. Some testers follow the good practice of reviewing the form with the participants to be sure they understand and are aware of all the information.

However, in some cases, the informed consent process is not as straightforward.

Some disabilities make it difficult for participants to read, understand, and/or sign the form. When testing low-vision and blind users, the form should be presented in an accessible format. This may mean sending the form to participants ahead of time or providing Braille or large print versions (Henry 2007; Swierenga and Guy 2003). Testers may need to help physically disabled participants sign the form. In addition, testers may also need consent forms for sign language interpreters if they appear in any recordings (Henry 2007). When participants have cognitive disabilities, testers should be sure to provide the informed consent in a manner that each participant can understand.

When testing minors under the age of legal consent, the testers must get a signed consent form from a legal guardian, often a parent (Ellis, Quigley, and Power 2008). The guidelines from the U.S. Department of Health and Human Services (2008) allow guardians to fax in their forms. When the participants are old enough, it might be beneficial to have them sign a form as well, being sure to use age-appropriate language. This will help ensure that the minors understand their participation is voluntary.

When conducting one-on-one remote testing, it can be difficult to get signed consent forms before the test session starts. Dumas and Loring (2008) provide a sample electronic form that can be e-mailed to remote participants. For online testing, the testers usually do not know who the participants are and there is no audio or video recording. There still may be emotional or psychological risks to online participants, but that issue has not been explored in the literature.

When testing international populations, it is important to be sure the consent form is in a language each participant can understand. Also, there may be special requirements for information contained in the forms based on local regulations. As with disabled participants, you may also need consent forms for interpreters.

53.14.1 Additional Ethical Principles

The principles of informed consent and confidentiality that have been discussed in the HCI literature have been borrowed from ethical practices in biomedical research. We believe that, on the whole, testers have followed practices borrowed from biomedical research appropriately but have not been aware of some additional principles from social science research (House 1990).

Because of the often dramatic harm that biological and medical experimentation have caused in human history, ethical principles to protect participants have focused on costs and benefits that result from the application of procedures that occur during research studies in those areas. By analogy, the usability test has been treated as a variation on the research experiment. Consequently, the focus has been on informed consent being voluntary and knowledgeable and on confidentiality restricting the use of participants, name and, sometimes, video image. It has been assumed that risks of physical harm to participants in usability tests are minimal.

On the positive side, the sample informed consent forms in the literature describe the activities participants will be asked to perform, their right to withdraw at any time without penalty, the methods used for recording, and the restrictions on the use of data including the use of participants' names and images. But the possible risks of psychological or emotional harm and challenges to self-esteem are seldom mentioned. Perhaps, testers are afraid that mentioning those possibilities will bias participants to have a negative attitude toward the product being tested. The analogous situation in biomedical research would be not to mention a potentially harmful side effect because it might bias patients to expect such effects.

There is a large volume of literature that stresses the differences between biomedical and social science. There are at least two areas that are relevant to usability tests. First, in the social sciences, the researcher and the participant are often presented as equal partners in the investigation. They work together as colleagues (Murphy et al. 1998). This is the way diagnostic usability testing typically is framed. For example, in formative tests, the test administrator is more engaging and active toward participants. While this approach is intended to make participants feel empowered and more comfortable, it can do just the opposite when participants struggle and fail at tasks. When that happens, it presents the tester and participants with a situation that is not covered by the typical informed consent statement. The hidden assumption behind letting participants fail is that, in a utilitarian accounting of harm, it is better that a few participants fail so that potentially many future users will not fail (see Dumas and Loring 2008). This utilitarian approach to ethics runs counter to a different approach that says that it is unethical to use a harmful means to achieve a beneficial end (Macklin 1982). According to that approach, knowingly causing distress and possibility lowering self-esteem cannot be justified without informed consent. At a minimum, informed consent forms for usability testing should describe the possibility of emotional distress.

A second difference is that violations to participants' confidentiality may come during the reporting phase, which may occur long after the test sessions (Hammersley and Atkinson 1995). While test reports almost never mention participants by name, their user role is often described. A common strategy for emphasizing the priority of a usability problem is to quote participants' negative descriptions of the product or even the company developing it. In tests with small populations that are performed on internal rather than commercial products such quotes may be attributable to particular individuals who then face the embarrassment of exposure. In addition to quotes, it is now technically easy to attach a segment of tape to a slide presentation showing the quote or task failures. In these situations, participants are used as ammunition in the battle between testers and developers over whether changes will be made to the product. Testers need to be aware of the ethics of these situations and take extra precautions to ensure that the identity of participants is not revealed.

53.15 CONCLUSION

Usability testing has evolved in line with changes in the user experience field. For example, practitioners have been exploring ways to work faster and cheaper and to be less formal in their preparation and reporting. In addition, we are just beginning to understand the impact of long-accepted think aloud methods. We now have a better understanding of the standard usability measures, but we also have new technologies, such as eye tracking, which provide new sources of data. Some issues, such as the number and types of participants to use, continue to be debated with no clear resolution. As evidence of this, there has been a push to find ways to conduct tests with both local, convenient participants (e.g., hallway testing) and diverse participants (remote testing). So although there has been progress on many fronts, there are still many areas left to explore.

54 Usability for Engaged Users

The Naturalistic Approach to Evaluation

David Siegel

CONTENTS

54.1 INTRODUCTION

This chapter is intended to give the reader an introduction to naturalistic usability, sometimes called field usability. The term "naturalistic usability" includes a range of approaches to evaluation that attempt to provide a more holistic and realistic assessment of usability than is possible in a conventional usability laboratory study. It attempts to come as close as possible to measuring usability as people actually experience it by exploring the user's interaction with technology in the user's natural context, based on the user's own goals and materials. These approaches also allow you to study both usability and utility conjointly and to explore both initial usability (e.g., discovery) and continuing task performance in a more balanced way than is usually possible in a laboratory study (Dray and Siegel 2009).

It will help focus the discussion to start by contrasting naturalistic usability with traditional laboratory-based usability testing on the one hand, and with two other approaches to user experience research in the field (ethnography and contextual inquiry) on the other hand. No single approach can provide more than a slice of the truth, and so these contrasts are not meant to show that naturalistic usability is better than other approaches, but rather to clarify how it complements them. After contrasting these approaches, we turn to discussion of some of the key difficulties that any attempt to assess usability naturalistically entails and describe strategies to address them. Next, we examine some case examples of naturalistic evaluation projects to show how different strategies might work in different circumstances. Finally, we consider how and when naturalistic evaluation fits into the product development lifecycle.

54.2 METHODOLOGICAL CONTRASTS

Arguments about nomenclature for professional communities and the practices that define them are extremely common. As professional communities grow, they tend to realize that their focus is more broadly relevant and to expand their mandate. Thus, they cross into each other's territory. At the same time, communities feel a need to defend their distinctiveness. This process has certainly occurred within the field of user experience (Siegel and Dray 2005). This can lead to endless turf battles, co-option of things that have to be done under other rubrics, and games of logical one-upsmanship (i.e., "My method subsumes your method.") Certainly, people may debate whether what follows draws the lines correctly. Please keep in mind that experienced and inventive practitioners can do a wide range of things beyond traditional methodological boundaries. Be aware, too, that the names of the methods do not map perfectly to the disciplinary titles of practitioners, that textbook definitions do not always agree, and that practitioners do not necessarily follow the textbooks. People who describe themselves as ethnographers can spend some time doing what looks very much like contextual inquiry, just as people doing usability evaluation in the laboratory may get insights about the deep goals of their users that are more traditionally thought of as the province of ethnography. Similarly, people doing naturalistic usability in the field may at times look like they are doing ethnography or contextual inquiry or even things not that different from standard laboratory evaluations. The discussion of methodological contrasts that follow is intended to emphasize contrasts for didactic purposes and to help the reader think about dimensions of difference. A given example of a real research project may be difficult to classify, and which zone in the space of methodologies belongs to whom is not the most important concern here.

54.2.1 Conventional Laboratory Usability Evaluation

Much, even most, usability testing takes place in a laboratory, which is a simulated environment, using simulated tasks. Typically, these studies are carried out using a sample of people who are not actual users, but who are instead selected to resemble real users on dimensions that the researcher thinks are relevant, including things such as the background and knowledge they bring to the task. This approach makes perfect sense if the goal is to come up with generalizable findings, like inferences about usability for people interacting with the technology for a wide range of tasks in a wide range of circumstances. An emphasis on generalizability requires constructing representative tasks in a form that is generic enough for the following:

- A sample of users drawn from different real contexts to understand and engage with them
- The findings to have implications across a class of similar real situations, despite presumably superficial differences

Paradoxically, although the goal is generalizability to the real world, the tradeoffs involved in creating broad representativeness in laboratory usability evaluation can actually *limit* its applicability to the real world. Doing the evaluation in a simulation environment means there are more layers of inference between observed behavior or problems in the test situation and the real-life contexts where usability problems really matter (Hartson, Andre, and Williges 2003). The following characteristics of laboratory usability evaluation (whether formative or summative) are some of the ways it tends to systematically exclude many factors that influence how usability is experienced in the real world:

- Lack of realistic user motivation
- Bias toward initial usability
- Restricted spectrum of scenarios
- Reliance on simulated data
- Focus on individual usage versus the social and organizational context
- Neglect of mobility

The following sections cover each of these in turn.

54.2.1.1 Lack of Realistic User Motivation

Tasks in a conventional laboratory-based usability evaluation are typically based on some premise or assumption about motivation or goal, which the user is asked to accept. The evaluation itself is not designed to provide direct evidence about what the goals of real users are. By using an assumed motivation as the starting point, such evaluations effectively attempt to abstract usability from motivation. However, it stands to reason that user motivation interacts with factors that determine usability, *both objectively and subjectively*. In the laboratory, it is extremely difficult to simulate the level of emotional investment in the task that real users feel and that lead them to undertake the task with varying degrees of commitment in the first place. How people approach a task, how tolerant they are of difficulties along the way, and how they judge the ease of the task after the fact will be influenced by things like how urgent the task is to them, how much other pressure they are under from other tasks, what their motivation is to accomplish the task, and crucially, how much benefit they expect and experience at different stages. Similarly, motivation will certainly affect persistence. In many cases, this may make the difference between whether you abandon the task a moment before discovering the solution, or persist until successful. These motivational factors could either exacerbate perceived usability or mitigate them, depending on the exact circumstances.

Next, the specific motivations of different users may lead them to take different pathways through the interface, thereby encountering different problems. In real life, users do not necessarily have the single goal that a laboratory task asks them to adopt. They may have clusters of goals with complex relationships among them. It is quite possible that nuances of the specific motivations of real users might lead to taking a different route through a UI, so that they encounter a different subset of usability issues from that experienced by simulated users, whose route may be more externally determined.

It stands to reason that there is a complex relationship between the usability that you experience and the benefit you expect or actually obtain from using something. Obtaining meaningful benefit often depends on time, sometimes requiring extended usage. If you persist long enough to experience major benefits, you may see that the effort was worth it and not judge the experience negatively. For example, the value of reporting functions in business software partly depends on how well populated the system is with data, which can take time. In the "real world" (as opposed to the laboratory), motivation and expected benefit may also determine whether you even attempt to use functionality that you reasonably expect to be challenging or complex, but which could open up potentially rewarding capabilities of the system. None of this is meant to imply that we should not strive to reduce ease of use obstacles for experiencing benefit, simply that benefit is separate from and interacts with ease of use.

54.2.1.2 Bias toward Initial Usability

Most definitions of usability (e.g., ISO 9241-11 1998) include efficiency of use. However, laboratory usability usually, and perhaps inherently, deals with people who are unfamiliar with the system being tested. This means it tends to be most sensitive to problems of initial discovery and is not particularly sensitive to the issue of efficiency of use by experienced users with stable, established usage patterns. Even if initial ease of learning some aspect of the UI is low, a benefit of mastering it might be a great increase in efficiency, thereby ultimately producing an eventual net increase in usability that would not be detectable for some time.

In a sense, expectation or awareness of the existence of a tool's capability is the first phase of the discovery process. At the same time that laboratory usability evaluation may emphasize discoverability, it can paradoxically introduce a bias, because simply presenting the task scenario to the user can imply that there is in fact some way of accomplishing the task. Sometimes the more important question is whether in a natural and unguided usage situation it would even occur to a person that the capability exists, so that they would look for it spontaneously.

While usability is assumed to include learnability, laboratory usability testing with novice users does not directly study the learning curve that will occur with repeat usage. We tend to assume that we can generalize from initial use in the laboratory to use over time, that things that are the hardest to discover will be the hardest to find in the future, that the hardest things to figure out initially will be the most likely to be forgotten, and that the tasks with the most initial errors will tend to be most error-prone over time. Although these sound like reasonable assumptions, it is easy to think of situations in which they may not be true. It is quite possible that things that require the most effort to learn will be the most deeply imprinted and that a wide range factors affect usability nonlinearly over time. Usability obstacles of different types may emerge at different stages of the learning process, but will not be likely to be detected in a single laboratory session with users new to the current design.

54.2.1.3 Restricted Spectrum of Scenarios

In the laboratory, we provide a limited sample of the spectrum of experiences a real user will have with whatever we are testing. We take tasks out of the context of other tasks. This may provide the test user with a very distorted experience. In our experience, many usability disasters have been driven by the desire to make all things equally available to the user. In real usage, it is normal for the user to expect some functionality to be less obviously available than others, but assessment of this will be limited if the user does not have the opportunity to experience a realistic range of usage scenarios and thereby to form realistic expectations of what should be prioritized. Also, the user in the laboratory can only guess at what his or her real life priorities will be in the real usage context.

54.2.1.4 Simulated Data

How easy something is to use depends partially on one's familiarity with the universe of data that populates it, and how that data is structured in one's experience. Different information terminologies and architectures can evolve within the same domain, often for historical or even somewhat arbitrary reasons. The use of simulated data in usability testing can, therefore, introduce a serious confound. It can be very challenging to separate inherent usability problems with the design from problems that result from a sense of disorientation that comes from working in a universe of unfamiliar data. Usually, usability researchers try to make sure that the data with which a test UI is populated do not include distracting cues. This can be extremely difficult to ensure, but even using totally neutral data, if such a thing exists, may not be enough. In real life, familiar data might provide important landmarks that help the user navigate the system. A simulated environment may be highly discrepant from that of users in their real lives, and it is almost impossible to tease out this influence.

54.2.1.5 Individual Usability Abstracted from the Social and Organizational Context of Use

Laboratory usability evaluations typically focus on individual users. However, usability of many tools depends on organizational and social issues in the usage context. This is obviously true for collaboration tools, but applies to many other types of tools that have to be implemented within a larger system or that are used by individuals in an organization. Ensuring that the tool is usable in principle for an individual user as measured through test tasks may still not address whether it is usable in the organizational context of work flow, technical infrastructure, and so on. Usability problems may well exist at the organizational level. This adds another layer to the interaction between benefit and usability discussed earlier. The process of implementation and adoption of a system in an organization typically takes time. The opportunity to experience the eventual benefit of the system is in the future, and the road map toward it may be more or less visible to users of different types. Many systems do not provide their value until they have been implemented and widely adopted. Therefore, for such systems, we need to understand the balance between usability obstacles, experienced value, and anticipated value at various stages of the organizational implementation and adoption process.

The usability that users experience in real life can be the result of the composite efforts of the designers and of intermediaries within the organization. The ultimate end user experience of many business applications is partly the result of the efforts of people who customize the system for a specific installation and then populate it with data that embodies an information architecture the software designers may not control. The challenge of providing software that is adaptable to a wide range of situations means that design teams have to allow modifications and customization. They may try to build in constraints on what local implementers can do, but their control over the usability impact on end users may be very indirect. From the users' perspective, though, it matters little at what level the usability problems are introduced into the system.

54.2.1.6 Neglect of Mobility

Mobile usability is also a priority area for naturalistic evaluation, although the logistics of evaluating mobile devices in the field are certainly great. However, not only do environmental conditions, such as noise and lighting, play a major role in mobile usability, but the varying social contexts of use also have a major influence. For location-based services, the value of evaluation in context seems even more compelling (Goodman, Brewster, and Gray 2004). Despite the apparent value of field usability studies in the mobile domain, a literature review by Coursaris and Kim (2007) found the majority of mobile usability studies were conducted in the laboratory and called for more emphasis on field research.

Duh, Tan, and Chen (2006) compared results from a usability evaluation of mobile phones in the laboratory versus in the field. Using a variety of self-report and behavioral (e.g., task time) measures, they detected different, more numerous, and more severe usability problems in the realistic environment. Although one can raise questions about their methodology, such as whether carrying out a structured evaluation in a public setting introduced a global negative bias for participants, their findings highlight the likelihood that evaluation in the natural setting may produce a very different view of usability issues. Nielsen et al. (2006) did a study in which they similarly tried to isolate the effect of setting by using the same test protocol in the laboratory and in the field. Their study seems less subject to the concern that testing in a public setting was a serious confound, because of the specific setting used—a warehouse as opposed to a commuter train. They, too, found more usability problems in the field, as well as problems in categories that the laboratory was not sensitive to (e.g., cognitive load). Kaikkonen et al. (2005) did a similar study that led them to question the value of field evaluation over laboratory evaluations, on the grounds that they found the same list of problems in the laboratory as in the field. However, they used a larger sample than is common in iterative usability research (20 in each condition), increasing the likelihood that their list of problems uncovered would be fairly exhaustive. Also, overall problems occurred more frequently in the field, suggesting that the field may have indeed provided a more sensitive test. It is worth reiterating that none of these studies used a fully naturalistic approach, in that they used the identical, predetermined (rather than personalized) task scenarios in both conditions. A fair comparison of naturalistic and conventional laboratory evaluation would have taken into account the advantages of testing a mobile telephone under conditions where the participants actually care about their activities (e.g., communication) using the device.

54.2.1.7 Summary of Contrasts with Conventional Laboratory Evaluation

In contrast with conventional laboratory evaluations, studying usability in context allows for exploration of goals that matter to the user, of dependencies on contextual factors, and of the complex interactions among motivation, expected benefit, experienced usefulness, and usability. It eliminates confounds such as those attributable to simulated data. It provides a more comprehensive view of usability than is possible in a laboratory because naturally occurring task scenarios tend to be more diverse. It also allows for a more comprehensive view over time because it can take a broader look at the facilitators and obstacles in the product design that influence various stages in the evolution of the user's experience over time. To illustrate this, consider the following proposed model of the stages, or hurdles, in the transition from the existence of a user need to full adoption of a product.

1. Need: How does the user experience desires, goals, challenges, objectives that could motivate goal-directed behavior, or change in current goal-directed behavior, to which the tool is intended to be relevant? How well does the product address these in principle?
2. Expectation, seeking: To what extent is the user looking for a technical method for fulfilling the needs? How established are their current practices to fulfill the need, and how satisfied is the user with those practices, and how aware that there might be an alternative?
3. Exposure: How does or might the user gain the knowledge that a potentially relevant tool exists? What are the channels through which and the conditions under which this exposure takes place? How effectively does the process of exposure reach the most likely target users?
4. Discovery, recognition: How does or might the tool convey to the user its relevance to the user's need?
5. Exploration: How does or might the user approach the tool and how does the product engage the user to communicate what it might do for him/her *in principle*? To what extent does the product deliver on the potential, and does the user experience an increment in value to motivate continued experimentation?
6. Experimentation: What is the user's experience during initial attempts to apply the capabilities of the tool to specific instances of need to evaluate its relevance and potential benefit to him/her? To what extent does the user's initial experience encourage continuing broader experimentation with the tool?

7. Incorporation, adaptation: How does the user modify other related practices to allow for repeated, ongoing use of the tool? What is the burden of making these modifications? How does the user experience accumulated benefit? Is it sufficient to encourage sustaining this process?
8. Adoption: How does the user modify other related practices by incorporating the outputs of using the tool, building it into a network of practices that sustains utilization?

Any of these questions can be the target of evaluation research. Admittedly, this model does not apply equally to all interactive products. For example, the later stages are not as relevant to some tools that can be judged adequately based on the quality of the single-use experience. Although it is rare that a single naturalistic usability study would cover all these stages, the approach is flexible enough to allow choices about what steps in the model to emphasize and to allow varying the approach and focus across participants in a single study who may be at different points in the sequence of steps. For example, it allows for adapting the protocol to study the very different user experience issues that are relevant with people who are already users of a website and with people who have never used the site for that particular purpose.

Laboratory usability tends to focus on steps 4 and 5. On the early side of the process, naturalistic usability evaluation allows space for the researcher to gather more direct evidence of the degree to which a user spontaneously seeks a capability within the tool to meet some identified need, before prompting him to try it out. Working in the user's context allows time to investigate issues relevant to stages 1–3 as well. On the later side of the process, for example, stages 6–8, naturalistic usability can investigate facilitators and obstacles that arise beyond the first trial use of a feature and that influence the degree to which the user moves toward stable adoption of the tool for some uses.

54.2.2 Naturalistic Usability Compared to Other Types of Contextual User Research

When usability was a relatively new practice, evaluation was often called in when a product was thought to be far enough along in the development to give users a high-fidelity experience of it. Unfortunately, the result was that evaluations often turned up problems that could not be solved simply or elegantly at the level of screen design, but only at a deeper level. The experience of discovering these deeper problems has sensitized many usability professionals to the need to become involved in the design process earlier. Testing of prototypes in rapid paper prototyping (Snyder 2003) and the RITE method (Medlock et al. 2005) are examples of responses to the need to incorporate evaluation early and iteratively during the design process.

But studying early design ideas is not enough. As discussed in Section 54.2.1.7, to ensure that products are not only designed properly, but also play appropriate roles and fit into people's lives, requires work in the usage context to understand user characteristics, goals, and needs that users bring with them as well as environmental factors like work practices, organizational factors, technical infrastructure, to name a few.

The very issues that tend to be neglected in laboratory usability testing have over the years become the focus of a group of approaches that focus on understanding user needs, motivations, goals, contextual constraints, and influences. No standard nomenclature exists to describe this group of approaches. Some people have simply expanded the meaning of "usability" so that it now incorporates issues of usefulness, experienced value, desirability, hedonics, contextual fit, and so on, rather than simply cognitive usability, or have referred to this broadened meaning as "Big U usability" (Barnum 2011). However, this potentially blurs the still meaningful distinction between the traditional narrower definition, focused on design attributes that facilitate cognitive and task performance aspects of the user experience, and this broader concept. We prefer the terms "User Centered Design Research" or "User Experience Research" to encompass the spectrum of research that attempts to facilitate designs that achieve the wider range of virtues we strive for beyond "small-u" (or traditionally defined) usability. These terms cover the very broad spectrum of approaches for introducing data from and about users into the design process. Among the most important of these are research techniques that study the behavior of users or intended users in their natural contexts to get at more fundamental issues that should influence design at deeper levels. Here, we address two main forms of this research, ethnography and contextual inquiry. Both these are discussed far more comprehensively in Chapters 43 and 45. The purpose here is only to contrast them with naturalistic usability evaluation. These contrasts are admittedly more subtle than the contrast with laboratory usability.

54.2.2.1 Ethnography

Ethnography was introduced into the world of product planning and design from the field of anthropology, as an approach to introducing deep knowledge of users into the product planning and design process. Just as with usability, there are some issues of nomenclature in regard to ethnography. As ethnography has become increasingly accepted in industry, more people have adopted (or co-opted) the term to describe what they do, to an extent that its meaning in practice can become diffuse. Nowadays, "ethnography" is too often used loosely as if it covers any research about users in their natural environment, even simply interviewing them on-site. The following paragraphs propose what is hopefully a more useful way of thinking about the distinctive character of ethnography, emphasizing things that differentiate it from naturalistic usability.

Ethnography as practiced in industry, or "design ethnography" (Salvador, Bell, and Anderson 1999), tries to understand the context of basic human and social functions within which a successful product must fit to help ensure that the product plays a meaningful and useful role. It tries to focus on a more basic level of human activity that is not tied to the particular tools currently used to fulfill those functions. For example, while a usability evaluation of a website might examine whether people can find the information they want regarding a product, an ethnographer might try to understand the concept of "confidence" in a purchase decision and the social dynamics surrounding it. Information may play a role in helping a person develop confidence in a service or product offering during online shopping, but any one piece of information or one website feature contributes only one small piece to the larger picture of "confidence." Understanding what is at stake for the individual in making a major purchase decision, what causes anxiety, what the balance is between rational decision making versus justifying an emotional decision, what the social dynamics are around establishing confidence of others in the judgment of the shopper and gaining their support for the purchase, and so on may all inform overall product strategy and help ensure that implicit levels of the user experience are aligned with these dynamics across many aspects of the design.

This focus on fundamental understanding can create a challenge for ethnography in industry because its implications for specific product-related decisions can be perceived as too indirect or abstract. Too often, the implications are expressed at a level that leaves room for a great deal of interpretation and inference on the way to a specific implementation. Product teams looking to ethnography for design guidance sometimes complain that the research gives them an interesting and vivid picture of the user, but leaves them guessing about the concrete product decisions they have to make. This issue has received a great deal of attention from the design ethnography community (e.g., Diggins and Tolmi 2003; Beers and Whitney 2006; Jones 2006). Design ethnography, done well, can have very powerful implications for products, but these are often at the strategic level rather than the more concrete design level of small-u usability.

54.2.2.2 Contextual Inquiry

Contextual inquiry (CI) is an approach to exploring people's interaction with technology by combining interview with observation while they are in the process of carrying out their work. It has been an extremely influential technique in user research. Beyer and Holtzblatt (1998) explain that it is based on the belief that only by grounding interviews in observation of actual work can you compensate for the weaknesses of self-report, such as biased recall, tendency to give summary information, and difficulty recognizing how one's own behavior depends on the context.

CI is not so much an evaluation of the tools observed, but an attempt to use observation of user behavior with tools, combined with a particular style of probing into the users' explications, to understand how users approach their work, to infer deeper levels of user goals and of how work is organized, and to suggest new design ideas. These ideas do not necessarily map in a direct manner to a list of solutions to identified problems (McDonald, Monahan, and Cockton 2006). Although CI certainly attempts to capture evidence of "breakdowns" or limitations in the usefulness of current systems by noting things like workarounds that users have developed, there remains a difference of emphasis between the typical contextual field study and naturalistic usability evaluation in how intensively they focus on strategies to elicit data that identify usability issues directly applicable to the new design.

One limitation of CI as an evaluation method is that it is normally carried out while people interact with their current, customary tools to achieve their goals. Experienced users have often adapted to some usability problems that might block early users. In a sense, this is the complement of a limitation cited above for laboratory evaluation—the focus on novice users and discoverability problems. Experienced users may or may not recognize ways in which their process could be more efficient or less error prone. Their work practices may have been designed around some of the main limitations of their tools so that they do not experience them as problems, even if these practices are in principle sub-optimal. Similarly, doing research with experienced users limits the researcher's ability to learn about usability obstacles that arise at different points in the discovery and learning process. If one plans the sample to address this, such as by including participants who have different levels of experience, or probes on less habitual tasks, the distinction between naturalistic usability and CI can begin to break down.

As stated in Section 54.2.2, the contrast between naturalistic evaluation and these two field research approaches is more subtle than that with laboratory evaluation. Focusing on the evaluation of technology in use makes it easier to derive concrete design implications than is usually the case with ethnographic approaches. This is also true of CI, but naturalistic usability evaluation also complements CI, because it does not limit the research to experienced current users of your tools, although it may include them. Also, while CI does allow for and indeed encourages probing of variations in people's task approaches under different circumstances, naturalistic usability goes beyond this as an evaluation method by encouraging people (judiciously and in a highly personalized manner) to undertake tasks and use features in ways they may not have done on their own.

54.3 METHODOLOGICAL CHALLENGES OF NATURALISTIC USABILITY

Doing naturalistic usability evaluations would be easy if all they involved was finding existing users, watching them do their tasks on their own, and seeing where they get into difficulty. Unfortunately, this is not the case. Intervention by the researcher is almost always necessary, at every stage from actively selecting a sample to exposing users to tools, to engaging them in tasks as naturally as possible, to probing their behavior and thinking during their task performance, to prompting their behavior. These actions obviously compromise "naturalness" of the research. This section discusses methodological considerations that the researcher must take into account to make sound decisions about these interventions and to manage their impacts.

54.3.1 Spectrum of Naturalistic Usability

We can distinguish highly naturalistic from semi-naturalistic approaches, with gradations between them, based on the amount of researcher intervention into the natural usage experience that they entail. A maximal degree of naturalism would involve almost no intervention and minimal interaction with the user. A minimal degree may involve a fairly structured usability evaluation in a simulated environment where the contents of the tasks are nevertheless highly personalized to the user. We can also make finer-grained comparisons among approaches based on choices about how to handle specific aspects or dimensions of naturalism. Semi-naturalistic evaluations may compromise on some of these dimensions while trying to preserve others.

In fully naturalistic approaches, the evaluation is done with people who have full freedom to use the technology as they see fit. They are intrinsically motivated to use it for a realistic spectrum of activities and to attempt to get value from it. The researcher has the opportunity to study their experience over sufficient time to understand the realistic spectrum of user-attempted tasks, and does not need to intervene in the natural process of usage, whether to prompt user behavior or even to ask probing questions to understand the user intentions. Unfortunately, situations where pure observation of completely unconstrained user behavior will provide adequate usability data are extremely rare, because of the type of information needed, practical constraints, and the fact that the researcher does indeed have an agenda.

Consider the following case situation where a fully naturalistic approach would make sense in order to appreciate how rare it is. It involved a single-purpose walk-up-and-use-system of a type that could be usefully evaluated through observation alone, without the need to interact with the user at all, namely, a self-service coffee machine. Its industrial design was beautiful. It looked like industrial sculpture, a robotic barista that took infinite care to brew each cup just for you. This beauty conveyed the promise of a very high quality cup of coffee. From the sounds it made, you could tell that it ground the beans, deposited them in some kind of receptacle, and injected hot water slowly over the ground coffee. About 10 seconds after the hiss of the water began, coffee would begin slowly dripping out of the nozzle. Probably because the process was so slow, it had been designed with a helpful LCD progress indicator (beautifully framed with polished brass trim) that would slowly fill from left to right. Three sizes of coffee were available. For a small cup, the progress bar would slowly fill once. For a medium cup, it would slowly fill once and stop when the cup was half full. After a slight pause, and some additional mechanical noises, the progress bar would start from the beginning a second time, and more coffee would begin dripping into your cup. For a Super Grande, the process was repeated three times. The problem was that, having waited so long for the coffee to brew, people had no idea what was going on when, although their cups were only half full, the progress bar seemed to give them the message that the process was finished.

Now a piece of context: the machine was in a cafeteria in a conference center. Naturally, most coffee was ordered at busy times, with a long line of people waiting, most of whom were encountering the machine for the first time. Any usability researcher could stand nearby and watch as one hapless user after another took his half empty cup from under the nozzle, stared at it in puzzlement, noticed with confusion that the machine had started up again all by itself, and thrust his cup back under the nozzle a moment too late when he realized that the liquid now dripping into the drain was the rest of his own order. The waiting customers (most of whom *were* usability researchers) could see that something was going on, but could not see what the problem was, and so repeated this experience one after another.

This case had a number of characteristics that would enable adequate understanding with a very simple methodology and make the cost of research per user studied very low.

- Users were motivated by their own goal without any need for artifice or special recruiting efforts.
- There was no need for them to explain their intent to the researcher, and their interpretation of the system feedback was obvious.
- The initial usage experience was by far the most crucial one (since a large percentage of users were going to be using the machine only once).
- The time needed to observe each user's complete experience was short.
- There was a naturally occurring concentration of users in time and space who provided a good sample of the spectrum of usage scenarios (e.g., small, medium, and large cups; regular coffee vs. cappuccino, etc.).

These are the opposite of the circumstances that apply in most naturalistic usability studies, however. It is far more common that the researcher needs to compromise some aspects of naturalism by applying active management strategies to ensure participant motivation and to balance user freedom and spontaneity with the goals of the research by intervening in the user's natural process of interacting with the tool. Any intervention on the part of the researcher introduces some degree of artificiality, but the goal of naturalistic usability evaluation is to minimize this by carefully "titrating" the researcher's influence. The rest of this section discusses methodological considerations for managing user motivation and user freedom and concludes with discussion of the special issues related to these topics in the case of longitudinal studies.

54.3.1.1 Ensuring Motivation

The primary dimension of naturalistic evaluations is user motivation. All naturalistic usability evaluations embody some strategy for achieving as realistic a degree of motivation or engagement on the part of the user as possible. Engagement is influenced by how committed the test user is to the goals that the tool being evaluated is supposed to support. This does not necessarily mean that naturalistic evaluation enforces this commitment either to the goal or to using the tool, because one of the research questions may be whether the tool itself or any feature of it (or any information about the tool the user may be exposed to) evokes motivation.

The design of the evaluation study can influence this by controlling such things as whether the user has actually made a personal investment in the tool being evaluated, expects to live with it for an extended period, sees its use as mandatory versus optional, and/or has access to appealing alternatives.

However, the agenda for most studies goes beyond assessing how effectively the tool as a whole attracts people to use it. More often, we want to assess the experience the tool provides to people who do engage with it, including how attracted they are to using components of it. Realistic motivation can be incorporated into a research project in a variety of ways. The specific approach depends on the goals of the research and the constraints of the available research opportunity. A usability evaluation of a newly implemented work system, use of which is not optional and that employees expect to have to live with for an extended period of time, might be highly naturalistic depending on how the researcher structures the interaction with participants. Another example would be an evaluation of a product with a user who has actually purchased it. An "out-of-box" evaluation (OOBE) with an actual purchaser of a new product, that is, setting it up for the first time in the intended usage environment, is a simple example of such a study. An intermediate level of naturalistic motivation can be represented by an evaluation during an agreed-upon trial period that is structured so that the person has a strong incentive to get meaningful benefit from the tool. For example, in a study on the experience of switching to a new e-mail tool, we recruited people who agreed to adopt the new tool for an extended period. Another step down in naturalness might be a situation in which participants use a tool that they are not necessarily expecting to adopt for an extended period, but that they use for test tasks that nevertheless do reflect their own goals. An example would be a test of a website where the user is attempting to get the information that they are actually interested in at the present moment. Finally, an evaluation of a system that the user is interacting with only for limited test purposes and for a limited number of task scenarios can still be considered somewhat (or minimally) naturalistic if the tasks are highly personalized to the participant, so that the participant cares about them. This can be achieved if the user has the possibility of deriving some meaningful benefit even from a brief interaction.

Even though the user's engagement should be determined by realistic motivation, project timelines typically require us to obtain data in concentrated form within a limited time frame. Therefore, a naturalistic study may require either a recruiting strategy for finding a sample of people who are naturally motivated to do a task at a particular time convenient for the research or finding people who have some meaningful pre-existing motivation and then inducing them to do the task at a particular time.

Obviously, the former is more "natural." In some studies, identifying such a group may be fairly easy: working through a hospital or clinic to recruit a group of patients who have just received a particular medical technology; partnering with a retailer to recruit a group of people who are new purchasers of a particular tool; studying the user experience in companies where a new system has just been implemented and large numbers of people are going through the migration process at the same time. Sometimes the study can be scheduled in a season when the behavior of interest is common in the population, making it easy to find users who are ready to proceed, for example, evaluating a gardening website in the late summer and early fall when local perennial gardeners are likely to be planning their fall planting, or evaluating a tax tool in the United States between January and April.

On the other hand, often the best one can do is to identify people for whom there is evidence of likely motivation but who are not yet engaging in the behavior of interest. E-commerce studies can often recruit people who are currently "in the market" and, therefore, can realistically engage in online shopping or even purchasing during a research session. An example might be recruiting people for a travel website study who are expecting to take a vacation in the next 3 months, who have not yet finalized their plans, and who expect to use the Web to make a reservation and arranging for them to do so during the study. One strategy to induce this behavior is to give people the incentive for participation in the form of reimbursement for or contribution to the purchase they make during the study.

Finding people who are at the appropriate point in their own process to fit the focus of the evaluation can be challenging. The recruiting itself can be done using a traditional screener or by selecting people based on some behavioral indicator of motivation. For example, people browsing in a certain department of a store may be recruited for an online shopping study for that type of product; families visiting college campuses may be recruited for a study of an online tool for college financing.

In any form of usability research, we should always consider biases that may be introduced by the recruiting and selection process, and this is certainly true here. In particular, it is important to acknowledge that people who are at a point where they are ready to take the action of interest to the researcher on their own may be different on average from people who are at an earlier stage and need to be induced to act. A sample of people who are shopping now but not quite ready to purchase on their own will include a certain percentage of people who would not otherwise follow through to an actual purchase. The researcher must pay attention to how stringent the selection criteria are regarding evidence of pre-existing motivation versus how strong the inducement to engage in the behavior needs to be. In some cases, one can get a quantitative sense of this by finding statistics about how strong a predictor the recruiting criteria or targeting strategy are of the behavior of interest. However, even in cases where only a qualitative assessment of this is possible, it is important to make it explicit.

54.3.1.2 Freedom

Naturalistic usability evaluation involves a range of freedom to interact with the technology in an unconstrained way. It can also vary in how much the research depends only on the tasks the user undertakes spontaneously. Most naturalistic studies require some degree of prompting to get participants to engage in particular tasks. The degree to which this is needed depends on the degree of spontaneous motivation in the sample the researcher is able to assemble and on the amount of time the researcher can allow during the evaluation for users to proceed on their own initiative.

Obviously, manipulating the timing of a task by inducing people to do something during the study that they may be close to doing on their own is one form of intervention in the user's natural behavior. In addition, the researcher often has to induce the person to use a tool that is different from what he or she would have chosen spontaneously. For example, people shopping for a cell phone might be given a specific phone to live with for evaluation purposes, even though they might not have chosen this one on their own. At a more micro level, even a naturalistic study typically requires some form of prompting for people to follow a different usage path than they would have done on their own, such as to use a feature or attempt a specific task. To the extent that the users are still guided by their own goal and that the task outcome matters to them, the study can still be considered at least partially naturalistic.

The degree of user freedom in a naturalistic usability study requires a special approach to scripting of the research protocol. A conventional laboratory usability study can be tightly scripted. Of course, room must still be given for users to construe some aspects of the task in their own way and to choose their own approach to attempting it. This is where the data comes from, after all. However, scenarios can be written and pilot-tested to ensure that the portions users "should" understand in a similar way are communicated clearly, so that the givens of each scenario (the starting point in the UI and the task assumptions) are standardized. The sequence of scenarios can be predetermined and assigned to users in a predetermined or rule-based way.

The situation is very different in naturalistic usability research, because the balance between freedom and scripting is shifted heavily toward freedom and open-ended exploration. This can shape even how the session begins. Laboratory usability sessions may start with a brief interview that includes some open-ended questions. These provide individual information beyond what is available in the screener data. Both the screener and interview data may help the researcher to interpret the user's response to the scenarios or to omit scenarios from among the pool that seem to be less applicable to the user. In a naturalistic usability evaluation, this individual background investigation is much more extensive and may take on the character of an extended interview or even an ethnographic investigation with each participant. The purpose is to understand as much as possible about the context and baseline practices of each user, not only to facilitate interpretation of the participant's subsequent behavior when interacting with the technology you are evaluating, but also to support deep customization and personalization of the evaluation process.

When work begins with the tools being evaluated, users are given much more freedom to define their own goals and tasks. The process of interacting with the user may look very similar to CI, with the difference that the user is not assumed to be an expert on the tool and that the researcher has a primary agenda of potential scenarios that focus on evaluation. If the researcher suggests tasks, they are typically delivered in an open-ended or general manner, with the user free to add concrete details that make the task personally relevant. Alternatively, the researcher may improvise task instructions in more detail based on the knowledge of the user's specific goals and self-defined tasks.

Decisions about prompting the user represent a compromise between some predetermined priorities for the research and the specific opportunities each user presents to probe different aspects of the interaction design. Because the researcher has more information about the user as the session (or, in the case of a longitudinal study, the sessions) proceeds, it becomes possible to make more and more nuanced decisions about how to balance the research priorities with the opportunistic aspects of the process. Therefore, the degree of direction and structure that the researcher provides typically increases during the evaluation.

The idea of the researcher prompting the user raises concerns about researcher intervention contaminating the findings. There is no perfect solution to this problem. It cannot be eliminated, only "managed." When prompting the user to attempt a task, the bias should normally be to start with as little direction as possible to allow the opportunity to observe the user's natural exploratory behavior, as a clue to motivation and interest. Similarly, once the user is engaged with a task, the process of probing or giving cues should proceed in small increments, as in any formative testing. This gives the researcher a chance to see what the minimum level of cuing is for the participant to move forward and to experiment with different cues to see which make the difference. Of course, the sequence of prompting must be carefully documented and used to help interpret subsequent findings. This information can provide clues about what cues the design must give to facilitate any step in the process of engagement and adoption, from leading the participant to consider exploring a tool or feature, to applying it to their needs.

The open and improvisatory character of naturalistic evaluation requires very different preparation from what goes into highly scripted laboratory evaluations. Typically, it is important to prepare a list of general categories of usage scenarios of interest, described in a fairly generic manner, to enable the researcher to recognize relevant scenarios that arise with each participant. These need to be matched with parts of the tool expected to play a role in supporting such scenarios. Identifying potential areas of design concern will help with prioritizing these. This is not inherently different from the process of choosing what you want to test in a laboratory evaluation, except that the list of priorities will often be much longer, because you need to be prepared for the wide range of opportunities the participants will provide based on their differing motivations and task approaches.

54.3.1.3 Special Methodological Issues for Longitudinal Studies

To this point, we have been talking about naturalistic studies as though they provide a snapshot of usability at a single point in the user's history with the tool, either with people having their initial experience or for people with more experience. But what if we want to understand the experience over time, for people with different amounts of experience? The choice is between cross-sectional versus longitudinal research. Cross-sectional research requires studying separate sub-samples that reflect different amounts of usage experience. It provides a series of snapshots. The problem with this approach is that the samples for the separate snapshots cannot be assumed to be equivalent, because of differences among the people who began their experience at different points in time (e.g., the "oldest" group might include more "early adopters" or may have experienced earlier versions of the tool) or because of nonrandom dropouts along the way. This may be less true with some business systems where usage is not optional, but to the extent that the samples are nonequivalent, the researcher will have difficulty teasing out this confound, which is known as "survivorship bias."

In contrast to cross-sectional research, longitudinal research follows a given sample over time so that the evolution of each individual can be tracked. This approach has many challenges of its own. The demands of participation that will extend over a longer period may make it harder to find willing participants, and thus, introduce a selection bias. In any sample followed over time, there will be attrition, with people dropping out for various reasons. Some of these reasons may be due to highly individual changing circumstances that make participation in the study difficult and are, therefore, in a sense "accidental" or random. But some of the reasons may be correlated with user experience issues. In many real life situations, people are free to abandon a tool to return to their previous one or a new one based on their experiences. As mentioned earlier, this may be less true in some business situations, but even in business settings people often have some freedom about how exclusively they rely on a tool and how many of its capabilities they explore and adopt.

In contrast to cross-sectional studies, longitudinal studies allow the researcher to obtain more direct evidence of what leads to the dropouts, which can be used to interpret the difference between the original sample and the end sample of survivors. However, it adds the problem of ensuring that you end up with enough people going far enough with the tool you are evaluating to cover deeply enough the design issues you want to explore. It is often hard to estimate in advance what the natural dropout rate will be. In longitudinal epidemiological studies, researchers trying to identify risk factors prospectively typically start with very large samples because they know that only a small percentage will develop the disease (and because of the number of variables they want to screen), but we do not have that luxury in user experience research, where we typically have small samples. In addition, in longitudinal research, there is a particularly large investment in each participant, so dropouts are costly.

This creates a strong incentive to try to retain participants who might otherwise have abandoned using the tool or to help them over a usability hurdle that would have blocked further development of their usage behavior. Of course, this means that findings from these people beyond that point may be more speculative. Nevertheless, they can still provide insight into usability beyond what would otherwise have been their stopping point. Clearly, the researcher must treat the need for this type of help as an item of data and carefully document it, as described earlier.

There is a more subtle form of attrition to consider as well. If an individual's exploration of the tool and experimentation in applying its functionality to their needs level off quickly, the amount of information obtained from them, and therefore their value in the study, may be out of proportion to the amount of time invested. On the other hand, people who persist in exploration spontaneously may not be representative of the wider range of users. They may be different either because the natural variability in their work tasks makes a wider range of tool features relevant to them and creates more opportunity to use them, or simply because of their own curiosity, comfort with exploring technology, and so on. Therefore, it can be necessary to push users beyond their existing usage behavior by negotiating usage experiments with them, incorporating content and addressing goals that are potentially meaningful to them. Again, it is important to document these decision points with each user.

54.4 CASE STUDIES

This section provides three case examples of naturalistic usability studies in the field. Each case includes a discussion of some of the findings, to show the particular benefits of the method, and discussion of the methodological decisions that had to be addressed for each study.

54.4.1 E-Mail Switching and Adoption

We did research for a client who offered an e-mail service as part of a collection of other web content and features available in both free and subscription packages. Users could adopt the e-mail as a stand-alone service or as part of a larger package of other services through a web portal. The client had developed specific tools to facilitate migration from a person's existing e-mail into the new service, such as tools to import contacts and existing e-mail folders, and to notify contacts of the person's new e-mail address. The client wanted to understand the usability of these tools and their contribution to the appeal of switching e-mail providers. We wanted to understand usability of these features in the context of how people actually set up their e-mail folders and managed their contacts. Also, the experienced value of the e-mail service had to be understood in relation to the experienced value of all the other services a person might encounter when adopting the new e-mail.

We discovered that people used the opportunity of switching as a time to "clean out" their old e-mails and existing contacts. This meant they needed a more convenient way of selecting items at a range of levels of granularity, rather than moving things en masse. This is something that could only be discovered by testing these features by having people manage their own data, since these are the data that they actually cared about.

We knew that a fair test of the e-mail service would require an extended time. For instance, one can only evaluate how well spam filter works when one has accumulated a reasonable experience base with it. Similarly, we needed to allow sufficient time for the process of discovering, exploring, and experimenting with various features both in the e-mail tools and in the associated web portal. This meant that we needed to recruit people willing to commit to the e-mail tool for an extended period. We gave them free subscriptions to the e-mail portal for 1 year and asked for them to use this new e-mail account and to commit to the research for a period of several months, with several visits scheduled during this period. Not only did this time commitment allow for the emergence and stabilization of usage patterns, but it also promoted their commitment to getting the best value out of the tool, since they were going to live with it for a while.

The demands of the study required that we recruit people willing to switch e-mail providers and that we pay them an appropriate incentive. This of course raises a question about the representativeness of the sample. We never conceptualize qualitative studies like these as statistical studies in which we are trying to find the average of certain variables and generalize it to a larger population. However, it is inevitable that the question will arise about whether our qualitative findings are applicable to real users or real likely users. For example, maybe the only people who would agree to switch their e-mail for research purposes were people for whom personal e-mail was not very important. To address these questions, we not only screened people to get a sense of their e-mail and web usage before recruiting them into the study, but also began the field research by doing an ethnographic study with participants to understand their baseline usage pattern and to make sure that the sample included a good spectrum of users. This of course also provided us with historical context for each participant to understand how e-mail fit into his or her life.

54.4.2 Real Estate Website

We did a series of studies on a website that allowed users to search or browse for homes listed for sale in a variety of ways, to identify real estate agents, request showings, get information about real estate-related services such as mortgages, and so on. The site allowed users to compose searches by selecting from a rich set of search criteria. They could save these searches and specific real estate properties located by the searches. They could set up e-mail notifications so that they would find out when new properties came on the market that met their criteria.

Contrasting two of the studies from this series will highlight the special challenges and benefits of naturalistic usability evaluation. The first study was a classic laboratory usability study. For this, we recruited users who were “like” real estate shoppers who might use a website like this. To be sure that any problems were not due to general lack of familiarity with the Web, they had to report a certain amount of prior online experience. To be sure that the kinds of terms and issues relevant to shopping for a new home would be meaningful to them, we required that they had purchased a new home within a certain time frame or anticipated doing so within a certain future time frame. Our client had commissioned the study because they had some very specific concerns about the understandability and navigational structure of the site. The task scenarios were, therefore, constructed to probe these issues, which meant that we prescribed task goals and specified certain other task parameters to the participants. All these were appropriate for exploring cognitive issues that might be inherent in the design in a way that was divorced or abstracted from the real context of use by people in the real estate market right now.

We learned many interesting things, for example:

- People were confused by search terms that overlapped in meaning and seemed to produce inconsistent results. For example, people were confused about why they would get fewer results when they searched for houses with a garage than when they searched for houses with a two-car garage. The answer had to do with problems in managing the process of entering property descriptions by real estate agents.
- People had problems dealing with the logical heterogeneity of the list of geographical areas they could use to filter searches. For example, when trying to filter a geography using a list of locations that included the names of cities, neighborhoods within cities, and towns, they were unclear how they would get to see properties in unincorporated areas of the counties that contained these towns and cities. If they selected the county, depending on the pattern of results, they were often confused about whether their search included results from the entire county *including* its cities and towns or if the results were only from the parts of the county *outside of* the listed cities and towns.
- When trying to decipher the underlying logic of the search options by testing them, they were often confused about whether the problem was with the logic of the classification, the accuracy of the search results, or something they may have done.
- When saving a search, they were often confused about whether they were saving the search parameters or the particular results the search had retrieved on that occasion.
- If they wanted to return to the search later, people looked in the “Search” tab rather than the “My Portfolio” tab, an ambiguous name that had been chosen because it subsumed both “saved properties” and “saved searches,” both of which would have been more concrete and understandable had they been easily visible.
- When given a task that asked them to set up notifications, they had difficulty finding the functionality; did not understand the relationships and

dependencies among saving a search, setting up a notification, and creating an account; and had difficulty navigating the interconnected processes for these functions.

To find out how to overcome these and other issues, we did a contrasting follow up study in a far more naturalistic manner. This time, the need to assure realistic, natural levels of engagement by participants was addressed by a different type of recruiting process. Through a network of real estate agents working for the large agency that owned the website, we identified a pool of people who were currently shopping for a home, from which we selected a sample covering a range of levels of engagement with the website. We accepted the tradeoff that people who already had a relationship with a real estate agent were probably more deeply engaged in the shopping process and would not be representative of people who might use the website while in an earlier or less serious stage of considering a move or a purchase (and took this into account in our interpretation).

We visited participants in their own homes or, for some people who were relocating to the area, in their temporary apartments, and explored the role that use of the website was playing in their larger process of house-hunting. For example, we were able to examine the role of the website in relation to their interactions with their real estate agent. By studying their use on their own computers, we were able to examine things like how they supplemented the website with handwritten notes, and what notifications they had received in e-mail and what they had done with them. We could examine to what extent and how they had used the many features of the website, and therefore, we could better understand the motivations that led them to these features in the first place, as well as the usability issues they encountered in the context of the usage scenarios they had attempted on their own. Many of these spontaneous scenarios were very different from what we had investigated in the laboratory, and they revealed a set of issues with a very different character. Finally, we could identify features of the website that held potential value for them, but that they had not discovered or had explored and not adopted.

We managed the balance of participant freedom and researcher direction through the process of data collection by combining elements of ethnography, contextual inquiry, and highly personalized usability evaluation. We began by exploring the participants' overall experience of house hunting and considering a purchase and a move, as well as the role of the website in the context of that broader experience. We studied their relevant artifacts—the traces left on paper or on their computers of their previous house hunting activities. When we turned to the website, we asked them to pretend that the visit had just happened to coincide with a time that they would have ordinarily done some online real estate shopping or research in whatever way they would typically do it. All the sessions involved some degree of prompting to attempt tasks on the website beyond what they had done on their own initiative. The selection of tasks included a mix of highly personalized ones to probe just beyond what each individual had already attempted, along with ones that pushed them to features we had our own questions about. With people who had less engagement with the website, we naturally used more probing to understand why this was the case and more active prompting to attempt tasks on the website that were relevant to what they were trying to do through other means. For all these "prompted" tasks, the content of the scenarios was improvised based on what we had learned about their own activities and interests.

Regarding the dimension of time, even though our visits were single sessions of 2 hours, we were able to get cross-sectional information and at least some retrospective historical information from them to get at least an indirect longitudinal view. Participants were naturally at different stages of the real estate shopping process (although all of them had at least moved to the point that they had a real estate agent working with them). In addition, their artifacts (e.g., e-mails, bookmarks, older saved searches, etc.) that we examined had often left traces from earlier phases of their shopping experience.

Here are some examples of the types of findings from this study that show the benefits of this approach:

- We identified a high priority group of users who were most likely to value the website but also most likely to have a particular difficulty. A surprising number of our participants were people transferring to the area. They had begun using the website before moving to temporary quarters while they continued their search. Clearly, this was a group for whom being able to begin their search remotely was a particularly compelling reason for using the website. However, for these people, managing the geographic scope of their searches was a particular problem, because of lack of the comprehensive local knowledge that the site assumed.
- Most people had not anticipated that a notification service was available and did not discover it. Once prompted to explore it, they saw its potential value, but then encountered the same usability problems we had seen in the laboratory.
- For those people who had discovered and begun using the saved search and notifications features, there were common problems with having constructed and saved logically overlapping searches, and so they received annoying multiple notifications on the same property, because there was no synchronization among searches.
- In trying to decide whether or not to save a search, people had difficulty determining whether a search that turned up few or no results was a "bad" search that should not be saved. They did not understand that, paradoxically, this was likely to happen when they had added many criteria, thus defining a very rare type of property, which was exactly the situation where saved searches and notifications would potentially be most useful.

- Not surprisingly, many people who were shopping for real estate were also selling their existing homes. Thus they turned to the website for different things, depending on whether they were wearing the hat of seller or buyer at any moment. We identified a number of ways in which usefulness and usability of the website could be improved to help them manage these two roles. As sellers, they were interested in different types of information on sold properties and needed better ways to keep their research activities as sellers and as buyers distinct.
- We identified different problems with the information architecture of search criteria (and the interaction with the underlying structure of the database and inconsistencies in data entry by listing agents) than we had seen in the laboratory, because in the field we were able to focus on issues with the types of criteria that were most important to them. We also were able to map some of these priorities and associated difficulties onto different user segments (stage of life, urban vs. suburban focus, etc.) in a way that would not have been possible with a sample of people who were not currently engaged in shopping.

54.4.3 Tablet PC Field Trial

Before the introduction of Microsoft's Tablet PC in 2002, we did a series of field trials in which groups of participants in several companies replaced their desktop PCs with functional prototypes of the new computer, which they used as their sole workplace computer for several weeks, while we studied the evolution of their experience longitudinally (Dray et al. 2002). The fact that participants needed to perform their real jobs ensured a realistic level of engagement with the device. The fact that they expected to rely on the devices for an extended period gave them a realistic motivation to learn how to use and try to derive value from it.

These studies were complex in many ways, including their logistics, their research agendas, and their data collection protocols. They involved longitudinal tracking of each user's process of discovery, experimentation, and personal experience and assessment of benefit, as they explored the capabilities of the Tablet and the experience of working with applications on this new platform. Investigation of usability was almost inseparable from investigating issues of user motivations, goals, and experienced usefulness or lack of it. The research protocol included a mix of the following:

- Ethnographic components to understand the work context and users' preexisting work practices
- Free observation of use of the prototypes under a wide range of work place situations, such as use at one's desk for a range of tasks and use in meetings
- Probing as users undertook tasks on their own
- A mix of opportunistic and highly personalized usability tasks closely tied to what users were spontaneously attempting on their own and somewhat standardized usability tasks following predetermined scripts
- Retrospective review of user experiences during the periods between visits, based on self report, logs of all service and support contacts, and walkthroughs of work artifacts

The research process involved a dynamic balance of user freedom and researcher direction. We had an extensive program of usability tasks that we administered in a planned sequence, tailored to fit the stages of the usage experience. These tasks varied greatly in amount of predetermined structure. Some of them were fairly standardized across users and were designed to evaluate things that were essential parts of the user experience, so that providing the task was not likely to bias the natural course of the evolving user experience. For example, an essential early activity for all users was learning how to use the stylus both to write on the screen and to activate on-screen controls (icons, menu items, links, etc.). We used standard tasks to test these things across users and repeated them at standard intervals to get a sense of the learning curve.

Other tasks were planned only at a generic level. For example, we knew we wanted to investigate the experience of converting handwriting to text and correcting conversion errors. We knew that handwritten input within dialogues, as opposed to free writing on documents, was a special case of this. The fact that people spontaneously and frequently attempted to do this in the "Save As" dialogue provided an opportunistic instance of this generic category of task. The fact that they did this at their desk and at meetings enabled us to evaluate the experience under different circumstances.

Finally, some tasks were highly opportunistic. Different users were naturally drawn to different Tablet features and to use different applications on the Tablet in different ways, according to their jobs and work practices. Therefore, different people provided different opportunities for evaluation. For example, one participant who was involved in contracting provided many opportunities to explore the use of handwriting to annotate digital documents. Mobility was more important to some participants than others. Specifically, since this study was done at a time when most people used desktop PCs wired to the network, we gained insights into problems they had in trusting that the document they opened on the Tablet during a meeting was the latest version that had been e-mailed to meeting participants. Highly mobile participants provided opportunities to evaluate power management issues. At a more granular level, people used different feature sets within applications, giving us a wide range of evaluation opportunities.

The fact that this was a longitudinal study in which there was very large investment in each participant (both in terms of research time and cost for things like the hand-built prototypes they used) intensified the issues around balancing user freedom with researcher intervention. We wanted to learn as much as possible about the natural and undirected process by which people would explore the capabilities and value of the Tablet. At the same time, we wanted to use the opportunity presented by this research to evaluate the Tablet as thoroughly as reasonably possible. This meant we had to decide what to do with people who would have explored only a very limited range of potential uses, applications, or functionalities left to their own devices. With these people, it was necessary to intervene in their natural process of exploration, discovery, and experimentation by at times prompting them to consider uses they did not think of on their own. To manage the issue of researcher influence, we carefully titrated the amount of prompting we gave them, starting with very open-ended questioning and gradually becoming more leading as needed, finally actually proposing a "usage experiment" the person might do for us.

At times, we used an upcoming business activity that we knew was on their agenda to negotiate usage experiments with them. For example, we knew that some people had spontaneously attempted to use the Tablet (which in this version had a detachable keyboard and so could be used in "slate mode") to hand-write responses to e-mails while on the airplane, something they found unpleasant to do in a cramped coach seat using a conventional laptop. If another participant, one who was not as active in trying out the Tablet for new scenarios, was planning a business trip, we could draw on this knowledge. Since we talked casually with participants about their work all the time, it was natural to discuss the upcoming business trip, to talk about the hassles of business trips in general, and to give the person plenty of opportunity to think of some way in which it might be interesting to try using the Tablet to reduce the hassle. This gave us a chance to find out if the idea of using the Tablet on the airplane even occurred to them. If it did not, we could ask progressively leading questions to see if there was anything that it might be useful to try. Finally, we could suggest a specific experiment, like working on their e-mail on the plane, and even negotiate this with them as an assignment.

As stated earlier in the section on methodological challenges of longitudinal research, to make this approach reasonable, it is very important to treat the amount of prompting needed as a piece of data, something that must be taken into account in interpreting the findings. The fact that prompting was needed does not invalidate the data about the user's eventual experience. After all, once a technology becomes widespread, people are exposed to all kinds of suggestions from other users that might induce them to try things they would not have attempted on their own. But for research purposes, one interesting question might be what types of potentially valuable application scenarios are more and less obvious to users.

As mentioned earlier, it is also important to take into account that people who undertake a task on their own might be different from those who undertake it in response to encouragement from the researcher. For example, in this case, perhaps people who had already experienced much success and benefit from writing by hand and converting to text were more likely to decide on their own to try writing e-mails by hand while on the airplane, converting them to text, and then sending them later when they connect to a network. The researcher needs to know enough about each participant to consider any such differences between people who need more prompting and those who need less and take this into account in the interpretation. Furthermore, in the course of "negotiating" usage experiments with the user, there should be an opportunity to explore their expectations of what the experience will be like and to understand their historical experiences that these may be based on.

54.5 WHERE DOES NATURALISTIC USABILITY FIT INTO THE PRODUCT DEVELOPMENT LIFECYCLE?

From the examples given earlier, it may seem as though naturalistic usability requires a fully functional system and, therefore, is applicable only late in the design and development process. Although naturalistic elements can be introduced into even early, rapid usability studies using low fidelity prototypes, the full benefits do require the possibility of a more complete representation of the usage experience. However, if naturalistic usability studies could only happen at the end of the development process, this would certainly be unfortunate, because the understanding they provide incorporates things that should be introduced into the early stages of product planning.

Part of the solution comes from thinking a bit more broadly about what to test. Naturalistic evaluation of competitive products or an earlier version of your own product can be extremely useful in providing guidance for current development efforts. Admittedly, while this is likely to suggest new design directions, it will not directly test them. Therefore, it does not replace iterative testing using simulations. However, it is quite possible to integrate some aspects of rapid prototyping of new interaction design ideas into the naturalistic evaluation. If, through probing of usability difficulties that arise while the user is performing a natural task, the researcher can develop a hypothesis about design changes that may eliminate or reduce the problem, or knows of an alternative design that is under consideration, it is often possible to do a low fidelity test of those alternatives in the context of the user's actual task.

It is certainly easier to produce a functional prototype of some products than of others. Devices that require manufacturing, firmware, and software are expensive to prototype. A device or system that requires a complex installation for realistic use in homes or work places adds another layer of complexity. With these, creation of a functional prototype for testing may be out of the question. On the other hand, a new website design may be fairly easy to implement in a functional version for limited release to test participants. With some software, it is worthwhile and feasible to evaluate in the field in a scaled-down proof of concept version (Allen, McGrenere, and Purves 2008).

Very few products spring forth with no antecedents. In many cases, there is an earlier version of the product in use, naturalistic evaluation of which should feed planning for subsequent releases. Too often, once a product is released, decisions about major changes come primarily from user complaints and requests rather than from disciplined evaluation in the field. Some products have a naturally limited first release that can present an excellent opportunity for naturalistic testing. We once worked on a browser-based tool for enrollment in an innovative employer-provided health insurance program that allowed personalization of a wider range of factors than was typical in health insurance. The initial rollout of this product involved a very limited number of employers, who held an informational fair for employees at the start of their annual open enrollment period. Carrying out usability research during these fairs with employees allowed evaluation with people who were actually signing their families up for coverage.

Finally, naturalistic usability can also be incorporated into other forms of field research, which do tend to happen early in the product development lifecycle or are construed as providing fundamental insights about users. Actual projects in the field often use hybridized methodologies. There is no inherent reason preventing elements of usability evaluation from being incorporated into contextual inquiry studies or even ethnographies. The obstacles may more often have to do with the fact that detailed evaluation of interaction design may not be the primary mission of these other studies, the need to prioritize how you spend your limited time in the field with participants, who the consumers of the research findings are (e.g., product strategists or designers), and the particular skill set of the researcher.

User-centered design includes a very long list of methods and techniques for introducing knowledge of the user into the product planning and design process, and no one technique is enough to ensure that design is fully user-centered. It is important to consider the complementary strengths and weaknesses of different approaches and to choose them consciously rather than out of habits of practice. To whatever degree you can incorporate it into your research program, naturalistic usability evaluation techniques will help bridge the gap between user research and simulation-based usability evaluation.

55 Survey Design and Implementation in HCI

A. Ant Ozok

CONTENTS

55.1 INTRODUCTION

Survey and questionnaire design has been a primary source of data collection within the Human–Computer Interaction (HCI) context since the early days of the science (Baecker et al. 1995). Within the HCI context, surveys are defined as compilations of questions that are implemented either via a computer or paper-and-pencil-based environment, that either have quantitative or qualitative scales, or are open-ended, and that target at extracting a variety of information from a representative sample of the target population (which is in most cases current or prospective users of an HCI system being evaluated).

Survey use is popular in HCI research as it allows researchers to collect, in a relatively easy manner, information based on users' satisfaction, opinions, ideas, and evaluations regarding a system. Design and implementation of surveys are not as costly as conducting experiments in closed environments with special equipment; advances in computer-based survey products and web-based survey services allow direct recording and easy manipulation of survey data by eliminating the need of translation from paper-based to an electronic environment; and, with each survey taking minutes to complete in most cases, given a large sample of potential participants can be reached, surveys are a good resource for collecting large amounts of data in a relatively short amount of time and with minimal resources, especially when compared to controlled objective experimental measures that involve in most cases lengthy tasks and recording sessions. On the other hand, surveys are constantly challenged in terms of their validity and reliability mostly due to their high reliance on participant opinions and the impossibility to measure with full reliability that the questions are answered by participants objectively. Quantitative survey research is also sometimes criticized due to difficulties related to survey scaling, as scales rely on an assumption that participants have the same or similar perceptions of scale responses that are subjective in structure (responses such as "I strongly agree" or "I often do it").

This chapter discusses the different aspects of survey design and implementation in HCI in a structured and comprehensive manner. After a discussion of the purpose and a brief history of surveys, the different types of surveys (content and structure-wise), application domains, design, and evaluation techniques are discussed with illustrative examples. The chapter is concluded with emerging and future trends in the HCI survey design and implementation areas.

55.1.1 Purpose of Survey Use and Survey Applications in HCI

Usability evaluation has been a primary component of HCI since its inception in the 1960s. User performance and satisfaction have long been tapped as the major components of usability testing and evaluation (Shneiderman 1992; Nielsen 1989). While user-performance measurement relies on objective methods such as software-based time and error measurement, user satisfaction requires more sophisticated tools to be measured objectively. User satisfaction is defined as the level to which a system meets its users' standards and requirements (Hackman and Oldham 1980).

Directly relating to user satisfaction, user preferences, opinions, and evaluations concerning HCI systems are also of strong interest to usability testing and evaluation processes. Since it is not possible to measure all of these usability components through unequivocal measurement methods, explicit tools have been developed to elicit information regarding user satisfaction, preferences, opinions, and evaluations both qualitatively and quantitatively through user surveys. Surveys serve this specific purpose well by posing targeted questions to users for the purposes of HCI design and evaluation.

While surveys can be designed to collect a variety of types of information concerning the target population, relevant to HCI research and literature (Card 1996), they are mostly targeted at collecting information in the following three categories:

1. User Evaluation: The category aims at collecting information regarding how much a system, product, or environment meets user goals, expectations, and standards. In this category, users are asked a number of questions regarding whether their overall impression regarding the object being evaluated is high, what exactly constitutes this impression, what and where exactly the problems are, and so on. Relating to user satisfaction, this category is also about determining user opinions specific to products or systems, where questions can also include users' opinions concerning whether tasks can be completed effectively and efficiently, whether the system is fast, and so forth.
2. User Opinion: The category can, but does not have to, be specific to products, systems, or environments. These types of surveys are aimed at determining what users think about the requirements from a system, product, or environment to fulfill its function satisfactorily. Examples can include surveys that aim at needs assessments for the next generation of cell phones (e.g., what new functionalities can be useful in newer cell phones besides those that already exist according to cell phone customers). Simply put, while the former category consists of surveys regarding the performance of existing systems, environments, and products, the current category is concerned with what users think about what might be useful concerning these systems in more general terms.
3. Others: The third category includes the remaining possible survey types aimed at collecting a number of different information types within the HCI context. One such category consists of surveys that are strictly concentrated on population demographics. These types of surveys do not contain questions relying on participants' evaluation of specific products or their opinions, but rather solely on qualifications they own, such as age, sex, education level, skill level, and so forth, or things they do, such as how frequently they go on the Internet or use a cell phone. These types of survey questions are less based on opinion-heavy responses than the previous two categories.

55.1.2 Brief History of Survey Design in HCI

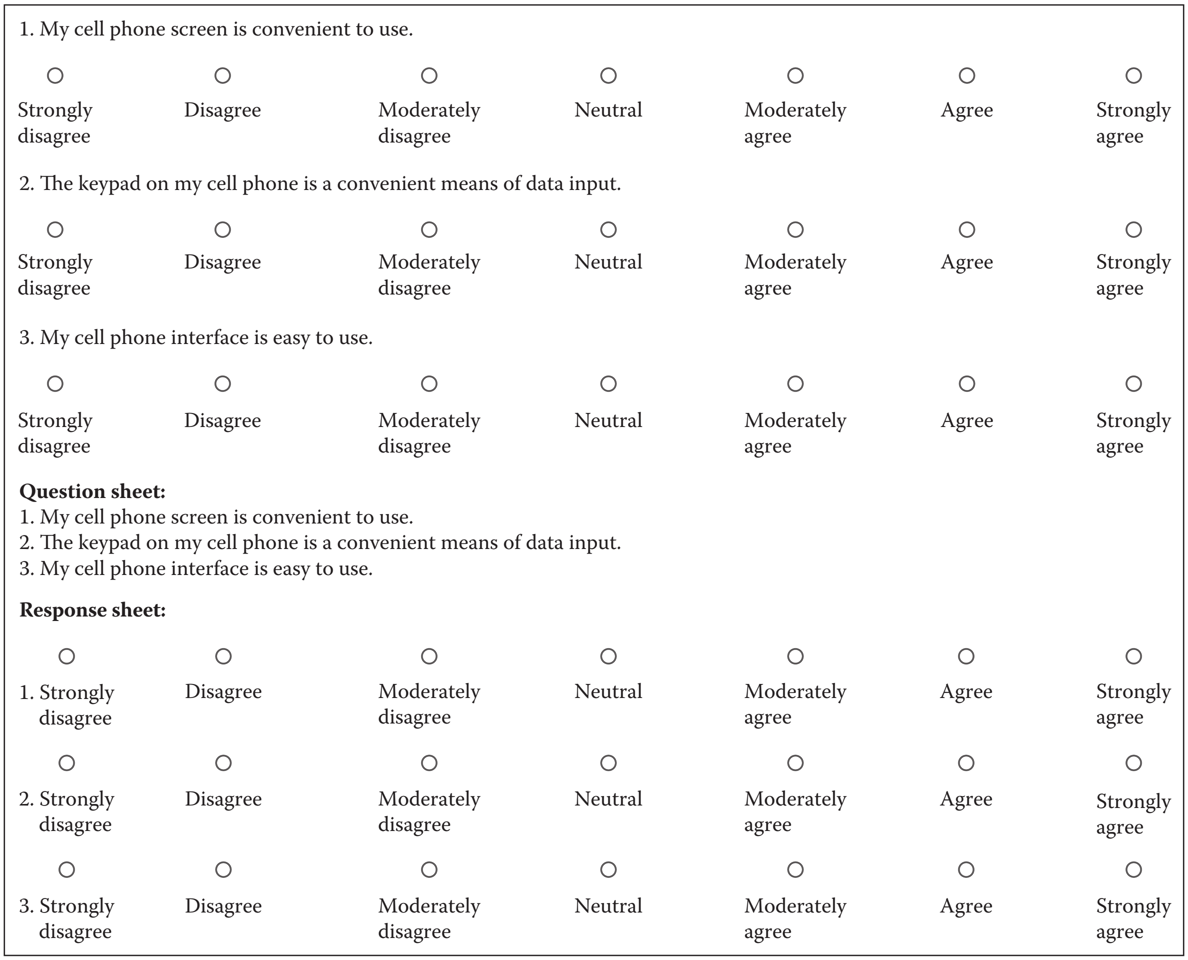
Surveys started being used as a computer science and, to a limited extent, an HCI research tool in early 1970s, borrowing techniques from anthropology and experimental and social psychology (Myers, Hollan, and Cruz 1996). With contributions from developments in the overall survey administration and language issues (Converse and Presser 1986; Belson 1981; Jenkins and Dillman 1997), researchers discovered early on that information regarding user attitudes, preferences, and evaluations within the context of computer technology (software and hardware) development can be collected fairly easily with paper-and-pencil surveys. Hence, in the 1970s and 1980s, user surveys were a part of computer research with a social psychology emphasis, but not directly relating to usability testing and usability-design issues. In the mid-1980s graphical user interfaces became an important part of end user computing and usability research took off. The surveys gained a more significant role in HCI research around the same time, and with the advent of graphical user interfaces, surveys in HCI and specifically usability research gradually gained importance. With the graphical user interfaces as we know today gaining high popularity with Windows 95, usability research accelerated (Myers 1996), and besides building usability laboratories, companies and research institutions started developing and implementing surveys to determine user trends and preferences in HCI. Advanced electronic and paper-and-pencil survey-design methods have been developed in the last decade (Dillman 2000), and user surveys have become an essential part of data collection in HCI research.

55.1.3 Paper-and-Pencil and Electronic Surveys

Survey implementation largely relies on practical factors. Besides the challenge of finding a sample size that is both large enough and representative of the population the study is targeted at, implementation challenges include presenting the participant sample with a survey that is quick and easy to complete, has a fun factor and a learning component for the participants, and does not require tedious data extraction and manipulation once implementation is completed. Additionally, surveys in every topic should be unambiguous, unbiased, correctly coded, piloted, and ethical (Stone 1993). Today's surveys are almost universally implemented in two forms: (1) paper-and pencil surveys, which require participants to mark or write their responses on response sheets that also contain questions, either on the same sheet or separately; and (2) electronic surveys, which require the users to use the screen, keyboard, and/or mouse of a computer to mark or type their responses on the screen.

Paper-and-pencil-based surveys require the survey material to be physically distributed, filled out, and returned. This process can occasionally be cumbersome and tedious. Moreover, these types of surveys also require manual entry of quantitative, and in most cases qualitative, data for analysis. One solution to the problem of translation of paper-based data into electronic format is using Scantron sheets, which are sometimes referred to as "bubble-sheets." In this system, designated areas (bubbles) on printed sheets are filled out by participants with a pencil, and these sheets are then fed into a computer and scanned for correct answers. This process, however, is quite costly due to the scanning equipment necessary for the process. Figure 55.1 shows two sample paper-and-pencil survey sheets, one with response spaces below each question and one with response sheets that are separate from the question sheets.

Although about 62% of all American households own one or more computers (U.S. Census Bureau 2005), computers are still not accessible to the entire population. Therefore, paper-and-pencil surveys are still widely popular. Paper-and-pencil surveys allow swift collection of large data quantities if they are administered to groups of participants simultaneously, such as a group of students during a class period who are asked to fill out and return the surveys immediately. One



1. My cell phone screen is convenient to use.

○	○	○	○	○	○	○
Strongly disagree	Disagree	Moderately disagree	Neutral	Moderately agree	Agree	Strongly agree

2. The keypad on my cell phone is a convenient means of data input.

Strongly disagree	Disagree	Moderately disagree	Neutral	Moderately agree	Agree	Strongly agree

Question sheet:
1. My cell phone screen is convenient to use.
2. The keypad on my cell phone is a convenient means of data input.
3. My cell phone interface is easy to use.

Response sheet:

○	○	○	○	○	○	○
1. Strongly disagree	Disagree	Moderately disagree	Neutral	Moderately agree	Agree	Strongly agree
○	○	○	○	○	○	○
2. Strongly disagree	Disagree	Moderately disagree	Neutral	Moderately agree	Agree	Strongly agree
○	○	○	○	○	○	○
3. Strongly disagree	Disagree	Moderately disagree	Neutral	Moderately agree	Agree	Strongly agree

FIGURE 55.1 Two paper-and-pencil presentations of the same survey, one with the response spaces below each question and one with separate question and response sheets.

other common way of paper-and-pencil-based survey implementation is mailing surveys to participants and asking them to return them via mail, in most cases in postage-prepaid envelopes. However, recent studies indicated that return rates of mailed-in surveys by the participants is highly variable depending on the type of survey (Dillman 1991, 2000). Taking into consideration the percentage rate of computer ownership among American households, mailed-in surveys can be concluded as a less-preferred means of data collection specifically within the context of the HCI research, and mail surveys are therefore not popularly used for HCI research purposes.

Computer-based surveys (sometimes referred to as PC-based surveys) have become popular with the advent of home computers in the 1990s, even before the high adoption of the World Wide Web. In computer-based surveys, participants are presented the survey on a specific, standalone (nonnetworked) computer. It should be noted that these types of surveys are not web-based, but rely on the software installed on the computer on which the survey is implemented.

Participants use the mouse to click on their responses of choice for multiple-choice questions. Mouse actions are generally implemented on dropdown combo boxes (where a dropdown menu opens up with the options when the user clicks on the button located to the right side of it) or radio buttons (a round area to the left of the option is clickable), or check boxes where multiple choices can be clicked on one at a time (a square-shaped box to the left of the option is clickable) (Ozok and Salvendy 2000). For text entries, participants can type text on specified text boxes. While computer-based surveys can be convenient because of having the initial data in electronic format and eliminating the necessary transformation to electronic format in paper-and-pencil-based surveys, they require the participants to be stationary on a specific computer. For large-size implementations, computer-based surveys can be extremely slow in collecting the data, mainly due to limited computer equipment and scheduling difficulties. It can be concluded that while computer-based surveys can be advantageous in the data-analysis stage and are still popular in kiosks stationed in public places such as shopping malls, they are not suitable for large-sample size and lengthy surveys, and hence are not the best solution in survey-based data collection in on HCI context.

With the advent of the Internet, web-based (online) surveys have become highly popular (Dillman 1999) and allow researchers to conduct surveys more effectively and efficiently than more traditional means (Zhang 2000). Server-based software allows survey participants to access a web page and fill out the survey, then submit their results mostly to a central server by clicking an on-screen button. Web-based survey interfaces in structure look very similar to computer-based surveys with the same interface elements of dropdown combo boxes, radio buttons, check boxes, and text boxes serving the functions of various data-entry types by the participants. The data are collected on a central web server in these types of surveys, which can be easily obtained and manipulated by the survey administrators. Additional data storage and analysis programs residing on these web servers can compile the data in a variety of formats such as Microsoft Excel, and also implement some automatic data analyses such as calculation of means and standard deviations (descriptive statistics).

One additional electronic survey type consists of the administration of e-mail surveys in which participants are e-mailed a survey and are asked to fill it out and e-mail it back. However, with the dramatic increase in the amount of spam e-mail users receive in recent years, it can be concluded that these kinds of e-mails are likely to be perceived as spam and are likely to be discarded. Therefore, e-mail surveys are not articulately covered in this chapter.

There are two types of methods used in web-based survey administration today. One method is to use a web survey administration service provider (such as SurveyMonkey.com) by paying it a monthly or yearly fee. In most cases, various packages are available ranging from a small number of surveys to unlimited administration of surveys. The web service providers also have a variety of options for the retrieval of survey data by the administrators, for example, in Access or Excel formats, with some, in most cases basic, statistical analyses (such as descriptive statistics and correlations) already performed on the data. Additionally, the services also give flexibility in customization of survey interfaces such as giving the freedom to the administrators (and in some rare cases to the participants) to choose their text and background colors, font sizes and types, how many questions to have per web page, and so on. Today, there are more than a hundred online survey-service providers with monthly fees varying from $3 for small-scale academic surveys to $500 for large-scale, mostly marketing-related surveys.

Another means of administering online surveys is to use one's own hardware and software. As a central server is necessary for collection and storage of the data, this hardware can either be purchased or rented, or an existing server can be used. The amount of storage space necessary largely depends on the length and sample size of the survey, but since most surveys contain textual data, it is almost unimaginable to need more than five gigabytes of storage space for a large-size survey for purposes of HCI research. A variety of open source (such as php ESP [Easy Survey Package]) and licensed software vendors (such as Inquisite) are available for survey implementation and administration on administrator-owned servers. Like survey-service providers, these software packages also allow a variety of customization flexibilities concerning the survey interfaces. Figure 55.2 presents a sample interface from an online survey.

For both paper-and-pencil-based and electronic surveys, human cognitive limitations should be taken into consideration and basic human factors guidelines should apply. Paper-and-pencil surveys should be administered with pencil to allow participants to go back and change their responses if they want to. White paper with black, 12–14-point-sized Times New Roman font text should be used, as those font sizes are the most common and easily readable text sizes in printed documents. Labels should be presented with bold,

THE INTERFACE LANGUAGE CONSISTENCY TESTING QUESTIONNAIRE (ILCTQ)

- Please evaluate each question on whether it is applicable to the interface by clicking to the left of "Yes" or "No". If it is not applicable, please proceed to the next question. If it is applicable, please proceed to answer the following items:
- Please rate how important the question is to the interface being evaluated.
- Please rate the interface to be evaluated on how much you agree with the statement in the question, or choose "not available" if the item is not available in the interface being evaluated.

a. Consistency of the Language with the Current Knowledge of the Average User

1. Are the words well-known?

Applicable? Importance? Agreement with Statement
The higher the number, the greater the importance
Yes ○ No ○ 1 ○ 2 ○ 3 ○ Not Available ○ 1 ○ Strongly Disagree 2 ○ Disagree 3 ○ Slightly Disagree 4 ○ Neutral 5 ○ Slightly Agree 6 ○ Agree 7 ○ Strongly Agree

2. Are the words used common words in English?

Applicable? Importance? Agreement with Statement
The higher the number, the greater the importance
Yes ○ No ○ 1 ○ 2 ○ 3 ○ Not Available ○ 1 ○ Strongly Disagree 2 ○ Disagree 3 ○ Slightly Disagree 4 ○ Neutral 5 ○ Slightly Agree 6 ○ Agree 7 ○ Strongly Agree

3. Are the words in the sentence in correct order?

Applicable? Importance? Agreement with Statement
The higher the number, the greater the importance
Yes No 1 2 3 1 2 3 4 5 6 7

FIGURE 55.2 Sample interface from an online survey.

16–18-point-size text, and while pictures are seldom presented to participants, if they are presented, they should have enough resolution to appear clearly on paper. In short, paper-and-pencil-based survey interfaces should be inspected to make sure they comply with the structural human-factors guidelines for paper-based interfaces.

Similarly, electronically administered surveys (web- or PC-based) also should follow basic human-factors guidelines for computer interfaces. For web-based surveys, it should be noted that participants will access the surveys from a variety of different types of machines, and basic computer and web design guidelines indicate 800 × 600 color screen resolution is the most common screen type (Nielsen 1993; Badre 2002) which should be taken into consideration when survey interfaces are designed, making sure that survey objects, mainly text fonts and some images if there are any, are easily visible on screens with this resolution. The basic rule of black text on white background in web usability should also be applied in computer- and web-based interfaces, and screen objects such as dropdown combo boxes, radio buttons, buttons, and check boxes should be the same size (mainly height) as text lines to ensure consistency and easy visibility and to allow users to click on them easily. Text boxes for the users to type in should allow text size consistent with the text on the question parts of the interface. Overall, again, it can be said that in web-based surveys, basic web-design guidelines can easily be adopted.

Additionally, one important item in survey design is to prevent survey participants from getting worried about the excessive length of the surveys, as too-long surveys may result in significantly decreased response rates (Lund and Gram 1998; Krosnick 1999). Taking also into consideration the fact that computer users don't enjoy scrolling down the screen in general (Shneiderman 1992), no more than 20 questions should be presented on one survey screen. For surveys containing more than 20 questions, subsequent questions should be presented on subsequent screens (again, each screen not exceeding 20 questions), which participants should move to by clicking on a screen link or button that should have a statement such as "Click here to continue."

Both paper-and-pencil-based and electronic surveys will continue to be used in HCI research. While it is unlikely that the former will go extinct any time soon, recent studies (such as Dillman 2000) showed that web-based surveys have very significant advantages in data collection and analysis stages of survey-based research. The fact that most HCI-related survey research uses computer-savvy sample participant groups is also a factor that helps the popularity of web-based surveys within HCI. It is therefore expected that web surveys will eventually constitute a large majority of survey-based research in HCI. While no previous study explicitly investigated the exact share percentage of paper-and-pencil-based and electronic surveys in HCI research, it is estimated that more than 60% of all surveys for HCI research are implemented on the web environment.

While the discussion in this chapter mostly concentrates on structural issues of paper-and-pencil-based and electronic survey design, a much larger research topic concentrates on how the actual survey content should be designed, created, and implemented. The next chapter discusses content creation in surveys within the context of HCI research.

55.2 SURVEY DESIGN IN HCI

A major part of survey-design research in HCI is concerned with the formulation of survey questions and scales. In comprehensive user surveys, questions may be presented as one large, continuous list. Related questions may also be presented in categories and sections, such as the demographic questions in the first section, questions evaluating the structural elements of the interface in the second section, and so on. As discussed earlier, surveys in HCI research are mostly concentrated on collecting two categories of information: participants' opinions and evaluations. These two survey types are discussed in the next section. This discussion is followed by an explanation of survey application domains and the survey design methodology.

55.2.1 Survey Types

55.2.1.1 Opinion Surveys

Opinion surveys aim at determining what participants think about issues pertaining to certain concepts. Additionally, opinion surveys can also measure participants' wishes, habits, and customs (Baker 1998). The way opinion surveys differ from evaluation surveys is that opinion surveys are not centered on a specific product or environment, but are more general in nature. For example, an opinion survey can target measuring cell phone users' habits and opinions regarding the use of the cell phone interface (whether they are happy with the screen size, whether they can easily enter data using the keypad, etc.). While questions are focused on a product in this example (e.g., a cell phone) the population of cell phone users is highly diverse, as are cell phone devices that are used by the population. Hence, such an opinion survey will measure general trends in usability concerning cell phone interfaces rather than evaluating a specific cell phone interface.

Opinion surveys are administered with more freedom than evaluation surveys, as the participants do not have to have the evaluated issue, product, or environment fresh in their memory. Hence, they can fill out opinion surveys at any time and in any environment that is convenient for them. Opinion surveys include questions that do not require any recalling process, meaning they contain questions which participants can answer without having to recall a specific feature or part of the environment, product, or issue. As opinion surveys ask general questions about participants' current standing regarding opinions, wishes, customs, and habits, the answers may sound subjective and vary greatly among participants. Sample questions for opinion surveys include statements such as "Does the use of computers in daily tasks contribute to your overall technology knowledge?" or "Are you in general satisfied with the amount of product information available on an e-commerce page you frequently visit?" or "How would you rate the customer services on the sites where you frequently shop?"

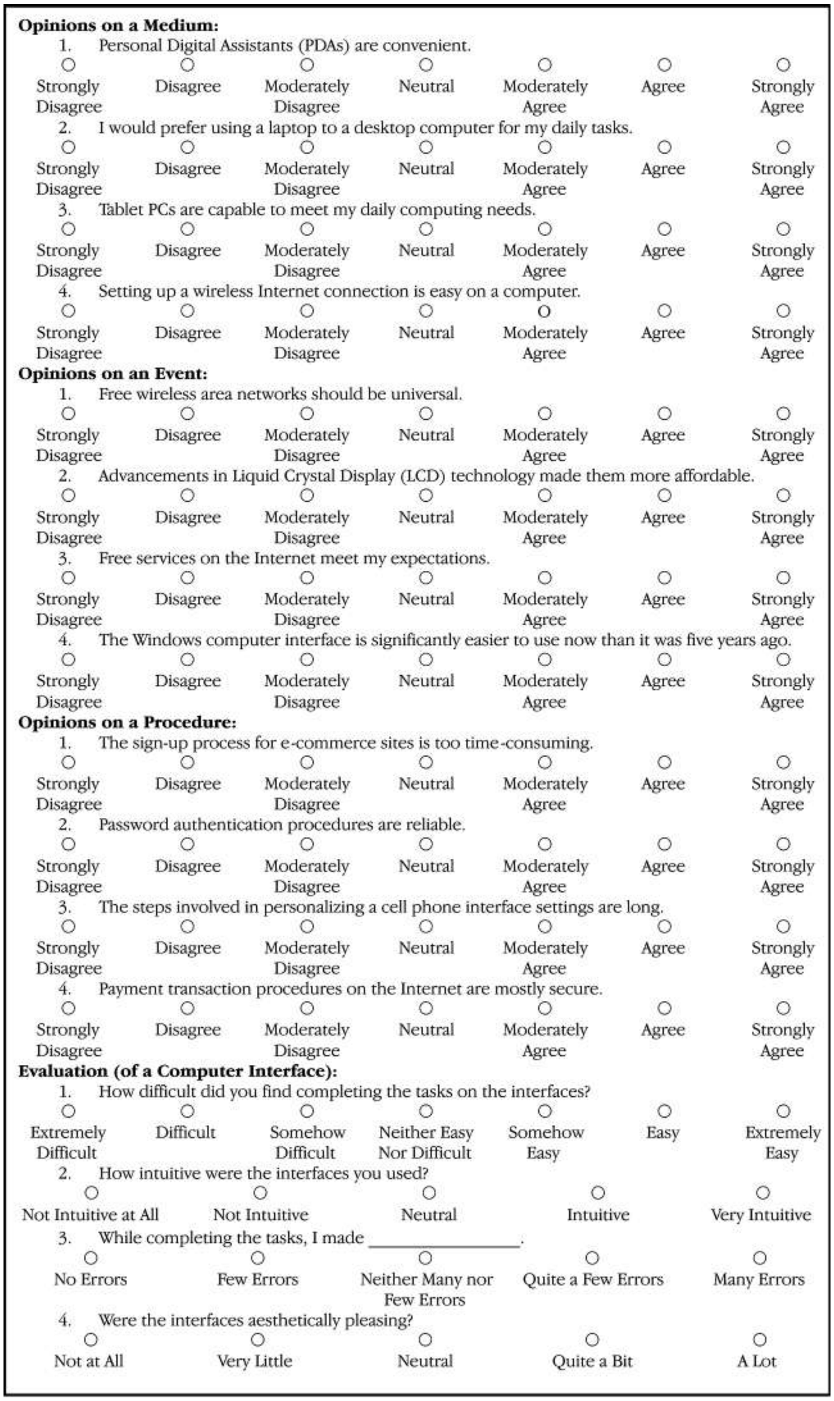
Opinion surveys can cover a broader variety of issues than evaluation surveys, which are more focused. They can include both qualitative and quantitative scales for their responses. Although no previous literature came up with a strict classification of opinion surveys, the following classification can help in structuring of opinion surveys and what kind of questions should be asked for what types of opinion-related survey categories in HCI research (sample questions for each classification of opinions are presented on Figure 55.3):

a. Opinions on a medium: Within the context of HCI research, these types of surveys concentrate in most cases on interface design, usability, user satisfaction, and user preferences issues concerning a medium the participants use in their daily lives. Most popular examples of this type of media include daily-used devices such as computers, Personal Digital Assistants (PDAs), and cell phones. These types of surveys concerning users' opinions on a certain medium aim at determining general trends in user opinions concerning whether the design of the medium is satisfactory and meets user needs and requirements, whether there are problems concerning the medium, and what can be possible solutions. Opinion surveys concerning a medium are also useful when they are used by usability specialists and engineers to develop new versions of products or to come up with new products, as the survey results can pinpoint the needs of the target population to be met regarding the medium. Sample questions for these types of surveys can include questions like, "Are you in general satisfied with the web browsing capabilities of your cell phone?" or "What additional capabilities would you like to see on your PDA user interface?"
b. Opinions on an event: Within the context of HCI research, user opinions on an HCI-related event can include what they think about certain HCI-related happenings. Examples can include opinions concerning certain HCI-related activities, with questions like, "Do you find the move from a text-based interface to a graphical user interface helpful?" These types of surveys are rarer in nature and aim at collecting basic trends concerning user opinions in current HCI-related activities.
c. Opinions on a procedure: These kinds of surveys aim at determining the user opinions on procedures to complete HCI-related tasks. They are similar to medium-related opinion surveys, but rather than questions about the medium itself, these surveys have the goal of determining user opinions on how it is used. In web and e-commerce design, these kinds of opinion surveys are helpful in determining whether the procedures to complete general tasks (for example, web navigation) meet user requirements and needs. A sample question in an opinion survey concerning a procedure could be, "Are you satisfied with how long it generally takes to purchase a product on an e-commerce site?" Surveys to explore opinions on a procedure are less common as HCI researchers usually resort to evaluation surveys to test procedures for use of computer interfaces and other media (explained in the next section).

55.2.1.2 Evaluation Surveys

More specific than opinion surveys, evaluation surveys (or questionnaires) are generally administered after a certain procedure is implemented on the participant group. While opinion surveys can be administered at any time to the participants, evaluation surveys are administered right after the participants have completed a certain procedure. In evaluation surveys, participants are asked about tasks they have just recently completed. Therefore, evaluation surveys are in most cases preceded by certain usability-related experimental procedures. Most common in HCI, evaluation surveys are administered after participants have completed a number of tasks in controlled computer environments. They are also implemented right after the procedure to ensure that memories regarding the procedure are still fresh in the participants' minds, as evaluation surveys require a high amount of recall of procedures and interfaces in the tasks that were just previously completed.

HCI-related evaluation surveys have the main goal of evaluating usability, user satisfaction and user preference issues concerning user interfaces or environments (Ozok and



Opinions on a Medium:

1. Personal Digital Assistants (PDAs) are convenient.
   ○ Strongly Disagree ○ Disagree ○ Moderately Disagree ○ Neutral ○ Moderately Agree ○ Agree ○ Strongly Agree
2. I would prefer using a laptop to a desktop computer for my daily tasks.
   ○ Strongly Disagree ○ Disagree ○ Moderately Disagree ○ Neutral ○ Moderately Agree ○ Agree ○ Strongly Agree
3. Tablet PCs are capable to meet my daily computing needs.
   ○ Strongly Disagree ○ Disagree ○ Moderately Disagree ○ Neutral ○ Moderately Agree ○ Agree ○ Strongly Agree
4. Setting up a wireless Internet connection is easy on a computer.
   ○ Strongly Disagree ○ Disagree ○ Moderately Disagree ○ Neutral ○ Moderately Agree ○ Agree ○ Strongly Agree

Opinions on an Event:

1. Free wireless area networks should be universal.
   ○ Strongly Disagree ○ Disagree ○ Moderately Disagree ○ Neutral ○ Moderately Agree ○ Agree ○ Strongly Agree
2. Advancements in Liquid Crystal Display (LCD) technology made them more affordable.
   ○ Strongly Disagree ○ Disagree ○ Moderately Disagree ○ Neutral ○ Moderately Agree ○ Agree ○ Strongly Agree
3. Free services on the Internet meet my expectations.
   ○ Strongly Disagree ○ Disagree ○ Moderately Disagree ○ Neutral ○ Moderately Agree ○ Agree ○ Strongly Agree
4. The Windows computer interface is significantly easier to use now than it was five years ago.
   ○ Strongly Disagree ○ Disagree ○ Moderately Disagree ○ Neutral ○ Moderately Agree ○ Agree ○ Strongly Agree

Opinions on a Procedure:

1. The sign-up process for e-commerce sites is too time-consuming.
   ○ Strongly Disagree ○ Disagree ○ Moderately Disagree ○ Neutral ○ Moderately Agree ○ Agree ○ Strongly Agree
2. Password authentication procedures are reliable.
   ○ Strongly Disagree ○ Disagree ○ Moderately Disagree ○ Neutral ○ Moderately Agree ○ Agree ○ Strongly Agree
3. The steps involved in personalizing a cell phone interface settings are long.
   ○ Strongly Disagree ○ Disagree ○ Moderately Disagree ○ Neutral ○ Moderately Agree ○ Agree ○ Strongly Agree
4. Payment transaction procedures on the Internet are mostly secure.
   ○ Strongly Disagree ○ Disagree ○ Moderately Disagree ○ Neutral ○ Moderately Agree ○ Agree ○ Strongly Agree

Evaluation (of a Computer Interface):

1. How difficult did you find completing the tasks on the interfaces?
   ○ Extremely Difficult ○ Difficult ○ Somehow Difficult ○ Neither Easy Nor Difficult ○ Somehow Easy ○ Easy ○ Extremely Easy
2. How intuitive were the interfaces you used?
   ○ Not Intuitive at All ○ Not Intuitive ○ Neutral ○ Intuitive ○ Very Intuitive
3. While completing the tasks, I made _______________.
   ○ No Errors ○ Few Errors ○ Neither Many nor Few Errors ○ Quite a Few Errors ○ Many Errors
4. Were the interfaces aesthetically pleasing?
   ○ Not at All ○ Very Little ○ Neutral ○ Quite a Bit ○ A Lot

FIGURE 55.3 Opinion and evaluation survey sample questions.

Salvendy 2001). After certain tasks are completed in these controlled environments, evaluation surveys aim at determining the exact nature and location of problems and points open to improvement in the human–computer environments. Therefore, evaluation surveys are in most cases relatively detailed in nature. In a sample procedure, for example, participants can be presented a number of web pages and asked to complete some common user tasks on those pages, tasks that can include text entry, direct manipulation, and form filling. An evaluation survey that would follow could include questions such as "Was the site navigation difficult?", "Was the text size on the site readable?", "Did you enjoy the overall experience on this site?", "Would you visit this site again?", and so on.

As their name indicates, evaluation surveys aim at evaluating interfaces, environments, and procedures from the user's perspective. For that purpose, they are tools to determine how participants evaluated those interfaces, environments, and procedures. In that sense, evaluation surveys are explicit and not that much different from objective measurement methods such as performance measurement in HCI tasks. Similar to opinion surveys, evaluation surveys use both qualitative and quantitative scales.

Evaluation surveys are not only helpful in evaluation of product interfaces, environments, and procedures. They can also be used in evaluating certain conceptual features. For example, a researcher may be investigating whether the introduction of a certain interface concept results in higher user satisfaction regarding the interface. If this particular feature is, say, that of interface visibility, the survey administrator can first present the participants with high-visibility and low-visibility computer interfaces, and the subsequent evaluation survey can contain questions such as: “Did higher visibility improve your overall satisfaction with the computer screens?”

Evaluation surveys are useful in a variety of HCI-related commercial and academic research activities. In academic research, different computer or computer-related interfaces can be evaluated through surveys to determine whether they result in better user preferences or higher user satisfaction. In commercial research, newly developed products (for example, a new computer peripheral), environments (for example, a new computer interface), or procedures (for example, the steps it takes to complete a transaction with a new e-commerce site design) can be empirically evaluated by having participants complete tasks with those products and procedures or in those environments, then filling out evaluation surveys consisting of detailed questions regarding their satisfaction and preferences regarding the said product, environment, or procedure. While quantitative evaluation results can give statistical backing to user evaluations, helping boost their conclusiveness, qualitative evaluation results can give the researchers who administered the surveys new ideas to improve usability/user-preferences-related design components. Therefore, evaluation surveys are the most commonly used survey types in HCI research and constitute one of the most common and effective user evaluation methods in HCI in general. Examples of opinion survey questions are also presented in Figure 55.3.

55.2.1.3 Other Survey Types

Besides the two main survey types mentioned earlier, one widely used survey type is the demographic survey. Although demographic surveys are almost universal, it would be incorrect to categorize them at the same level as opinion and evaluation surveys, as most user surveys have a section concerning user demographics. Hence, in most cases demographic surveys are essential parts of opinion and evaluation surveys rather than stand-alone surveys. In some cases HCI researchers administer surveys consisting of demographic questions only—for example, to determine the demographics of a user group using a specific application. However, more commonly, HCI surveys consist of opinion and/or evaluation questions in addition to the demographic questions.

Demographic questions play an important part in HCI-related survey design, as most variables of interest in HCI research are also dependent on the factors that are specific to the target population. Consequently, research findings can only be generalized in most cases to the target population from which a representative survey is sampled.

Demographic surveys (or survey sections) in most cases consist of a standard set of categories: age, sex, education, and occupation of the participant. Age can also be asked in the form of “birth year,” and for the question regarding sex, options in the form of “Male/Female” can be presented to participants to mark on the computer or with the pen/pencil. Education level can be left to type in or write, or options can be presented. The question is usually formulated as: “What is the highest degree for which you won a diploma?” or “What is the highest degree you earned?” Typical options for this question are “Elementary school,” “Middle school,” “High school,” “College or university,” “Graduate degree,” and “Post-doctoral graduate degree.” The occupation question is about what kind of job the participant has. For this question, usually the participants are asked to type or write in the designated area, due to the high variety of possible occupations participants may have, although presenting options for this question is also possible if some general occupation categories are all that is needed, for example, options such as “Private sector,” “Academia,” “Student,” and so on.

In addition to this basic set of survey questions, demographic surveys can also include general questions regarding daily habits or current standing issues concerning the participants. Most commonly, demographic surveys in the HCI area contain questions regarding computer use habits of participants, such as “How many times a day do you check your e-mail?” or “How many times in the last year did you shop from a web-based e-commerce company?” These types of questions are usually customized according to the type of information needed for the specific research being conducted and can therefore greatly vary in nature, but in principle they aim at collecting information on computing-related habits in most cases. Table 55.1 presents a set of sample demographic questions as part of a survey regarding cell phone use.

It should be noted that demographic questions are of a more personal nature than opinion and evaluation questions. Some participants may feel that their privacy rights are being violated by being asked to provide their age and education level. For this reason, providing anonymity in surveys and informing the participants about their provided information being not personally identifiable—in other words, providing anonymity—is greatly crucial in HCI research. Knowing that their data cannot personally identify them usually takes care of privacy worries and is known to improve participant enthusiasm. Challenges concerning privacy in survey implementation are described later in this chapter.

There are no other significant survey types widely used in HCI research. Some niche survey types may still exist but are

TABLE 55.1
Sample Demographic Questions from a Survey on Cell Phone Use

Your Age:
Your Gender:
Your Occupation:
How many times a week do you go on the web?:
_____ Less than once a week
_____ Between once and three times
_____ Between three times a week and every day
_____ Every day

In the past year, how many times did you shop online (Please put a number)?: ____

Do you own a cell phone, a Personal Digital Assistant, or a Combination Device?
_____ Yes
_____ No

In the past one year, how many times did you shop online using a cell phone, a Personal Digital Assistant, or a Combination Device (Please put a number)?: _____

few and far between. Therefore, surveys aimed at collecting information relevant to HCI research usually belong to one of the categories explained in this section. In the next section, application domains of surveys relating to HCI research are discussed.

55.2.2 Survey Application Domains

Survey applications are highly popular in a broad range of application domains, in areas ranging from social sciences to marketing, education to production, customer to worker satisfaction, and many more. Today, results obtained from surveys, which in most cases ask comprehensive questions, are deemed reliable and valid in both scientific and industrial projects. The most common application domains of survey research include the following:

- Sales and Marketing: Companies that offer products and services for both consumers and industries use customer/client surveys for both needs-assessment and evaluation purposes. A large number of companies are also solely dedicated to implement customer surveys for companies, analyze the data, and deduct conclusions for sales and marketing purposes. Customer satisfaction, product evaluation, customer relationship management, and customer demographics are only a few of the topics surveyed by sales and marketing forces.
- Medicine: Medical research is not limited to trials relying on objective measurements. Surveys can be helpful in collecting patient data for development of medicine or treatments.
- Education: Educational surveys can help determine population preferences in education as well as education levels and education-related difficulties among population segments.
- Information Technology Research: In the field of information technology, surveys are widely used in connection to software and hardware design and evaluation, covering a broad variety of areas including software engineering, systems analysis and design, and of course HCI, which this chapter covers.

The earlier-mentioned relevant list covering the application domains of surveys is far from complete, but a sample of application domains are presented in the list. The list will no doubt continue growing with the advent of new technologies and sciences. The HCI area is seen as a major application domain of surveys, and is expected to continue to be so.

55.2.3 Survey Design Methodology

Survey design is a methodological activity that requires a systematic design procedure. Survey design techniques and procedures are discussed in this section, including content design and scale design, followed by survey design and redesign issues, a survey design example, and a discussion of challenges in survey design.

55.2.3.1 Survey Design Techniques

Survey design mainly consists of two components: the design of the survey content and the survey scale. They are both discussed in this section.

55.2.3.1.1 Content Design

In the heart of the survey research lays the issue of producing the actual questions to ask the participants. Designing the survey content is actually producing these questions along with their scales. Deciding on which questions to ask the participants in the survey largely depends on three resources: literature, expert opinions, and individual experiences.

A large number of survey questions are based on previous research in the focus area. Relying to some extent on previous literature allows the researchers to achieve high validity of their survey structure, as previously validated research allows current survey design to have strong backing in terms of its content and the targeting of the questions concerning the particular research topic. Therefore, it is best to have backing from previous studies at least for the majority of the questions while designing the survey.

While a designed survey's content may consist largely of questions that are based on the relevant literature in the area, there will be most likely some issues that are intended to be included in the survey but are not covered in the previous literature. Therefore, HCI researchers sometimes rely on experts in the area to cover additional points to be included in the survey. A preliminary survey may be sent in this context to the area specialists to determine the most significant items to be covered in the investigated area. For example, if a survey research is trying to determine the most significant interface design items in e-commerce that affect buying behavior, a preliminary survey may be sent to experts in the area (for example, e-commerce company managers and professors in business schools specializing in e-commerce) to determine the general classifications of interface issues relating to the buying decision. In addition to the literature, these responses from experts can be used as a major resource of question generation for the resulting survey.

Researchers can also rely on their own heuristics and expertise in producing questions. To prevent being accused of "making up the questions," the researchers would need to explain logically why the questions were included in the survey. In these cases, researchers can include questions based on what they think is a significant part of the research item being investigated, or based on the impression that, although the literature did not explicitly point out the issues in these types of questions, there was an implicit indication in previous research towards this particular direction.

Design of survey content is not a difficult task once the researcher has a reasonable background in the area of interest. One common mistake done in design of survey content is the researchers missing important questions during the design and ultimately not addressing those questions. Therefore, cautious, repeated reviews and revisions are necessary before the final implementation of the survey.

55.2.3.1.2 Scales and Open-Ended Questions

Just as important as the content of the questions, the scales for the survey questions in HCI are essential for the accuracy and validity of survey results. Scales are created to attribute numerical values to participant responses in the survey, thereby allowing statistical analyses and giving statistical backing to conclusions obtained from the research. To respond to a scaled question, the participant marks one of the several options, the option which best represents his or her opinion regarding the item in the question. If the question has a large variety of possible answers, or if it requires a lengthy answer, then an open-ended response style may be preferred rather than presenting a scale to the participant. For open-ended responses, participants are mostly given the freedom to write or type as much as they would like.

Both scaled and open-ended questions are suitable for different question types and types of information being obtained from the participants in the survey. Quantitative studies have to use numerical scales to statistically test their hypotheses and support their findings. Qualitative research, on the other hand, analyzes survey data without the involvement of numbers. Because participants have a much higher degree of freedom when responding to open-ended questions, qualitative responses are not restricted to the defined response universe determined by survey designers (also referred to as "survey authors"). On the other hand, conclusions derived from qualitative responses may be more arguable because they cannot be tested statistically.

One more type of response in HCI surveys includes participants being given the freedom to mark more than one response choice. While these types of responses are generally not assigned numerical scales, these types of responses are presented in demographic surveys. In these types of questions with possible multiple responses and in open-ended questions, it is useful to present the option of "Other (please specify):" to the participants, as there is always a possibility that the survey designers may not present the option which the participant would like to give as a response. A sample question of this sort could be "Where do you generally access the Internet?" with the possible responses "Home," "Work," "School," "Coffee Shop," "Internet Café," and "Other (please specify)."

It should be noted that one alternative to open-ended survey questions are interviews and focus groups, and these more interactive data-gathering techniques are likely to result in the collection of richer data than open-ended survey questions as they allow real-time interactions between the researchers and participants. Therefore, it is not highly common in HCI research to use surveys with open-ended questions only. In most cases, especially in quantitative survey research, a mix of both open-ended and scaled questions often proves to provide the best empirical results. Due to their higher frequency of use, this book chapter is more focused on the design and implementation of scaled surveys rather than surveys with open-ended questions. As part of this direction, scale design is discussed in the next section.

55.2.3.1.3 Scale Design

While a large variety of scaling techniques are available for surveys in sociology and psychology research, HCI surveys mostly rely on Likert scales (Medsker and Campion 1997). While contrast scales consisting of yes-or-no questions with 1/0 corresponding scales are also used, five- and seven-point Likert scales are highly common (Aiken and Lewis 1996). In most cases, a scale needs to consist of an odd-number of options. This way, the option in the middle can correspond to a "no preference" or neutral" opinion (Dillman 2000). Each response on the scale is attributed a number to allow the researchers to conduct statistical analysis on the collected data. Item scales need to be kept consistent during the data analysis phase, meaning items should be lined up in the same direction, whether they are positive or negative—in most cases positive responses scoring high and negative responses scoring low on the scales. Inverted questions (questions that ask items in the opposite direction, as discussed later in this chapter) should have their scales reversed in order to keep consistency and allow correct data analysis. A large amount of data analysis mistakes in surveys usually happen because of scaling problems. For example, if the researchers forget to invert scales of reverse questions, then correlations and differences between responses will not come out correctly, resulting in lack of validity of research conclusions.

Scales can indicate a number of different issues. Some scales are concerned with user opinions while others are concerned about frequencies. Most common scale types include agreement measurement ranging between "Strongly agree" and “Strongly disagree”; frequency measurement ranging between “Not at all” and “Very often”; quality opinions ranging between “Very good” and “Very poor”; opinions regarding probability ranging between “Very unlikely” and “Very likely”; and so on. It should be noted that survey scales offer a certain amount of freedom to survey designers on how to name the possible response options for their questions, and therefore scales come in many different varieties, from those measuring amounts (a lot, quite a bit, etc.) to frequencies (very often, often, etc.) to yes-or-no scales. Normally, in most cases a “Not Applicable” or “Not Available” option needs to be added to the scale. When this option is marked, this particular question of this particular subject is eliminated from the analysis. Note that this is different from giving a score of zero to that question in the analysis. Table 55.2 presents a sample of possible response scale sets along with possible number correspondences to the responses.

55.2.3.2 Survey Evaluation Techniques

After the initial design of the survey questions, scales, and instructions to the survey participants on how to fill the surveys out, surveys need to be evaluated to determine whether they are measuring what the designers intended them to measure, whether they are reliable, and whether they produce valid results. Pilot testing is one common method to preliminarily address these issues. However, full evaluation of a survey can mostly happen only after substantial data have been collected with the survey as a tool. Therefore, the evaluation of a survey is conducted based on the data collected by it, and the two components of survey evaluation are the measurement of the survey’s validity and reliability.

TABLE 55.2
Possible Survey Responses and Their Numerical Equivalences

Strongly Disagree	1	***Never***	1
Disagree	2	***Very Seldom***	2
Moderately Disagree	3	***Seldom***	3
Neutral	4	***Neither Seldom Nor Often***	4
Moderately Agree	5	***Somewhat Often***	5
Agree	6	***Often***	6
Strongly Agree	7	***Very Often***	7
Excellent	5	*None*	0
Good	4	*Very Few*	1
Fair	3	*Few*	2
Poor	2	*A Fair Amount*	3
Very Poor	1	*Quite a Bit*	4
Not Applicable	—	*A Lot*	5

Inconvenient	3	***Not Difficult***	3
Neutral	4	***Easy***	4
Somewhat Convenient	5	***Very Easy***	5
Convenient	6	*Yes*	1
Highly Convenient	7	*No*	0

55.2.3.2.1 Survey Validity and Validity Determination

While the reliability of a survey is determined after the survey data have been collected, the validity of the survey has to be determined prior to the implementation. As the name implies, validity of a survey is the degree with which the survey instrument is valid in the results it produces or, in other words, whether the survey is measuring what it says it is measuring (Litwin 1995). Generally, within the context of HCI, validity is covered twofold: *construct validity* indicates the degree of how much the survey is backed by previous research in its field, how solid its construct is. In general, as in every research, development of a survey needs to rely on previous research to give the tool literature backing, proving that the survey didn’t come out of the imagination of the designer, but rather relies on a number of different research studies conducted by a number of different researchers. To prove the construct validity of their survey, designers need to prove the case that the questions they put into their survey are based on previous literature. Hence, in survey design, it is imperative to ensure that a majority of the questions have been implicated in the previous literature as items relevant to the current topic of interest. Without being able to prove this validity, it is not possible to make a convincing case regarding whether the survey is doing an undisputed contribution to the overall research topic of interest. However, it should be noted that it is almost impossible to provide a survey in which every single item has a full set of articles or books backing it. In most cases, some survey questions may have some indirect mention in the previous literature, and some survey questions may be solely based on the individual experience and/or opinion of the survey designers. This type of question generation is also acceptable, as long as the designers can prove that those questions are also based on solid research. In short, construct validity of a research survey in HCI aims at proving the conclusion unarguably that results obtained from this survey are on target and valid. Validity is therefore crucial to the success of the research conducted, of which the survey is a part.

Predictive validity is, simply put, the ability and power of the survey to predict correct results in repetitive use. A survey with predictive validity indicates that the results obtained from it in the current and future uses have the power of predicting accurate results. For example, if a comprehensive survey has been produced measuring the usability of a website, researchers will need to prove as part of their study that once this developed instrument is administered, the results that are produced accurately reflect the usability level and attributes of a website. Additionally, the survey also needs to accurately reflect usability levels and attributes when it is administered on other participant groups for evaluation of other sites. If these capabilities of the survey can be proven by the researchers, then the survey can be said to have predictive validity.

Like construct validity, predictive validity does not have any quantitative measurement method to be used. Hence, a survey's predictive validity again relies on qualitatively proving that the survey results are based on solid research notions, and hence the results are accurate. Survey designers need to explain that the results produced from their surveys have been proven to accurately reflect current situations concerning the target population's specifications, evaluations, and opinions, and will continue to do so in future applications when it is administered again. For this purpose, the elements of the survey need to be proven as elements that accurately predict results concerning the topic in focus. To make accurate predictions, surveys need to consist of elements that make accurate predictions themselves when their results are analyzed, and to ensure that these elements have predictive power, they need to rely on accurate literature findings and real-life situations. In short, similar to construct validity, predictive validity of a survey can be accomplished by ensuring that the survey relies on solid previous literature and the researchers' findings. Sometimes, to ensure that survey findings and questions have predictive power, they are evaluated by experts in the area prior to the implementation. Pilot testing is addressed later in this chapter.

55.2.3.2.2 Survey Reliability and Reliability Measurement

Reliability of a survey is the measure of whether the survey is measuring things consistently, and whether the results obtained from the survey can be relied upon. A survey's reliability affects its validity, as a survey that is not reliable in its measurements cannot produce fully valid results.

While there are a number of quantitative reliability measurement techniques for survey design, especially in psychology and sociology, the two most common reliability measurement techniques used in HCI research are *internal and inter-rater* reliability techniques.

The internal reliability technique is concerned with whether the survey questions are understood by the participants the way they are intended to be understood when they were prepared by the survey designers. An internally reliable survey contains questions that are all comprehended the same way by all participants at all times in repeated measures when it is administered. A lack of internal reliability is a common phenomenon, as different participants can understand survey questions differently if they are not asked in a highly clear and unambiguous fashion. Therefore, to improve the internal reliability of surveys, designers need to make sure to use statements that are entirely clear and leave no room for interpretation on what is meant in the questions. An example of a low internal reliability survey question would be "Did you have tremendous difficulty completing the tasks on the web page?" In this question, participants who had little difficulty, no difficulty, and a moderate amount of difficulty may respond to the question in a very similar way, resulting in confusion regarding whether the tasks were difficult or not. Additionally, if participants had difficulties in some tasks and no difficulties in the others, a question such as this may confuse the participants on what types of tasks (difficult or not difficult) they should base their response on. Obviously, in survey design it is important to be careful not to confuse the participants while they are filling out the surveys. Potential confusions can mostly occur on the participants' parts regarding what is meant by the survey question, and what the survey question is about (Cronbach 1990). Surveys may have high construct validity, meaning they may have been designed based on solid research, but if they confuse the participants with their questions, they will obviously lack internal reliability and, consequently, predictive power.

The most commonly used measure for internal reliability of surveys is called "Cronbach's Alpha Internal Reliability Coefficient" (Cronbach 1990). The coefficient relies on checking whether participants respond to the same question the same way when it is asked the second time, in a similar form. These types of questions are called "duplicate questions." The Cronbach's Alpha Coefficient is a correlation coefficient that determines the correlation between the duplicate questions, thereby giving an indication of whether the participants have the same understanding of a question when it is asked in a slightly different way, more than once. In many cases, the opposite, inverted form of the same question can be asked later in the survey. An example of two duplicate questions would be one question early on in the survey such as "Did you find the web design effective to complete the tasks?" and later, toward the end of the survey, "Was the web design effective to complete the tasks?" Alternatively, a question asking the same issue of web effectiveness in a reversed manner can also be posed later in the survey in an inverted question such as "Did you find the web design ineffective to complete the tasks?"

In general, one or two duplicate question pairs are put into surveys of moderate size, up to 40 questions. It may be more helpful to insert more than one pair of duplicate questions into surveys that contain more than 40 questions. Also, if the survey has sections (for example, in a survey measuring web usability, sections may include usability of colors, layout, navigation, etc.) it is recommended to have one duplicate pair of questions for each of the sections to have freedom about determining the individual internal reliabilities of each section.

The Cronbach's Alpha Coefficient is a correlation coefficient that produces a value between zero and one. The correlation between the duplicate questions is measured, and if the coefficient is equal to or greater than 0.7, then a survey is accepted as having high internal reliability (Cronbach 1990). A set of duplicate questions, another set of duplicate, inverted questions, and a sample Cronbach's Alpha Coefficient computer output from the SAS (Statistical Analysis Software) computer package are presented in Figure 55.4.

Internal reliability cannot be measured for surveys that contain open-ended questions. In empirical HCI research, however, most surveys with quantitative parts are required to have a satisfactory internal reliability coefficient in order to prove the reliability and validity of their results. Simply

Duplicate Pair with Same Question:

1. How would you rate the convenience of this interface?

○	○	○	○	○
Very Inconvenient	Inconvenient	Neutral	Convenient	Very Convenient

2. In general, how convenient was this interface for you to use?

○	○	○	○	○
Very Inconvenient	Inconvenient	Neutral	Convenient	Very Convenient

Duplicate Pair with Inverted Question (Inversion of the Scale Needed for Second Question):

1. How easy were the tasks?

○	○	○	○	○
Very Difficult	Difficult	Not Difficult	Easy	Very Easy

2. How difficult were the tasks?

○	○	○	○	○
Very Easy	Easy	Not Difficult	Difficult	Very Difficult

Sample SAS Output:

          Question 2   0.71750   1.00000
                       <.0001
```

FIGURE 55.4 Sample duplicate questions and cronbach's alpha internal reliability coefficient SAS computer package output.

put, lack of internal reliability may result in the questions not measuring what they are intending to measure. Therefore, it is imperative in HCI research to insert at least one pair of duplicate questions into quantitative surveys.

More controversial than the internal reliability measure, the inter-rater reliability of a quantitative survey is concerned about the consistency among responses given by different participants to the same question. One argument is that in objective surveys, a consistency should be expected to some level among participant responses given to the same question in the same survey. While this argument may stay true to some extent in evaluation surveys, opinion surveys, as the name indicates, are about participants' opinions, which will obviously differ from person to person. Hence, it is arguable that the inter-rater reliability coefficient is a valid measure in opinion surveys. Additionally, a certain amount of variability is always present among responses to evaluation survey questions, even if the participants are all exposed to the exact same environment prior to the implementation of the surveys. The inter-rater reliability coefficient is a correlation coefficient among these responses given to the same question by different participants. And expecting a correlation as high as 0.7 among the participant responses may in most cases not be very realistic as a proof of reliability of a survey. Hence, while the inter-rater reliability coefficient is used in a number of survey types primarily in psychology, it is not seen as an essential measurement coefficient for survey reliability in relation to HCI research (Ozok and Salvendy 2000). The inter-rater reliability coefficient is also used to determine how professionals in psychology and sociology rate the same situation, but this type is not covered in detail due to its lack of relevance to HCI.

Measuring the designed survey's reliability is crucial to producing useful results in HCI research. Therefore, comprehensive survey designers must pay attention to these reliability measures while designing their surveys, ensuring that the results obtained from their surveys in current and future studies will have high reliability, thereby improving the theoretical and practical impact of their research.

55.2.3.2.3 Other Survey Evaluation Issues

A large part of evaluation of the surveys usually happens after they are administered. However, in most cases an equally crucial evaluation of a survey happens just prior to the implementation. This evaluation is the actual *pilot testing* of the survey, sometimes also referred to as "pre-testing" (Dillman 2000). As is the convention with most experimentation techniques in HCI research, the near-complete surveys can be administered to a group of participants. After this initial administration, the participants can be asked some questions about positive, negative, and missing issues in the survey, and any questions or sections that were incomprehensible or unclear. Based on the feedback, the administrators can revise the survey and prepare it for the final administration. While there are no firm guidelines regarding the number of participants the pilot testing of surveys should be run on, in most cases a minimum of three participants is recommended for moderate-size surveys (less than 200 participants). For large-size surveys, up to 10 participants are generally useful (Dillman 2000), although there is no upper limit for the number of participants to be used for the pilot study. Most surveys require revision after the pilot study, as in most cases there are some points the survey designers miss without the perspective of actual survey participants. In rare cases when no revisions are made to the surveys after the pilot survey administration, data obtained from the participants in the pilot can be included in the actual participant data pool.

How well a survey is designed is directly related to the validity and reliability of the results the research produces. Hence, the evaluation techniques covered in this section are crucial to the overall success of the designed survey and the research itself.

55.2.3.3 Survey Design, Redesign, and Revision

Design, redesign, and revision procedures for surveys to some extent bear some similarities to product design, redesign, and revision procedures. The initial design of surveys, as explained earlier, consists of generating questions based on the literature, expert opinion, and heuristics. Redesign and revision procedures mostly rely on the implementation of the survey on the entire group or a subgroup of participants. In most cases after a pilot test, surveys need revision which consists of changing or revising questions, scales, or instructions in the survey to make them clearer and more understandable for the participants. If there are errors in question structures or spelling errors, those are also located and eliminated after the pilot study. In rare cases, the required changes may be significant to the level that the survey may need redesign through the revision and change of most questions, scales, and instructions. It can be said that most small-scale survey revisions happen based on the feedback obtained from the pilot study.

Showing a certain amount of similarity to consumer products, frequently used surveys also need redesign and revisions over longer periods. Specifically in HCI, user habits and evaluation criteria for technology and technology-related products and issues change. It is therefore recommended that validated surveys that are used as empirical measurement tools in HCI should be reevaluated and updated about once a year to ensure they are up-to-date measurement tools and contain the latest additions to the HCI area as far as evaluation and opinion elements and techniques are concerned.

55.2.3.4 Illustrative Survey Design Example

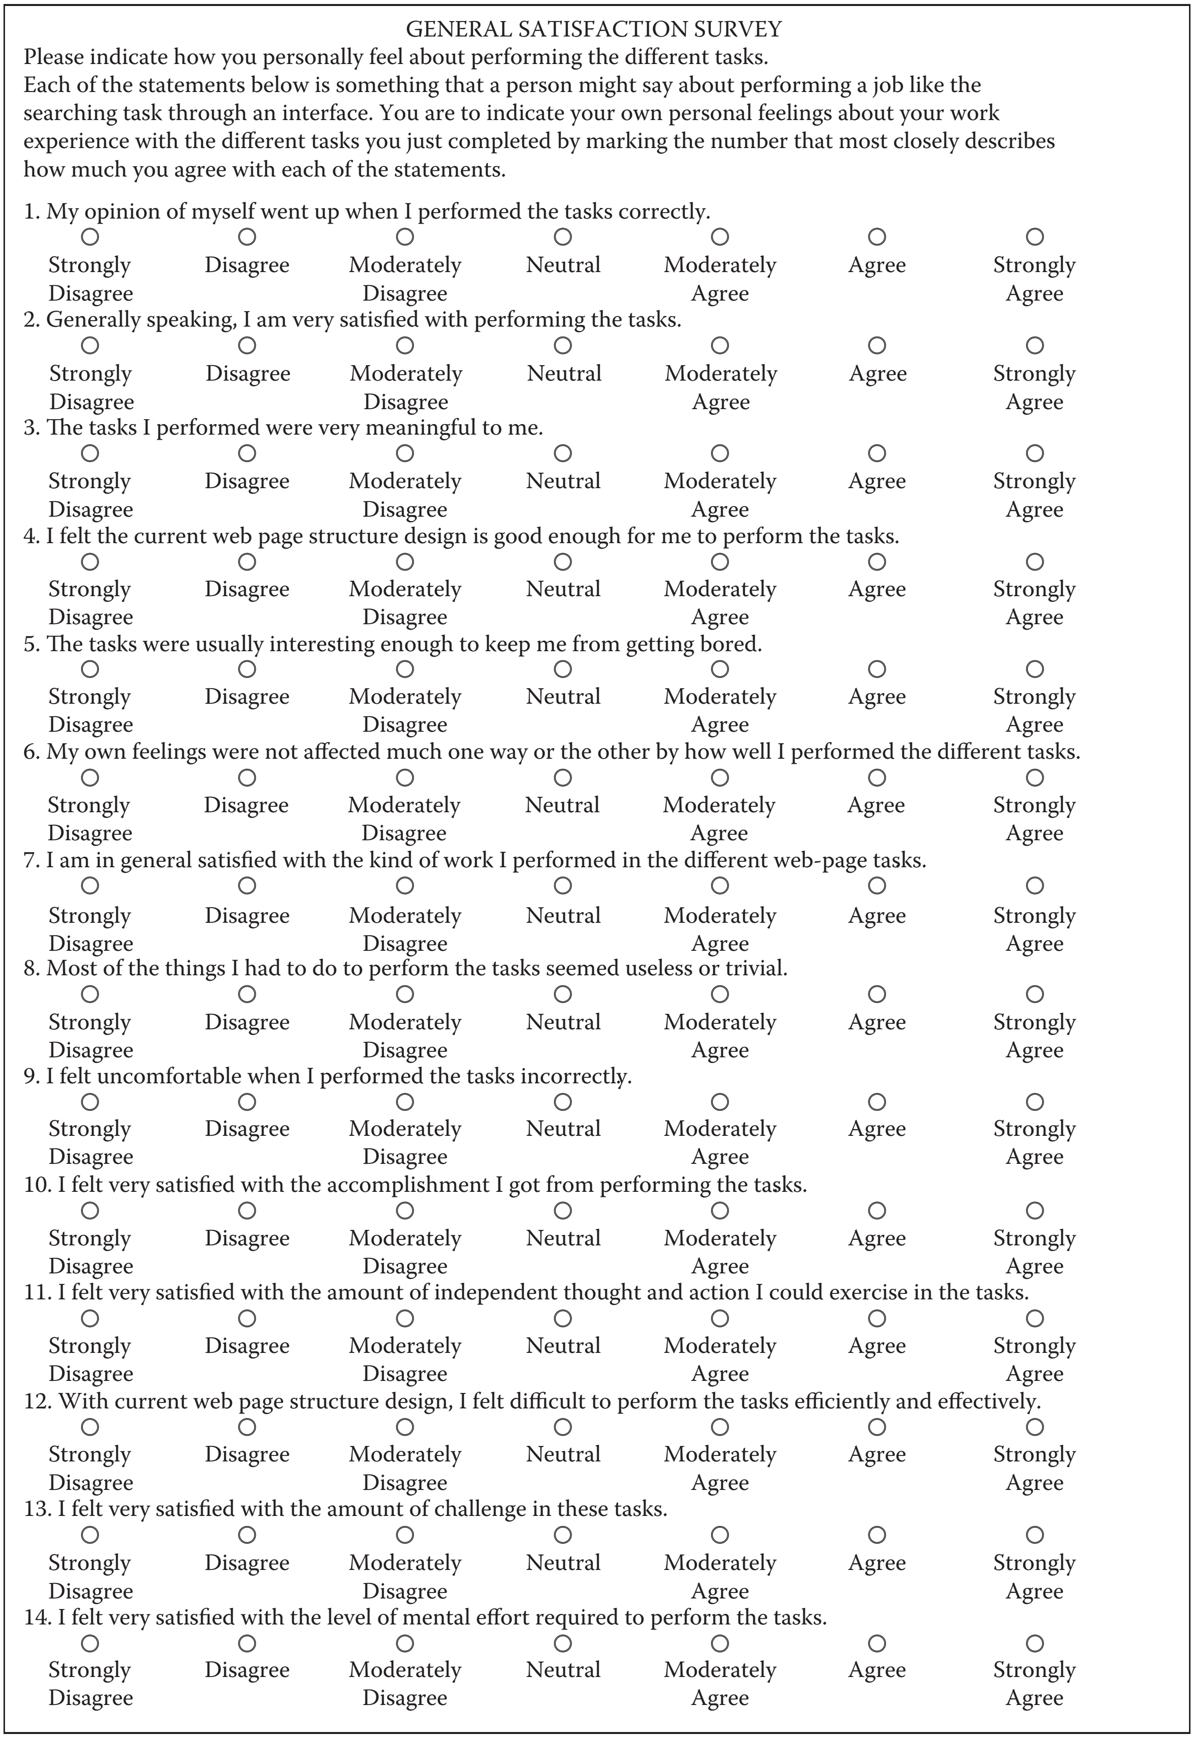
Figure 55.5 presents a sample of a complete, generic paper-and-pencil survey in the example of a postexperimental task satisfaction survey. In the design of a survey measuring the Tablet PC usability issues among academic professionals, the first step is to develop a literature portfolio. This portfolio should cover literature on both mobile computer usability and Tablet PC usability. Next, researchers may send an inquiry to a group of academicians who use Tablet PCs, inquiring about major usability categories in relation to Tablet PCs in open-ended questions. Based on the input from literature and expert opinions, the researchers create an initial set of questions and scales, pilot-test it, and administer the survey, most likely in an environment where they give specific Tablet PC tasks to participants in a controlled environment, preceded by the actual survey administration.

55.2.3.5 Challenges in Survey Design

Survey design challenges mostly deal with possible mistakes in producing the survey questions and scales. Additionally, some problems may occur due to the questions having no validity backing. Therefore, the key for HCI survey researchers is to gain strong background in the area through literature and expert opinion before designing the surveys. After this background is gained, researchers are likely to have no difficulty designing the surveys with the appropriate number and content of questions and scales, and a comprehensive set of instructions to be presented to the participants on how they should fill out the survey.

55.3 SURVEY IMPLEMENTATION IN HCI

Survey implementation can be categorized into open and controlled survey implementation environments. In this section, these two environments are first discussed, followed by



GENERAL SATISFACTION SURVEY

Please indicate how you personally feel about performing the different tasks.

Each of the statements below is something that a person might say about performing a job like the searching task through an interface. You are to indicate your own personal feelings about your work experience with the different tasks you just completed by marking the number that most closely describes how much you agree with each of the statements.

1. My opinion of myself went up when I performed the tasks correctly.

○ Strongly Disagree ○ Disagree ○ Moderately Disagree ○ Neutral ○ Moderately Agree ○ Agree ○ Strongly Agree

2. Generally speaking, I am very satisfied with performing the tasks.

○ Strongly Disagree ○ Disagree ○ Moderately Disagree ○ Neutral ○ Moderately Agree ○ Agree ○ Strongly Agree

3. The tasks I performed were very meaningful to me.

○ Strongly Disagree ○ Disagree ○ Moderately Disagree ○ Neutral ○ Moderately Agree ○ Agree ○ Strongly Agree

4. I felt the current web page structure design is good enough for me to perform the tasks.

○ Strongly Disagree ○ Disagree ○ Moderately Disagree ○ Neutral ○ Moderately Agree ○ Agree ○ Strongly Agree

5. The tasks were usually interesting enough to keep me from getting bored.

○ Strongly Disagree ○ Disagree ○ Moderately Disagree ○ Neutral ○ Moderately Agree ○ Agree ○ Strongly Agree

6. My own feelings were not affected much one way or the other by how well I performed the different tasks.

○ Strongly Disagree ○ Disagree ○ Moderately Disagree ○ Neutral ○ Moderately Agree ○ Agree ○ Strongly Agree

7. I am in general satisfied with the kind of work I performed in the different web-page tasks.

○ Strongly Disagree ○ Disagree ○ Moderately Disagree ○ Neutral ○ Moderately Agree ○ Agree ○ Strongly Agree

8. Most of the things I had to do to perform the tasks seemed useless or trivial.

○ Strongly Disagree ○ Disagree ○ Moderately Disagree ○ Neutral ○ Moderately Agree ○ Agree ○ Strongly Agree

9. I felt uncomfortable when I performed the tasks incorrectly.

○ Strongly Disagree ○ Disagree ○ Moderately Disagree ○ Neutral ○ Moderately Agree ○ Agree ○ Strongly Agree

10. I felt very satisfied with the accomplishment I got from performing the tasks.

○ Strongly Disagree ○ Disagree ○ Moderately Disagree ○ Neutral ○ Moderately Agree ○ Agree ○ Strongly Agree

11. I felt very satisfied with the amount of independent thought and action I could exercise in the tasks.

○ Strongly Disagree ○ Disagree ○ Moderately Disagree ○ Neutral ○ Moderately Agree ○ Agree ○ Strongly Agree

12. With current web page structure design, I felt difficult to perform the tasks efficiently and effectively.

○ Strongly Disagree ○ Disagree ○ Moderately Disagree ○ Neutral ○ Moderately Agree ○ Agree ○ Strongly Agree

13. I felt very satisfied with the amount of challenge in these tasks.

○ Strongly Disagree ○ Disagree ○ Moderately Disagree ○ Neutral ○ Moderately Agree ○ Agree ○ Strongly Agree

a discussion of sample representativeness issues, an implementation example, and discussions of implementation challenges and emerging and future trends in survey design and implementation.

55.3.1 Open versus Controlled Implementation Environments

Survey implementation (also referred to as "survey administration") occurs in two alternative environments. In controlled survey implementation environments, participants fill out the survey in an environment specifically designated for and arranged according to their activity. An open implementation environment, on the other hand, does not contain any specific environmental traits for the participant to implement the survey. Open environments also mostly do not include any restrictions on time or other factors.

Controlled environments for implementation of surveys usually have the goal of preventing any distraction for the participant to hinder his or her understanding or judgment. Controlled survey environments are in most cases well-lit experimental rooms with appropriate equipment to make the participant moderately comfortable (often consisting of a chair and a table). Both computer and paper-and-pencil-based surveys can be implemented in either open or controlled environments. If the survey is implemented in a controlled environment in front of a computer, the survey implementers need to make sure that the computer's alignments (screen brightness, glare, screen distance, keyboard height, and other ergonomics issues) are optimized for the participant. In controlled environments, in most cases a survey administrator is also available to answer possible questions from the participant. These types of controlled survey administration environments are usually used to implement evaluation surveys as in most cases participants had just completed computer-based tasks and for them to be able to evaluate the interfaces or any other HCI-related environments, products, or procedures, controlled environments force them to do those evaluations immediately, while the memories of the items for them to evaluate are still fresh in their minds. Opinion surveys are generally not implemented in controlled environments. In some rare cases in which recording participant behavior during survey implementation is part of the experimentation, a controlled environment can provide the equipment to nonintrusively record participant behavior/activities during the implementation of the survey.

While surveys are in some cases implemented in closed environments, doing so may be costly and time-consuming. Therefore, unless there is explicit need for a controlled environment, surveys are more commonly implemented in open environments. Open environments are environments of the participants' choosing, in most cases environments from their daily lives. In open environments, a survey administrator is not present. Implementing surveys in open environments has the advantage of giving the participants the choice to choose the time and place of the implementation. This flexibility above all increases the ease of finding participants. Additionally, the freedom for the participants to fill out the survey at their convenience also improves their feeling of freedom and may increase their enthusiasm, thereby improving the accuracy of the survey results (Dillman 2000). On the other hand, the surveys being filled out without the presence of a survey administrator will prevent the participants from asking any questions regarding the survey during the administration. Additionally, previous research has indicated that if participants have no particular motivation to fill out the survey, they may complete it very quickly without paying much attention, resulting in inaccurate survey results (Cochran 1977).

Both controlled and open survey implementation environments have advantages and disadvantages. In most cases, however, open environments are faster and more convenient to collect the needed data due to the flexibility they offer to both the participants and implementers.

55.3.2 Sample Representativeness in Survey Implementation

To ensure the validity of the results obtained from surveys, it is imperative to choose a representative sample of the target population to successfully implement the survey. It is common knowledge that the validity of the survey results improves with larger sample sizes. Therefore, researchers need to carefully choose both the sample sizes and the sample participants.

There are no strict rules for determining sample sizes in survey implementation. The size of the survey sample, meaning how many participants should fill out the survey, depends on the type of the survey and survey questions, as well as the number of questions in the survey. Thiemann and Kraemer (1987) summarized the statistical methods of determining sample sizes based on the number of variables being measured in the experiment. In most cases, surveys measuring general topics (for example, surveys about cell-phone-use habits of a certain population, such as college students) should be implemented on relatively large sample sizes, possibly no less than 60 participants for a survey consisting of up to 30 questions. For survey implementation, as a rule of thumb, the number of participants should always be bigger than the number of questions in the survey. While there are no set rules on choosing sample sizes for survey implementation, large sample sizes always improve the probability of obtaining high validity of surveys. For more on how to calculate optimal sample sizes in survey implementation to obtain satisfactory statistical power, see Thiemann and Kraemer (1987).

When surveys are administered, one of the most critical issues is to administer the survey on a balanced, nonbiased, and representative sample. In general, for surveys administered online, the survey should be sent to as big a potential participant pool as possible to ensure heterogeneity. A large group of potential participants should also be sought if the surveys are paper-and-pencil-based, by, for example, mailing out a large number of paper surveys. A balanced sample size in terms of race and gender ensures higher validity as well as a broader application of the results, and this can be achieved by sending the survey to a large base of participants. The demographic information collected also helps determine exactly whether the participant sample accurately represents the target population. As in any experimental or survey-based research, heterogeneity of the sample size allows the researchers to strengthen their argument that the results of their study are applicable and generalizable to the majority of their target population. For example, if there is a vast majority of males compared to females in the sample while the gender distribution in the actual target population is estimated to be about even, then the validity of the results may be argued upon as the variation of the results due to the females would not be taken into consideration in the population, and consequently in the conclusions derived from the survey results. Therefore, survey participant pools should be chosen carefully, and they should also adequately represent the target population. Especially in large sample sizes, sample characteristics may vary greatly, especially concerning age, education, and occupation demographics. In these cases, the demographics should be presented in detail as part of the research results. In most cases, a detailed explanation of demographics concerning participants' education and occupation can justify the representativeness issue of survey results, as long as the levels of these attributes do not differ very greatly between the sample and estimated target populations. In those cases, the results of the survey findings should indicate that the findings are likely to apply to the particular segment of the population that had an overwhelming majority among participants in the sample size. For example, suppose a survey on habits of the general population concerning the use of cell phones has been conducted. If the vast majority of the participants (more than about two thirds) are university students, then the researchers should indicate in their report of results that they measured the cell phone habits of the university student population, which constitutes a large percentage of avid cell phone users (Ozok and Wei 2004).

Survey participant pools require caution when they are chosen, and in cases when the researchers are convinced that the sample is not highly representative of the target population, they need to make clear that the results of their survey may possibly have a narrower focus. In most cases, such narrowing of the target population that the research is aimed at does not result in validity problems, but rather makes clear which population or population segment the results of the survey study apply to.

55.3.3 Challenges in Survey Implementation

As indicated in previous sections, surveys are a relatively easy way of collecting data. They usually don't require expensive equipment for implementation, and with the advent of the Internet, can be easily distributed, filled out, returned, and analyzed. However, there are still some serious challenges in survey implementation in both paper-and-pencil and electronic environments.

Looking at the big picture, surveys are sometimes referred to as "subjective measurements." While the author of this chapter strongly disagrees with this statement, the distinction should be made between measurement environments where performance measurements are taken objectively and unequivocally through camera recordings and software, and environments where participants are asked to indicate what is going through their minds. In the latter environment, obviously, there is no way to ensure that participants are putting on the surveys exactly what they think about an issue, an environment, a tool, a product, or a procedure. It is not uncommon that participants fill out a survey without paying much attention, or even randomly mark responses without reading the questions. The survey-reliability measurement techniques to some extent prevent this type of random data from being used. For example, whether participants took the survey questions seriously can be determined by looking for discrepancies between Cronbach's Alpha duplicate questions. Additionally, strict instructions given to the participants at the beginning of the survey in written or spoken format can also to some extent improve the probability of participants taking the time to read the questions and give replies carefully. Researchers using surveys as their primary research tool always reserve the right to eliminate participant data that look ill fated or incomplete. However, the researchers need to have evidence in their hands that the participant did not complete the survey by obeying the rules that were presented to them, not on any other ground such as the participant responses not being in accordance with the majority of other participants or with the direction of results that are expected from the research.

Another challenge is the "return rate" of surveys. Response and return rates among surveys that do not offer any compensation are extremely low—less than 20% (Dillman 2000). HCI research may involve lengthy surveys as well (more than 30 questions) which can potentially result in even lower return rates. Therefore, it is recommended that some sort of compensation should be offered to participants in survey research, whatever the resources will allow. This compensation may be small gifts (e.g., a pen or notepad), gift certificates, or cash compensation. Any of these types of incentives will surely improve the return rates of surveys (Miller 1996). Additionally, surveys can contain statements to convince participants that they will also learn important issues concerning the research while filling out the surveys. It should be noted, however, that the practical issue of finding subjects should not bias the sample, and recruiting of participants should be arranged according to the data-collection needs of the research, not according to what kind of participant groups are the most practical to collect data from. Recruitment activities need to be targeted to ensure a representative sample.

In most implementation activities, participants should be given their privacy while filling out the survey, ensured that their data will be kept confidential, and be provided a comfortable environment. Otherwise, they may want to either quit or finish as soon as possible without any consideration of the accuracy of responses. It should also be noted that surveys are voluntary, and therefore survey implementers should indicate the voluntary nature of the surveys and not pressure the participants. Research indicates that when participants are pressured to give accurate responses or when a mutual trust between the administrator and the participant is not established regarding the sincerity of both sides, they mostly produce very unreliable survey results (Dillman 2000).

Other survey implementation challenges involve participants' interaction with the survey interface. In paper-and-pencil surveys, the fonts on the paper should have enough size and familiarity for all participants, a pencil with an eraser head will allow participants to correct their responses, and survey elements such as questions and scales should be adequately distinct from each other to prevent any mistakes. Survey designers should use a very simple language in the surveys and avoid any little-known words and sentence structures (Gendall 1998). Surveys consisting of multiple pages should be clearly numbered on each page. This kind of a convenient interaction environment will improve participant enthusiasm and increase response rates as well as accuracy of survey results. Additionally, while some studies expressed concern about differences in survey responses among computer and paper-and-pencil surveys (Sanchez 1992; Cole 2005) and issues concerning the format in which online surveys are presented (Couper, Traugott, and Lamias 2001; Couper et al. 2004; Kiernan et al. 2005), a recent study indicated that the accuracy of survey responses did not significantly differ between surveys administered online and those administered paper-and-pencil (Carini et al. 2003).

In electronic surveys, the computer interface should be very simple and participants with little experience with computers should not have any difficulty using the interfaces. In most cases, participants are required to mark their responses with a mouse and type their responses on clearly marked, designated text spaces that have adequate size for visibility purposes. Some special equipment may offer some additional conveniences, such as touch screens. Screen glare and font sizes should be given consideration too. It can be recommended that computer surveys should be implemented on screens no smaller than 12 inches of diagonal size, with a refresh rate of at least 60 MHz. For surveys longer than one screen, scrolling should be minimized. It is recommended that each survey screen should not require more than two screen-heights of scrolling, and should be connected with hyperlinks or screen buttons, meaning once a participant completed a screen, he or she should be required to move on to the next screen by clicking on a screen button or a link. Besides the scrolling issue, if a participant sees a lengthy survey all presented on one screen, he or she may get discouraged to fill out the survey due to its length.

An additional potentially problematic item is the number of questions to ask participants in a survey. In most cases, the attention span of participants is very short, and surveys that do not offer any compensation are recommended to be shorter than 30 questions. In most cases, participants are not interested in spending more than 15 minutes in filling out surveys for which they don't get any compensation. There is always a trade-off between the size of surveys, meaning the ability to collect all the necessary data, and the ability to recruit subjects. Long surveys are more difficult to recruit participants for. Researchers should think carefully about compensation methods (money, gifts, gift certificates) if they intend to implement large-scale surveys.

Finally, Internet surveys also carry the potential of technical difficulties due to the variety of computers the participants may be using. Schleyer and Forrest (2000) identified usability problems, programming errors, and incompatibilities/technical problems as main problems identified in web-administered surveys. Therefore, Internet-based, especially web-based surveys, should not require any scripts or plug-ins to run and if possible should consist of simple Hypertext Markup Language (HTML) code, as HTML is universally recognized by all browsers.

These are the major challenges the survey implementers currently have to deal with. However, with careful design and implementation, as well as strict instructions containing comprehensive information presented to the participants regarding the survey, the challenges can be easily overcome, resulting in valid and reliable survey results.

55.4 EMERGING AND FUTURE TRENDS IN SURVEY DESIGN AND IMPLEMENTATION IN HCI

Surveys have retained their structure, more or less, for many decades. It can be said, however, that electronic and especially Internet-based implementation has changed the convenience level of survey implementation and data analysis in a significantly positive way. It is difficult to predict whether any new groundbreaking techniques will cause further leaps in survey design, development, and analysis, but if significant new developments will happen in the near future, they are likely to happen in the implementation technology. Internet surveys are on the rise, with the percentage of Internet-based surveys being on the rise for the past five years. While Internet-based surveys comprised 15% of all surveys implemented in 1999, this number increased to 70% in 2004, according to Nua Internet Surveys (2005). With the improvement in voice recognition and voice synthesis technologies, future surveys may eliminate the need of a visual interface; however, human-factors issues in these types of interfaces specifically for surveys are still to be explored. It is apparent that the number of surveys implemented through the Internet and other networks will continue to climb in the years to come, due to cost savings and a number of other convenience issues. In the future, HCI research is also likely to continue to use surveys as a main data-collection tool. With HCI research becoming a more integral part of technology design and creation (for example, human-factors engineers and software engineers working collaboratively in the software-design process), user surveys may become more integrated, collecting data for current or future users regarding both HCI and other technology issues. Additionally, computer literacy is increasing at a fast pace (U.S. Census Bureau 2005), which allows HCI survey researchers more freedom in asking more sophisticated questions concerning interface evaluation, current user trends, and more. All that said, the contribution of surveys to HCI research is highly significant these days, and will likely continue to be so in the many years to come.

56 Inspection-Based Evaluations

Gilbert Cockton, Alan Woolrych, Kasper Hornbæk, and Erik Frøkjær

CONTENTS

Usability inspection methods (UIMs) are approaches to usability evaluation based on expert inspection of a user interface and the probable user interactions with it. They can be applied to any designed artifact during development: a paper prototype, a storyboard, a working prototype (e.g., in Macromedia Flash™ or in Microsoft PowerPoint™), tested production software, or an installed public release. They are *analytical* evaluation methods, which involve no typical end users, unlike empirical methods such as user testing. UIMs require only availability of a designed artifact, trained evaluators, and supplementary project/evaluator resources. The resource requirement for evaluation is thus low: UIMs were one of the first groups of *discount methods* within human–computer interaction (HCI). Their origins as discount methods are important. Their inventors focused on reducing the cost of usability evaluation to a level that they judged to be acceptable for software development projects in the early 1990s. This focus on cost was at the expense of critical reflection and systematic scientific evaluations. Perversely for a user-centered field such as HCI, there was limited consideration of how evaluators would actually use methods, both *cognitively* from a perspective of problem-solving behaviors, strategies and tactics, and *socially* from a perspective of usability evaluation as *work* within project *contexts*. More recently, HCI has focused more on the affective aspects of interaction, and these too now need to be considered when assessing UIMs. It is not enough for UIMs to be better assessed and supported by better advice on their use by evaluators within usability work contexts. UIMs must also "feel right" to evaluators. It is important that evaluators believe that UIMs are helping them to find important usability problems and to understand and apply them well enough to be able to recommend effective design changes to remove the problems. It is unrealistic to expect UIMs alone to guarantee high quality evaluation. Interaction design is a complex challenging activity that demands extensive expertise and understanding.

This third version of this chapter takes a more critical perspective than previous ones, drawing on recent research in the context of 4 years of collaboration between researchers from over 20 European countries (the MAUSE project on Maturity of Usability Evaluation, www.cost294.org). At the heart of the problem with unrealistic expectations for UIMs is the word "method" itself, which hides many pitfalls for the unwary. Clearly, no published generic method can be complete. For example, accounts of user testing "methods" may give guidance on recruiting and screening test users and on designing and facilitating test tasks, but these accounts will never tell you who to recruit or which criteria to apply when screening potential test users, nor will they tell you exactly which tasks to facilitate. No account of user testing could possibly do this, because different interactive systems are designed to support different tasks for different groups of users to different standards of work or other qualities. While this all should be obvious, it is worth reminding anyone new to a design or evaluation method that practitioners and researchers *must work to get methods to work*. Methods do not apply themselves, nor do they provide all the resources (e.g., project-specific participant screening criteria) required to apply them.

Methods only exist in the past tense: you know what your method *was*, but at the outset of usability work, you are highly unlikely to know what your method *will be*. At best you will have a firm outline, supported by extensive project-specific details, of how you will *approach* usability work. We prefer to use the word *approach* to "method." In much commercial work, clients ask about a potential supplier's overall approach, rather than for step-by-step details of the methods that they will use. We believe that "approach" is a more accurate term for project-independent work structures, that is, prefigured activity skeletons that must be configured for specific projects. As with all human activities, methods are achievements and can never be premonitions. Evaluators need to see through the commodification of resource bundles as "methods," and be realistic about their real value prior to configuration and augmentation for specific evaluation contexts.

This chapter introduces UIMs, presents several example methods, and highlights the limited resources provided by each. Risks clearly arise from these limited resources, but well-informed practices disproportionately improve evaluation performance, improving cost-benefit ratios. Well-informed usability practices rely on additional resources provided by specific project environments, including evaluators themselves. Thus, evaluators must complement UIM resources with their own. As a result, it is very hard to rank UIMs or to make firm recommendations for the superiority of one UIM over another, even in fairly specific circumstances. The reason for this is that actual performance with a UIM depends on how it is configured and used in practice. This chapter, therefore, focuses on what is required to turn the rough approaches of UIMs into effective methods.

56.1 DEFINITIONS AND CONTRASTS

A UIM is an analytic approach to usability evaluation based on expert inspection of a user interface and the probable user interactions with it. A UIM *provides* resources that can be *applied directly* to an interaction design artifact, and/or probable user interactions with that artifact, and does not require end user resources. A resource is any element of an evaluation method, for example, knowledge about interaction design, evaluation procedures, problem report formats, checklists, or problem severity criteria. *Direct application* contrasts UIMs with model-based methods, which are *indirectly* applied via design representations (or models), requiring construction of models and secondary application of analyses to designed artifacts. Using the GOMS (Goals, Operators, Methods and Selection rules) method, for example, a task model would be analyzed and the results would have to be reframed to address the actual design artifact. In contrast, UIMs such as heuristic evaluation (HE) directly identify design features that may cause user difficulties. UIMs require fewer resources than model-based methods and thus commit evaluators to less work. While the reduction in costs could be accompanied by a reduction in benefits, the increase in costs for model-based methods may not be justified by a commensurate increase in benefits. In short, there is no fixed connection between the resources provided by evaluation approaches and their cost-benefit ratios. Evaluators thus need to pay careful attention to planning, supported by continuous critical reflection on the effectiveness of specific usability work practices. We next briefly review three UIMs to informally identify resources associated with, and missing from, each.

56.2 THREE EXAMPLE USABILITY INSPECTION METHODS

56.2.1 Heuristic Evaluation

With HE (Nielsen and Molich 1990; Nielsen 1992, 1994b), evaluators inspect a system with a view to discovering breaches of heuristics, which are "rules of thumb," rather than focused usability guidelines or exact style conformance rules. Breaches of heuristics indicate possible usability problems. One example of a heuristic breach is when a file is downloaded from a website, or intranet, without visible feedback to inform them of download progress. The failure to provide feedback breaches Nielsen's *visibility of system status* heuristic.

Heuristics are HE's main resource. The 10 current heuristics (Figure 56.1) were derived from analysis of 249 known usability problems, which had been established from evaluation of

1. Visibility of system status
2. Match between system and the real world
3. User control and freedom
4. Consistency and standards
5. Error prevention
6. Recognition rather than recall
7. Flexibility and efficiency of use
8. Aesthetic and minimalist design
9. Help users recognize, diagnose, and recover from errors
10. Help and documentation

FIGURE 56.1 HE's heuristics. (From Nielsen, J. 1994. *Usability Inspection Methods*. John Wiley & Sons. With permission.)

11 different interactive systems (Nielsen 1994b). The objective was to produce a compact heuristics set that best covered a set of known usability problems. HE also prescribes a specific procedure for performing an evaluation. Nielsen (1994b) recommends that analysts go through the interface at least twice. The first "pass" allows the evaluator to get a "feel" for the system, that is, both the general scope of the system and the flow of interaction. In the second and subsequent passes, the evaluator can focus on specific elements of the user interface. This procedure is HE's second resource, but advice is not given on how to structure the first pass or on how to focus in the second pass and associate possible usability problems with breached heuristics. These two critical resources must be provided by evaluators and/or their project/organizational context.

56.2.2 Cognitive Walkthrough

Cognitive walkthrough (CW) (Lewis and Wharton 1997) is a UIM primarily concerned with learnability, initially developed to assess "walk up and use systems" and later extended to task-based assessment of more complex systems. In CW, evaluators first of all assess if the user can form appropriate goals (Question 1) and then assess if the user can choose the appropriate actions to achieve their goal (Questions 2–4). The four CW questions are the following:

1. Will the users try to achieve the right effect? Does the user know what to do? Is it the correct action?
2. Will the user notice that the correct action is available? Is the action visible? Will users recognize it?
3. Will the user associate the correct action with the effect to be achieved? The action may be visible, but will the user understand it?
4. If the correct action is performed, will the user see that progress is being made toward solution of the task? Is there system feedback to inform the user of progress? Will they see it? Will they understand it?

The four questions, and an associated outline walkthrough procedure, are CW's main resources. Assuming the appropriate goal has been formed, the evaluator then breaks the "goal" down into the component task steps required to successfully achieve it. At each step, the evaluator asks questions 2–4. A negative response to any of the CW questions indicates a *possible* usability problem. To identify *probable* problems, evaluators must form success or failure judgments based on the cumulative impact of possible problems for a task. CW provides no guidance on the selection of tasks or on procedures for deciding success or failure cases. As with HE, these two critical resources must be provided by other means.

56.2.3 Metaphors of Thinking

Metaphors of thinking (MOT) (Frøkjær and Hornbæk 2002, 2008; Hornbæk and Frøkjær 2004) is a psychological-based inspection technique developed explicitly to address users' thinking, in the belief that the importance of such thought affects interaction. The metaphors are intended to support both evaluators and designers in understanding the importance of human thinking in interaction and to "stimulate critical thinking." Figure 56.2 summarizes the five metaphors. The basic method of performing an MOT inspection is that evaluators define representative tasks and "walk through" the interface. Evaluators make note of any usability problems identified, typically through violating the criteria in each metaphor. The main resources provided by MOT are thus these five metaphors and the prescription for their use. As with HE and CW, all other resources must be provided from other project/evaluator sources.

Metaphor M1: Habit Formation is Like a Landscape Eroded by Water

This metaphor is based concerned with the human trait of habit forming. The example used to illustrate this metaphor is that of adaptive menus that prevent habit forming. Since the menu's position can change from when an item was previously selected, habit forming is almost impossible.

Metaphor M2: Thinking as a Stream of Thought

The benefit of this metaphor is explained by the fragility of "stream of thought" and how interruptions can severely impact on task completion time. The example to illustrate this is that concentration can be affected even by such useful tools as e-mail alerts and automatic spelling checkers that, despite their respective benefits, can be distracting.

Metaphor M3: Awareness as a Jumping Octopus

This metaphor draws attention supporting users' associations with effective means of focusing within a stable context and, like CW, prompts consideration of whether users associate interface elements with the actions and objects that they represent. Users should be able to switch flexibly between different parts of the interface.

Metaphor M4: Utterances as Splashes over Water

This metaphor addresses support for changing and incomplete utterances, prompting consideration of alternative ways of expressing the same information, the clarity of interpretations of users' input in the system, and the risks of systems making a wider interpretation of users' input than users intend or are aware of.

Metaphor M5: Knowing as a Building Site in Progress

This metaphor is based on the notion that human knowing is incomplete, so users should not be forced by the application to depend on complete or accurate knowledge or to pay special attention to technical or configuration details before beginning to work.

FIGURE 56.2 Metaphors of thinking. (Adapted from Frøkjær, E., and K. Hornbæk. 2008. *ACM Trans Comput Hum Interact* 14(4):1–33.)

56.3 USABILITY WORK AND PRACTICE

Until recently, evaluation methods have been effectively viewed as if they were very similar to task methods in model-based approaches such as GOMS (Chapter 57), that is, evaluators follow a fixed predictable sequence of task steps to perform an evaluation. This has never been stated explicitly within evaluation method research, but many method comparisons assume that there will be a strong *method effect*, even when the *evaluator effect* (Hertzum and Jacobsen 2001) has been so clearly demonstrated and documented. In other words, comparisons have continued to assume that methods have strong effects even when it has been shown that evaluators are responsible for large variations in outcomes. Method effects require any differences in performance between evaluators to be solely due to the UIM being used. Gray and Salzman (1998) in their thorough critique of 1990s' evaluation method comparisons noted that the causal factor was more likely to be *evaluators using method X* rather than just *method X* alone. For the latter to be so, UIMs would have to be well defined and complete as to eliminate evaluator effects. Given the limited evaluation resources provided by HE, CW, and MOT, this is unlikely to be so.

The persistence of method effect assumptions in comparison studies reflects the origins of usability engineering in the *first wave HCI* of the 1980s, which was strongly influenced by cognitive psychology. The GOMS method, a first-wave HCI approach, used a very crude approximate model of expert human planning, which ignored two fundamentals of planning within HCI (Young and Simon 1987). First, the activity of planning is intimately interleaved with the execution of plans, and second, simple, partial plans are more appropriate than complex, detailed ones. Thus by the late 1980s, cognitive scientists such as Young and Simon had shown that viewing methods as rigid pre-scripted plans was wrong. Second wave HCI, with its “turn to the social” in the 1990s, reinforced these positions with rich accounts of human work that showed that plans were *resources* and not *scripts* (e.g., Suchman 1987). However, only in the last few years has HCI research on evaluation method usage finally treated usability practices as human work, with all the variations and contingencies that this involves. We now briefly review this delayed “turn to the social” in evaluation method research and next clarify its implications for our understanding of usability evaluation.

56.3.1 Realities of Usability Work

Some HCI research has continued to compare evaluation methods based on an unrealistic position on the power of methods, but usability specialists cannot base their work on such illusions. Extensive project-specific requirements (e.g., choosing participants, reporting results) distance methods in use from published methods, even when these superficially appear to be detailed step-by-step practitioners' “cookbooks.” Usability work does not get by through “choosing a method”; however well such a choice can be grounded. Instead, usability work *combines* several methods (Rosenbaum 2008), which generally compensate for each other's weaknesses, reducing or even removing the relevance of rankings or assessments of isolated methods. Molich et al. (2004) showed how teams that tested the same website differed on many specific choices on how to conduct a usability test. For instance, with respect to test reporting and task selection, marked differences were found. The nine teams not surprisingly found different sets of problems. Yet, very few scientific studies look at the combination of methods (though see Uldall-Espersen, Frøkjær, and Hornbæk 2008); this supports our argument that very few comparative research studies' evaluation investigates methods as they are used in practice. Rosenbaum's (2008) account of the evolution of usability practice shows a clear move over the last decade to project-specific combinations of multiple methods. To use a culinary analogy, usability work prepares meals, not individual dishes.

Method research in HCI should not primarily focus on supporting the choice of *a* method, nor should it attempt to answer questions such as what, in some specified context, is the “best” method, where “best” may mean most productive, most thorough, most valid, easiest to use, or cheapest to use, casting usability work as a simple choice of methods. Once chosen, the expectation is that evaluators will faithfully adhere to a method. Real world choices can never be specified wholly in terms of options and selections. There is more to choice than the menu. There is also the diner and their needs. While criteria such as nut allergies have straightforward consequences for choices from menus, wanting something “interesting and different” does not. The goodness of a choice lies in the context of the choice. Thus, Furniss (2008) argues that an appropriate choice and use of a method is functionally coupled to the project context, including client biases, practitioner expertise, their relationship, the budget, the problem, the time, auditing potential (for safety critical systems development), and persuasiveness.

56.3.2 Method as Achievement

It is over two decades since Suchman (1987)'s breakthrough critique of intelligent photocopiers. Suchman's research readily exposed how the plan recognition built into an intelligent photocopier was no match for the variety of real user behaviors. By treating a plan as a script, the intelligent photocopier was too rigid and unimaginative in its interpretation of user behaviors. Suchman argued that plans should be regarded as *resources* that have some fit to potential real world situations, but to achieve fit such plans need to be modified and extended to cope with the situated realities of human behavior. If we accept that it is highly unlikely that scripted plans in intelligent appliances can ever support management of situated human behavior, designers of usability methods face even bigger challenges, since usability work is far more challenging and complex than, for example, photocopying. We need to remove such inconsistencies within HCI thinking. If we cannot script user interaction, then we cannot script usability work. This has been shown for the user of user testing methods by Nørgaard and Hornbæk (2006), who studied how think aloud tests were conducted in seven Danish companies; they found that immediate analysis of observations made in think-aloud sessions was only performed sporadically, if at all. Usability approaches must then be designed, understood, and assessed within a framework that recognizes the situated nature of all human activities. Within such a framework, evaluation methods can never be anything more than weak prescriptions.

UIMs thus cannot be provided in any complete form by usability researchers or leading practitioners. Instead, what is provided are *approaches* that commoditize a set of resources by packaging them together under some method "brand name" (e.g., HE, CW). To return to a culinary analogy, what are called UIMs have much more in common with a Chicken Fajita *kit* on a supermarket shelf than with a Chicken Fajita *meal* in a restaurant. Consumers of the former expect it to be incomplete, and they expect to have to source some key ingredients and then prepare them, combine them with the kit, and cook them. Purchasers of the latter just expect to eat Chicken Fajitas and would be very dissatisfied if they had to prepare or cook anything. Evaluators who expect methods to be like completed meals will be similarly dissatisfied. They should expect *approaches* that require them to augment and adapt. With this in mind, we now further review UIM "ingredients," both those provided by "branded methods" and those developed within HCI research that can readily be combined within a range of evaluation resources.

56.4 RESOURCES FOR USABILITY INSPECTION

Attending to the resources present in (or absent from) descriptions of UIMs offers several benefits to researchers and practitioners. First, the important choices in usability inspection are among resources, not among methods. Second, resources may be configured and combined as evaluators see fit, which is overlooked when the focus is on methods. Third, some approaches to inspection require resources that are implicit or unusable, which a focus on resources can better expose. Fourth, focusing on resources allows sharper and more controllable research studies with a more realistic chance of benefitting practitioners. The studies can focus on specific aspects of usability work (resources) rather than incomplete combinations of resources (approaches).

56.4.1 Resources within Three Example Usability Inspection Methods

To exemplify the notion of resource in UIMs, we return to the three example UIMs outlined earlier in this chapter. First, for HE, we have already identified heuristics as the key resource. The two original papers on HE (Molich and Nielsen 1990; Nielsen and Molich 1990) listed nine heuristics (e.g., "simple and natural dialogue" and "prevent errors"). Subsequently, the heuristics have been through several iterations. Nielsen (1994b) did a post hoc analysis of 249 usability problems to find seven heuristics that could have predicted many of those problems and added three others to produce a more comprehensive set.

As noted earlier, HE also provides a procedural resource, but descriptions of it vary in their recommendation of the use of *task resources*. Originally, Nielsen and Molich (1990) mention no need for formal or informal understanding of tasks for evaluators. Later, Nielsen (1993) mentions that in contexts where evaluators lack *domain knowledge* (which Nielsen had shown to be a critical evaluation resource), they may be supplied with "a typical usage scenario" (p. 159) even though "evaluators are not *using* the system as such (to perform a real task)" (p. 159). Despite many studies of HE, we are unaware of any that have tried to manipulate task specification and analysis resources, even though Sears (1997) showed that combining CW's strict procedure with HE's loose sweep improves over the performance of HE alone.

In themselves, heuristics are not very usable. Both studies of, and practical introductions to, HE provide further tutorial material. Nielsen and Molich (1990) suggested that the heuristics could be presented to evaluators in "a single lecture" (p. 250). Nielsen (1994b) walked through a set of heuristics, explaining and exemplifying them almost 50 pages. Because of this variety in introductory material to HE, some experiments have used lectures and tailored material to standardize evaluator education (e.g., Cockton and Woolrych 2001, which identifies when task resources are essential to identify heuristic breaches). The extent to which such additional *knowledge* resources influence performance with HE is presently unclear.

Given the limited and varied resources associated with HE, it is no surprise that HE's resources alone cannot explain documented evaluation outcomes. Jeffries et al. (1991) asked evaluators note how they identified problems when using HE. Analysis of their notes showed that roughly a quarter of problems were found via "side effects" (e.g., from prior experience) and about a third of the problems were found "from prior experience with the system." Cockton and Woolrych (2001) demonstrated that many outcomes of HE could not be attributed to its resources, since evaluators successfully predicted usability problems with which no heuristic could be credibly associated, and thus had to inappropriately associate a standard heuristic with many of the one third of usability problem predictions that were confirmed by carefully focused user testing.

Turning to CW, as noted, its key resource is its prescribed procedure, based on a set of tasks, which answers four questions for each step of a task. In contrast to HE, CW's procedure is clear and always task-centered, although the final step of forming success/failure cases is not well described. CW forces use of task resources by requiring analysts to answer four questions for each task step, and then construct a success and failure case for the task. However, there is no support from CW for forming success and failure cases, nor is there support for task selection and specification. Even so, CW's success and failure cases are rare examples of an *analysis resource* for *problem elimination*, letting analysts argue that some apparent design flaws would not automatically cause severe usability problems. In contrast, most UIMs provide *discovery resources* that guide evaluators to find *possible* problems. To avoid a high proportion of *false negatives*, UIMs need to also provide *analysis resources* that support evaluators in deciding whether a found problem is *probable*, and thus should be reported, or *improbable*, and thus should be discarded.

The cost-benefit balance arising from CW's task-based procedures may be unfavorable. Early studies such as John and Packer (1995) found that going through CW was "very tedious." Early versions of CW required analysts to explicitly consider users' goals (e.g., Lewis et al. 1990; Polson et al. 1992). For example, the version presented by Polson et al. (1992) required three pages of questions for each action; one page to address users' goals, one to cover choosing and executing the correct action, and a final page of questions covering the effect of taking the action on the user's goal structure. The overhead of CW and difficulty applying it led to the cognitive "Jogthrough" (Rowley and Rhoades 1992) and multimedia tool support for CW procedures (Rieman et al. 1991), which increased evaluation efficiency markedly, that is, they improved CW's cost-benefit ratio by adding a further *tool resource*.

A simpler version of CW was developed by Wharton et al. (1994), which de-emphasized "the explicit consideration of the user's goal structure," resulting in the current set of four questions, although a subsequent variation (Spencer 2000) reduced these down to two! Overall, later versions of CW reduced extensive preparation materials for analysts, making them less unwieldy as discovery resources, but perhaps losing some benefits that arise with interaction-centered methods, with some benefits preserved via the use of task descriptions, but others lost due to the progressive simplification of CW and the resulting loss of explicit resources for evaluation support.

Early versions of CW emphasized *theory as a resource*. Answers to questions should be supported by empirical data, experience, or scientific evidence, all knowledge resources external to CW, except for CE+, a theory of learning (Polson and Lewis 1990) that provided CW's foundations. For example, CE+ predicts that users new to a system will choose an action with a good match to their current goal. This reflects the relation between interaction-centeredness and grounding in theory, in that the system-centered methods such as HE are generally atheoretical. Later versions of CW backgrounded the CE+ theory of learning (Wharton et al. 1994; Spencer 2000), suggesting that there is a tendency to favor concrete (notations, questions) over abstract resources (theories, concepts) and practical ones (e.g., procedures) over propositional resources (e.g., knowledge, information).

As noted for the third example UIM above, MOT's key resource is the five metaphors and their associated key questions (Table 56.1). Metaphor choice was guided by considerations of how this resource would work for analysts. MOT's inventors argued that "use of metaphors as a communication device supports intuition and requires active interpretation; an effort orthogonal to developing inspection techniques that are more strictly formal and piecemeal analytical" (Frøkjær and Hornbæk 2008, p. 3). The extent to which the metaphors and key questions actually work in this way for analysts is, however, only investigated through summary measures of evaluation performance and through analysts' comments on MOT.

The procedure of MOT is similar to that of HE (Frøkjær and Hornbæk 2008), but contains more detailed instructions on how to conduct an evaluation (Hornbæk and Frøkjær (2002). The instructions mention that the analyst must use "typical tasks" to drive the evaluation, but does not provide any resources for identifying these. MOT thus provides similar task resources to CW, that is, stating that they must be used, but providing no support for selecting and specifying them.

In the above analysis, we have begun to distinguish different classes of resources. Two broad classes are *discovery*

TABLE 56.1
Summary of the MOT-Technique: The Five Metaphors, Their Implications for User Interfaces, and Examples of Questions to Be Raised

Metaphor of Human Thinking	Implications for User Interfaces	Key Questions/Examples
Habit formation is like a landscape eroded by water.	Support of existing habits and, when necessary, development of new ones.	Are existing habits supported? Can effective new habits be developed? Is the interface predictable?
Thinking as a stream of thought.	Users' thinking should be supported by recognizability, stability and continuity.	Does the system make visible and easily accessible the important task objects and actions? Does the user interface make the system transparent or is attention drawn to non-task related information? Does the system help users to resume interrupted tasks? Is the appearance and content of the system similar to the situation when it was last used?
Awareness as a jumping octopus.	Support users' associations with effective means of focusing within a stable context.	Do users associate interface elements with the actions and objects they represent? Can words in the interface be expected to create useful associations for the user? Does the graphical layout and organization help the user to group tasks?
Utterances as splashes over water.	Support changing and incomplete utterances.	Are alternative ways of expressing the same information available? Are system interpretations of user in-put made clear? Does the system make a wider interpretation of user input than the user intends or is aware of?
Knowing as a site of buildings.	Users should not have to rely on complete or accurate knowledge—design for incomplete-ness.	Can the system be used without knowing every detail of it? Do more complex tasks build on the knowledge users have acquired from simpler tasks? Is feedback given to ensure correct interpretations?

and *analysis* resources, which respectively support finding possible usability problems and deciding on their probability and severity. *Task specification resources* are a subclass of discovery resources when used to guide problem discovery. However, information on *task frequency and criticality* can be regarded as analysis resources when they are used to determine the severity of a probable problem. Here, they would also be instances of *severity rating* resources that *rank* probable problems by their *likely impacts* on users. Other examples of evaluation resource include *matching and merging* resources (to *consolidate* the predictions of one or more evaluators into a single set of probable problems) and *expressive resources for reporting* (to support merging/matching and/or communication of the final problem set). Further types of evaluation will be identified in the next two subsections.

56.4.2 Resources within Other Usability Inspection Methods

We now introduce four further UIMs. The first, *Heuristic Walkthrough* (HW: Sears 1997), is a hybrid approach that combines the resources of HE and CW. HW also requires a prioritized list of user tasks, which should include frequent or critical ones, and may also include tasks designed purely to ensure coverage of the system being evaluated. HW thus provides more guidance on task selection than HE, CW, or MOT. This *discovery* resource is complemented by a further procedural resource that provides additional support for discovering possible problems by combining and extending the basic discovery procedures of CW and HE. It has two phases: task-based and free-form. In the first phase, evaluators explore tasks using a set of thought provoking questions derived from CW. They are free to explore the tasks in any order, spending as long as they need, but they should be guided by task priorities. In the second phase, evaluators are free to explore the system. They use the set of thought provoking questions *again*, plus HE's heuristics. Sears (1997) compared HW against CW and HE. HW found more actual problems than CW and had fewer false positives than HE. Overall, Sears' merge of HE and CW improved evaluator preparation and discovery resources, with evidence of improved analysis resources (reduction in false positives), which may be due to the initial CW inhibiting discovery of unlikely problems. HW appears to encourage more self-reflection on the part of evaluators relative to HE, but this is not due to the "method as a whole," but to a single procedural resource (two phase problem discovery structure).

Turning to our next UIM, *Ergonomic Criteria* (EC: Bastien and Scapin 1995; Scapin and Bastien 1997) uses a set of 18 ergonomic criteria. They were formed by reviewing around 800 existing guidelines and experimental results (Scapin 1990). Not surprisingly, HE's heuristics and EC are often very similar, for example, Immediate feedback (HE: visibility of system feedback) and Quality of error messages (HE: help users recognize, diagnose, and recover from errors). Each has a definition, a rationale, and examples of guidelines plus comments that include help to disambiguate any related criteria. There are eight main (top level) criteria: guidance, user workload, user explicit control, adaptability, error management, consistency, significance of codes, and compatibility. Five of these are further subdivided, resulting in 13 second-level criteria: prompting, grouping and distinguishing items, immediate feedback, clarity, brevity, mental load, explicit actions, user control, flexibility, users' experience management, protection from errors, error messages, error correction. Further subdivision results in overall 18 criteria at three levels of abstraction and structure.

While some accounts of HE provide similar support (e.g., Nielsen 1993), EC's consistent structures are rare for UIMs. EC's structure is likely to assist evaluator preparation for using it. EC thus considers evaluators' learning needs and provides structure and detail to prepare them for using it. Important preparation resources including scoping, axiological and knowledge resources (Woolrych, Hornbæk, Frøkjær, and Cockton 2012), which respectively indicate the scope of a UIM, the values underlying its design, and the knowledge required to fully understand it. Note that these resources have an impact before inspections are attempted in better *preparing* evaluators. Preparation resources are distinct from discovery or analysis resources, although both of the latter clearly interact with the former. EC also requires evaluators to be provided with description of the *purpose* of the product, a preparation resource that is lacking in HE, CW, MOT, and HW. EC also provides procedural resources that support discovery and analysis: a first phase follows a task-based walkthrough, while a second phase focuses on problem diagnosis.

Our reviewed UIMs so far have distinct motivations. HE focused on discounting evaluation costs, CW on learning walk-up-and-use systems, MOT on empathy with user behaviors, EC on supporting evaluator learning, and HW on trading off one evaluation cost (false negatives) against another (first pass walkthrough costs). Our next reviewed UIM, *Cognitive Dimensions* (CD: Green and Petre 1996), sought to improve evaluators' conceptual vocabulary, moving them away from technical surface features (Green 1991). CD attempts to capture a set of orthogonal dimensions for restricted set of systems called "notations," which are used to design information structures, for example, programming languages and spreadsheets. These dimensions are not necessarily criteria for a design but a characterization of the design space.

Sample of dimensions are shown in Figure 56.3. The dimensions embody a theory about how people use notations

Hidden dependencies occur when one cannot see how a value is calculated, for example, a spreadsheet where a small change can have unexpected effects. All dependencies that are important to the user must be accessible.

Premature commitment occurs when a user is forced to make a decision before the necessary information is available.

Viscosity is resistance to change or a measure of how much work is needed to achieve a change.

Abstraction gradient: An abstraction is the grouping of objects into one object, which can make a system easier to understand.

FIGURE 56.3 Example cognitive dimensions.

to build information structures. A simplified theory of action would involve people translating goals into specifications, then into actions, and executing them. Rather, people work bottom up, top down—goals and subgoals may be attacked at any moment. Green (1991) claimed the preferred strategy is opportunistic where high- and low-level decisions are mingled; commitment can be weak or strong and development in one area may be postponed because of problems foreseen in other areas. The vocabulary of dimensions may act as a discovery resource, sensitizing analysts to generic interaction difficulties. However, once associated usability problems are discovered, there appears to be little further support for problem confirmation or elimination. Even so, as with CW's CE+, CD provides *theoretical knowledge resources* that provide valuable *preparation* resources for evaluation, without which CD would provide little guidance on applying the dimensions. A notation called "ERMIA" (Green 1991) was proposed as a method of exploring dimensions. Interestingly, this notation seems to have been developed (Green and Benyon 1995, 1996) into a stand-alone UIM without dimensions. ERMIA is our second example of a tool resource (Rieman et al's automated CW was the first). Thus, as well as practical knowledge resources (list of cognitive dimensions), CD provides a tool resource that supports evaluation practices. The theoretical focus on opportunistic planning draws on work by Green's colleague Young at MRC Cambridge (Young and Simon 1987), and thus strongly resonates with the position on usability work in this chapter that evaluators do not systematically follow methods top down.

Our final reviewed UIM, *Pluralistic Walkthrough* (PW: Bias 1994), originated at IBM. In PW, an administrator leads a team of three diverse participants (a representative user, a product developer, and a usability specialist) who pretend to be system users. Each is given a set of hard copies of screens and task descriptions. For each screen, the participant is asked to write down in as much detail the next action (or set of actions) that the user would take to achieve the task and any comments they have about the screen. Once each participant has written down the next action, the screen is discussed. When the representative users have finished talking (e.g., about problems), the usability specialists and product developers talk (e.g., to explain the rationale of certain features). No assessment of this UIM has been published; however, there are clear potential benefits from *preparation* resources (hard copies of screens, task descriptions), and the combination of representative users, product developers, and usability specialists provides further discovery and analysis resources in the form of *knowledge of users* (from representatives), of the *product* being evaluated (from developers, who also provide *technical* background knowledge), and of *tasks* and *interaction* (from usability specialists). PW is distinct in adopting a *social* strategy to provide evaluation resources. Usability specialists draw up task descriptions, developers provide copies of relevant screens for the task, representatives provide user knowledge, and the administrator provides procedural knowledge of PW. In some ways, PW anticipated the recent and long overdue "turn to the social" in HCI evaluation research and practice, motivated by the opportunity to draw on evaluation resources that already exist within the project context. Unlike Spencer's (2000) restrictions on CW, PW treats project social interactions positively, rather than a potential negative source of disagreements.

56.4.3 Generic Resources for Usability Inspection

In addition to resources that are closely associated with particular UIMs, many resources are discussed outside the context of particular UIMs or are common to several. Table 56.2 summarizes some of the most important generic resources for usability inspection. First, *task selection and specification* are often key to preparation and provide a resource for many inspection and model-based approaches. As with individual differences, the selection of particular tasks has a large effect on the interaction with computers and hence on evaluation outcomes (Lindgaard and Chattratichart 2007). Sears and Hess (1999) described how the amount of detail in task description affected which problems were found in CW. Analysts who used detailed task descriptions found significantly more

TABLE 56.2
Generic Resources for Usability Inspection

Resource	Purposes	Examples
Task selection	Selecting and specifying tasks for inspection or user testing	Sears and Hess (1999)
Task walkthrough	Supporting inspection methods with ways of going through tasks and interfaces	Sears (1997)
Heuristics	Resources for discovering and thinking about usability defects	Hvannberg, Law, and Lárusdóttir (2007); Mankoff et al. (2003); Somervell and McCrickard (2005)
Reporting formats	Helping communicating problems and solutions for subsequent analysis, evaluation auditing, iteration, and customer communication	Cockton, Woolrych, and Hindmarch (2004); Capra and Smith-Jackson (2005); Theofanos and Quesenbery (2005)
Problem analysis and classification	Ways of classifying problems so as to analyze, merge, or reject them	Andre et al. (2001); Cuomo and Bowen (1992)
Problem merging	Identifying similar problems, for instance, through tool support or using different definitions of similarity	Connell and Hammond (1999); Hornbæk and Frøkjær (2008a); Howarth, Andre, and Hartson (2007)

low-severity problems, but fewer problems relating to feedback from the system, compared to evaluators who used less detailed descriptions. Similarly, obvious differences have been shown to exist in user testing between user-generated tasks and set tasks, and also between open-ended and closed tasks (Spool and Shroeder 2001), but little research has been conducted on the impact of task types within usability inspection.

Similarly, CW and related UIMs are the only ones to provide resources for guiding evaluative task walkthroughs. There is also considerable scope for research here to compare the costs and benefits of different task walkthrough procedures. For example, when using CW, once one of the four questions has been answered in the negative for one step, it may be the case that all subsequent task steps should have negative answers for the same question. Alternatively, the answer to a question may have to be deferred for several steps, until it can be confidently answered. This is especially the case for the fourth question: *if the correct action is performed, will the user see that progress is being made toward solution of the task?* This may not become clear for several steps after the correction action is performed. There is thus scope for streamlining task walkthroughs by propagating/deferring answers to later steps. However, the effectiveness of such streamlining needs to be demonstrated through research. The only relevant research here currently relates to the presence or absence of task walkthroughs (e.g., HE vs. HW, Sears 1997).

While HE provides the best known set of heuristics for usability inspection, *alternative heuristics* are possible: Hvannberg, Law, and Lárusdóttir (2007) have compared Nielsen's heuristics to Gerhardt-Powals' cognitive engineering principles. Mankoff et al. (2003) developed and tested a specialized set of heuristics for ambient displays. Somervell and McCrickard (2005) have developed similar heuristics for large-screen information exhibits through the use of a structured process that relies upon critical parameters. Muller et al. (1995) rightly claimed that Nielsen's (1994b) heuristics ignore usage contexts. They added three extra heuristics to assess how well a design fits user needs and the work environment:

1. Respect the user and his or her skills
2. Pleasurable experience with the system
3. Support quality work

These studies have shown how specific heuristic resources impact evaluation performance. Heuristic sets vary considerably in their generality and derivation (e.g., empirical for HE and EC, systematic focus for Somervell and McCrickard, theory for CD and Gerhardt-Powals), as well as in their structure and presentation (e.g., HE vs. EC). There is again considerable scope for practically oriented research that can isolate the varying impact of overall philosophies, systematic foci, structure and presentation, and formal derivation of heuristic sets. Effective innovation in any of these areas would improve evaluation performance using heuristic sets.

Task selection and task walkthrough procedures, plus heuristic focus, derivation and presentation are relevant to only UIMs that include or require them as resources. However, some resources are rarely provided or required by UIMs, and yet are unavoidable. For example, the way that usability problems are reported plays an important role in usability inspection, and thus report formats are potentially a key evaluation resource.

Cockton et al. (2003) demonstrated that an *extended problem reporting format* can positively impact evaluator performance on false positives and appropriate HE use, with results here replicated in Cockton, Woolrych, and Hindmarch (2004). This extended format required evaluators to explain how they found a possible problem and how they decided whether to confirm it as a probable problem or discard it as an improbable one. This appeared to have improved evaluators' self-awareness and repertoires when *looking for* possible problems, making problem discovery less tacit. It also appears to have improved self-awareness and repertoires when *analyzing* possible problems, encouraging them to carefully consider whether a possible problem should be treated as probable or improbable. More explicit behaviors appear to have been prompted by the need to explain problem discovery and analysis, confirming the wisdom of an earlier conjecture that having justifications for why something is a problem is important (Jeffries 1994); the downstream utility of problem descriptions seem to increase with such justifications (Hornbæk and Frøkjær 2006).

Structure and its content are generally created simultaneously for problem report formats, but adding a single content item to an existing format can significantly improve evaluation quality. For example, evaluators in a think aloud test were instructed to consider *business goals* while evaluating and to report, together with typical parts of problem reports, the importance of a problem in relation to business goals (Hornbæk and Frøkjær 2008b). Compared to a control group, this format made evaluators report fewer problems, but the problems reported were seen as being of more utility in the development process. Although the benefits of this report item were demonstrated for user testing, it is reasonable to assume that similar benefits would arise if used alongside UIMs and might be particularly useful for evaluators with limited knowledge of the business goals for an application. Such a small change with a potential large impact further illustrates the value of focusing UIM research on the impact of specific resources, rather than on the overall impact of highly variable incomplete "methods."

A further specific report format element is the *type* of the usability problem, for example, its severity class (e.g., Jeffries et al. 1991). Types may be based on a range of constructs, for example, by relation to stages in Norman's (1986) theory of action. Using such a coding scheme, a study (Cuomo and Bowen 1992, 1994) found that an early version of CW tended to focus on problems related to the formation of actions and was poor at finding problems concerned with evaluating the display. A similar coding approach was used for an assessment of a later version of CW (Sears and Hess 1999), which demonstrated the impact of short and (very) detailed task descriptions on analyst performance. The impact of each resource was assessed by coding problems by the CW question relevant to the prediction. Short task descriptions resulted in relatively more predictions related to finding actions (CW Question 2). Detailed descriptions (to the level of naming and locating controls) resulted in relatively more feedback-related predictions (CW Question 4). Sears and Hess (1999) explain the differences through the impact on how evaluators discovered problems. Detailed descriptions led to finding fewer action specification problems than short descriptions did, but left evaluators with the energy to look for feedback problems.

In most usability work, individual problems are predicted or discovered that are instances of more general and/or frequent user difficulties. Such individual problem instances need to be matched to reduce a large set of individual predictions or user difficulties to a master set. *Problem matching and merging* is a major source of confounds when comparing usability methods (Cockton and Lavery 1999; Connell and Hammond 1999; Hornbæk and Frøkjær 2008a; Lavery, Cockton, and Atkinson 1997). Hornbæk and Frøkjær (2008a) showed how differences in instructions for how to match usability problems significantly affected the number of problems that could not be matched with other problems (in a set of 55 problems): The degree to which a single problem type emerges from UIM use matters a lot to research, but in this study, it was strongly affected by how matching was performed. This is not only a problem for research, since usability practitioners must match and merge problems for inspections with multiple evaluators, suggesting that matching and merging are unavoidable in usability work. Once multiple evaluators are used as recommended for HE (Nielsen 1994), the evaluators require analytical resources for matching and merging problems. These analysis resources may be procedural (e.g., for use by a chief evaluator), structural (based on matching report format elements), or social (e.g., merging by a group of evaluators in face-to-face discussions). Matching and merging resources determine the final problem set (types with instances) that forms the basis for understanding and addressing usability problems within iterative development. They are thus no less vital a resource than heuristics (criteria, dimensions), task selection (as in HW), or task walkthrough procedures (CW, HW, PW), and yet, along with problem reporting formats, they have received very limited attention from UIM developers and assessors.

56.4.4 Evaluation Resource Types for Usability Inspection

We can thus see that a wide range of resources will impact evaluators, with some resources being particularly relevant to specific steps in usability inspection, with which we can associate a *logical* (rather than temporal) structure with logically distinct phases that overlap during inspection. Inspection is essentially a search problem. Evaluator behavior is close to the generate and test strategy from early artificial intelligence research, where possibilities are first generated (e.g., moves in a chess game) and then tested to identify possibilities with specific attributes (e.g., the best next move). Note that the role of evaluation does not extend to fixing problems, even though methods such as *Rapid Iterative Testing and Evaluation* (RITE) (Medlock et al. 2005) have problem fixing within scope. RITE is structured around three questions: Is it a problem? Do we understand it?, and Can we fix it? Only the first question and some of the second are within scope of evaluation methods. The rest of RITE (really understanding and fixing problems) is an *iteration* method with (empirically) grounded redesign decisions, based on all relevant project information.

In the first *logical phase*, evaluators study UIMs and related resources. Also, each time a UIM is configured, augmented, and applied, evaluators must study the target design in the form provided, as well as the intended usage context. These *preparation* steps are followed by two logical generate and test phases of UIM application, which is followed by a final reporting phase. We can thus model usability inspection as having four distinct logical phases: (1) analyst preparation, (2) candidate problem discovery, (3) confirmation or elimination of candidate problems, and (4) problem reporting, with initial support for problem understanding and change recommendation. This results in four major *uses* of evaluation resources: preparation, discovery, analysis, and reporting. Evaluator preparation has been given limited attention in the UIM research literature. A notable exception is the preparation of tutorial material for HE (Lavery, Cockton and Atkinson 1996a), CD (Lavery, Cockton and Atkinson 1996b) and other UIMS. This HE tutorial was used in Cockton and Woolrych (2001).

Most UIMs focus on discovery and analysis. The DARe model (Discovery and Analysis Resources, initially DR-AR, Woolrych and Cockton 2002) was formed when exploring HE's scope and accuracy (Woolrych 2001), especially the causes of false positives. In any predictive method, analysts inspect a design for potential usability problems. Where multiple evaluators use a UIM, their problems must be merged into a "master" problem set. This will invariably contain false positives (problems predicted by evaluators that are not problems for actual users). Now, these can *only* be problems that have been *incorrectly analyzed*. They could not have been incorrectly discovered, as *the only discovery error is a genuine miss*—analysis is responsible for all other errors. Not all false positives are predicted by every evaluator, leading to a question: can some analysts correctly eliminate these through a process of analysis as true negatives? This conjecture arises directly from the DARe model, with its two logical phases, where analysts first discover possible usability problems, then through analysis either confirm them as probable problems or eliminate them as improbable problems.

The DARe model guided research to focus on the evaluation resources used in usability inspection and particularly those that were not provided by the UIM in use. Studies of problem reports have identified seven groups of knowledge resources that can influence problem discovery and analysis (Woolrych, Cockton, and Hindmarch 2005):

- **User** (knowledge of/beliefs about users, especially experience and abilities)
- **Task** (knowledge of what users want to do and how they prefer to accomplish this)
- **Domain** (domain knowledge that is specific to the system being evaluated)
- **Design** (knowledge and experience of interaction design principles or beliefs in lieu of)

- **Interaction** (knowledge of how humans actually interact with computers)
- **Technical** (knowledge of platform technologies such as browsers and toolkits)
- **Product** (information about the system and its capabilities)

These resources are known as *Distributed Cognitive Resources* (DCRs), so called because they are unevenly and unpredictably *distributed* across project contexts (UIMs, evaluators, other project resources). Evaluator effects (Hertzum and Jacobsen 2001) can be explained via different individuals possessing and/or accessing DCRs in different ways during inspection. All types of DCR have already been encountered above when reviewing UIMs, but this empirical study (Woolrych, Cockton, and Hindmarch 2005) showed all in use with HE, which provides few of them directly. In principle, MOT promotes *user* resources, as did early versions of CW, and PW supplies them directly. CW, HW, MOT, and PW require *task* resources. Nielsen's studies of HE usage have highlighted the importance of *domain* resources, as has Cockton and Woolrych (2001). HE and EC distill both *design* and *interaction* resources into heuristics and criteria, respectively. PW also provides both, as well as *product* and *technical* information, through its involvement of specialists. CW and CD embody theories of interaction. EC requires some product information to be provided. However, HE neither provides nor prompts for all seven groups of DCR, and yet Woolrych, Cockton, and Hindmarch (2005) were able to identify multiple instances of each in HE problem reports. Student evaluators were clearly augmenting HE with personal resources (they lacked a project context that could have provided any additional DCRs). Two evaluators in Cockton and Woolrych (2001) were asked to not use a specific UIM, but were instead given specific tasks to complete. Inspections that require no resources beyond the evaluator are called *expert inspections*. Here, expert inspections were supplemented with tasks based on domain goals (copying diagrams with a drawing tool), discovering problems that over 90 other student evaluators using HE did not.

DCRs can be used for both discovery and analysis. Extended structured problem reports that require evaluators to externalize their discovery and analysis steps are needed to distinguish the use of a DCR for discovery from use for analysis. System-centered resources (design, product, technical), as well as user-centered ones (user, task, domain, interaction), can guide discovery. The use of knowledge resources can be structured or unstructured, resulting in four broad classes of *problem discovery method*. There are system-centered unstructured and structured methods: *system scanning* and *system searching*. HE distills interaction design knowledge into heuristics. If HE in any way supports problem discovery, it is through heuristics that focus attention on design features such as error messages and navigation. Similarly, there are user-centered unstructured and structured discovery methods: *goal playing* and *procedure following*. These two discovery methods either use contextual information about users, tasks and domains or they substitute evaluators' beliefs about them. CW relies exclusively on task information to find problems. Appropriate task, technical, and domain knowledge can aid analysts in valid problem discovery and analysis. Knowledge of tasks allows analysts to discover problems that require sophisticated levels of interaction with the system before they become obvious. Simple system-centered discovery approaches would be unlikely to discover such problems.

Incorrect beliefs about users often lead to false positives, whereas product and interaction knowledge can avoid them (through correct elimination of improbable problems). Knowledge of how people interact with computers can imply that apparent design flaws will have no impact, for example, because users will never notice them (selective attention) or because they can learn what they need through interaction (distributed cognition). Technical and design knowledge can be used to correctly confirm a problem. However, reuse of resources in both discovery and analysis introduces risk of confirmation bias. Using the same resources in analysis as discovery adds nothing and is thus a source of false positives (Cockton, Woolrych, and Hindmarch 2004).

56.4.5 Project-Based Resources for Usability Inspection

Methods are only one aspect of usability work and thus successes or failures cannot wholly be explained in terms of resources within approaches. Instead, resources within the surrounding project context can have as much, if not more, influence on success or failure than the textbook resources of evaluation approaches in HCI.

We make no attempt here to survey all the factors that have been shown to shape usability work, but instead focus on some research that considered the broader context of method use. Theofanos and Quesenbery (2005), for instance, listed a variety of factors that influence how to report results, including the size of the recipient company, the kind of products evaluated, the audience, and the existence/absence of a formal usability process. Similarly, the software development approach used in a development project will influence usability work. Sy (2007) described how various approaches to usability evaluation had to be modified to fit the agile software development approach. For instance, reporting of problems was done through the daily scrum meetings and in process planning sessions, rather than through reports, and thus specific evaluation resources were not needed here (although usability roles may well have kept their own informal records).

We now quickly list several factors of which we are aware from research that has addressed how project- and organization-specific factors influence configuration and combination of evaluation resources. These include the following:

1. Client needs and expectations
2. Design purpose and vision
3. Project-, product-, and service-specific prioritization criteria
4. Business context
5. Budgetary and other logistical resources (e.g., time available)

6. Project leadership and design champions
7. Development approach and stage
8. Relation of usability work to the overall software development approach
9. Experience and competence of usability practitioners
10. Training and tutorial support on evaluation approaches
11. Professional/specialist education on general discovery and analysis resources in evaluation
12. Field research methods (users, tasks, etc.) and result communication formats
13. Task specification and notations used at design stage
14. Participant and evaluator recruitment strategies
15. Alignment of design purpose and evaluation purpose

The first five factors relate to the client and their economic/market context (or policy context for public sector projects). The next six factors (6–11) relate to the development team, with a specific focus on management and expertise. The last four factors (12–15) relate to design activities (last two focus on evaluation). These factors, and many others not listed above, severely limit the ecological validity of formal comparisons of evaluation methods, even in the unlikely event of confounds being so well managed that no issues could arise here.

Few factors above could be addressed substantially by generic HCI evaluation resources. All, however, are present to some degree in actual project and organizational contexts. Currently, the bulk of the resources that are critical to working out methods within usability work are external to documented HCI evaluation approaches. Given this, academic attempts to "compare methods" are bound to "fail the practitioner" (Wixon 2003), since as far as providing comprehensive support for usability work is concerned, all current documented approaches have already failed practitioners to some extent by not providing them with comprehensive resources. However, much of the success of "discount methods" such as HE may be due to the sparseness and flexibility of the provided resources, which let skilled evaluators fill gaps with resources from personal, project, or organizational sources.

56.5 ASSESSING AND COMPARING USABILITY INSPECTION METHODS

Having identified the broad range of evaluation resources that are needed, but with few provided directly by UIMs, it should be clear that assessing and comparing UIMs could be a hopeless endeavor, since what actually gets used is *never the UIM alone* (at least for current UIMs), since evaluators must draw on DCRs beyond a UIM to be able to carry out usability work. However, it is still worth reviewing the two main broad approaches for assessing and comparing UIMs—one qualitative and the other quantitative. *Qualitative* approaches code predictions as a basis for scoping the capabilities and defects of UIMs. *Quantitative* approaches relate the performance of one method to another, often expressed as a percentage, for example, to express proportions of correctly predicted problems. We first review quantitative approaches and then review qualitative ones. The critiques of both approaches to assessing UIMs as complete wholes adds to the insurmountable challenges for direct assessment and scoping of "pure" UIMs, which are next summarized. With this critique in place, we review how resources beyond the assessed and compared UIMs can account for differences in evaluator performance as readily, if not more so, than the few evaluation resources that a UIM actually provides.

56.5.1 Summative Assessment and Comparison

The fundamental purpose of usability inspection is to find and report any potential user difficulties for remedy in redevelopment. Ideally, a UIM would find *all* usability problems that may arise from use of an interactive system; in other words, it would be *thorough* and, hence, not miss any elements that may cause user difficulties. The final problem set achieved through usability inspection would also only comprise *valid* problem predictions, with no false alarms reported. Consequently, finding all problems without false alarms, the result of a usability inspection would be wholly effective.

Unfortunately, any predictive methods such UIMs are not completely thorough nor are the predictions always valid with the subsequent impact on UIM effectiveness. *Validity*, *thoroughness*, and *effectiveness* are quantitative measures of UIM capability for which Sears (1997) suggested the following formulae:

$$\text{Validity} = \frac{\text{number of } \textit{real} \text{ usability problems } \textit{found} \text{ by UIM}}{\text{number of usability problems } \textit{predicted} \text{ by UIM}}$$

$$\text{Thoroughness} = \frac{\text{number of } \textit{real} \text{ usability problems } \textit{found} \text{ by UIM}}{\text{number of } \textit{real} \text{ problems that } \textit{exist}}$$

$$\text{Effectiveness} = \text{Validity} \times \text{Thoroughness}$$

The scores derived from the formula are between 0 and 1, where 1 would be the *perfect* score. Such scores are often expressed as percentages (e.g., 0.5 = 50%). For validity, a perfect score (of 1) would mean *all* problems found by the UIM would be real problems, that is, with no false alarms. Similarly, if the count of real problems found by the UIM equals the count of problems that exist, this too would result in a perfect thoroughness score of 1. With perfect thoroughness and validity, effectiveness too would also be a perfect 1 ($1 \times 1 = 1$), that is, *all predictions valid, no false alarms, all problems found*. With thoroughness of 0.7 and validity of 0.5, effectiveness would be 0.35.

Many assessments of UIMs have only used thoroughness as a quantitative measure and have shown, for example, how the use of multiple evaluators increases thoroughness (Nielsen and Landauer 1993). However, when validity is also calculated, the benefits of rising thoroughness are soon undermined by falling validity and hence reduced effectiveness (Cockton and Woolrych 2002). Giving equal weight to thoroughness and validity may not be suitable for all evaluation contexts (Hartson, Andre, and Williges 2001). However, relying solely on thoroughness and validity measures is inadvisable: as well as it being extremely difficult to calculate validity, they have no diagnostic power for explaining a lack of thoroughness or validity, and thus cannot guide the selection of complementary methods that can compensate for a UIM's weaknesses.

Two values in Sears' equations present severe research challenges. First, the denominator for thoroughness (number of real problems that exist) relies on the implicit *closure* of "all of the usability problems for a design," but "all" can never be determined confidently: there can always be undiscovered problems. All thoroughness measures are always upper bounds that reduce as newly discovered real problems increase the denominator. For the validity numerator (number of real usability problems found by UIM), we only need to find real usability problems that match those predicted by a UIM. Hence all validity measures are always lower bounds and increase if any newly discovered real problems match predictions, increasing the numerator.

While Sears' formulae are attractive and offer the simplest possible way of comparing UIMs, they rely on closures that mostly exist in mathematics (closure of a set under some operation). In the real world, we use the word *all* for *enumerations*, such as "prohibited items in carry-on baggage," where closure results from human decisions, and even this uses very broad categories (e.g., ammunition; automatic weapons; axes and hatchets, unless part of aircraft equipment; billiard cues; billy clubs; and blackjacks). However, *all* in the context of thoroughness has the sense of a closure and not an arbitrary human enumeration. Such conceptual dead ends are compounded by miscounts of problems that are discovered through user testing (the default source of number of *real* problems that *exist*). Evaluators appear to miss most problems in video data (Jacobsen, Hertzum, and John 1998), and further *miscounts* may arise from poor merging of usability problem sets (Cockton and Lavery 1999). Connell and Hammond (1999) showed that the impact of multiple evaluators on cumulative problem counts depends on how predicted problems are merged, resulting in a slower increase in cumulative thoroughness than showed in Nielsen and Landauer (1993). Also, specificity of description determines problem count according to Cockton and Lavery (1999). As usability problems become more specific, problem counts rise. For example, "misleading status bar messages" is one problem, but "incomplete prompts" and "technical vocabulary in message" are two, and more would result if we distinguished between prompt problems such as "no instruction to close free form with double click" or "no instruction to use control-click to delete vertices" (for drawing objects).

For thoroughness, *asymptotic testing* has been proposed as a means to ensure the highest possible denominator (Hartson, Andre, and Williges 2001). However, this is generally understood as continuing to test additional users using the same test protocol until no new problems emerge. Changing the test protocol, such as between different sets of fixed tasks, between free and fixed tasks, or between individual think aloud and peer tutoring, also reveals new problems (Lindgaard and Chattratichart 2007). Also, adding analysts and/or applying a structured method such as SUPEX could extract more problems from video data. As with most attempts at closure, methods to find *all* problems simply expose a further unachievable closure, that is, in *all of the ways to find all* the usability problems. However, maximizing the numerator for *validity* is more tractable. When real problems are found by fixed task testing, a *falsification methodology* can expose users repeatedly to predicted problems (Woolrych, Cockton, and Hindmarch 2004). Missed problems here will have two types of cause: errors in test task planning (which can be fixed) and an inability to put the system in a state where the problem would appear (which can be very difficult to achieve; Lavery and Cockton 1996).

Some quantitative measures are not prone to insurmountable mixes of conceptual and practical impossibilities. Cockton and Woolrych (2001) coded heuristic applications for nonbogus predictions as being appropriate or inappropriate, based on explicit criteria from the HE training manual (Lavery, Cockton, and Atkinson 1996a) provided for analysts. This provided conformance questions that stated, "What the system should do, or users should be able to do, to satisfy the heuristic" (p. 4). Such questions are answered with conformance evidence, such as the "design features or lack of design features that indicate partial satisfaction or breaches of the heuristic" (p. 4). For many heuristic applications, these criteria were clearly ignored. Only 39% of the heuristics applied to nonbogus predictions were appropriate (and only 31% for successful predictions). Such measures of appropriateness are important in identifying the extent to which problem discovery and analysis are due to UIM or other evaluation resources. Heuristics tended to be best applied to predictions that turned out to be of low frequency and/or severity. These were likely to be predictions that seemed less probable than ones that turned out to be of high frequency and/or severity, which presumably were so obvious that the 13 heuristics (Nielsen 1994a, plus three specific to visualization; Lavery, Cockton, and Atkinson 1996a) were not properly reviewed to strengthen analysis. Furthermore, given HE's known limited coverage, there may be no appropriate heuristic for some predictions. Nielsen (1994b) found that seven factors could only account for 30% of the variability in his corpus of 249 usability problems, and 53 factors were needed to account for 90%, too many for HE. The names of the seven factors, which were chosen by Nielsen, included "visibility of system status," "match between system and real world," and "error prevention." This supported his claim that the factors (the first seven heuristics in Figure. 56.1 along with 8 and 9) form a basis for a set of heuristics that has remained the main resource for HE; the 10th, "Help and Documentation," was later added. It is not clear, however, how much the additional three heuristics extend the coverage of the sample problem set beyond 30%, but this is very unlikely to reach 40%. As a result, HE cannot cover most likely usability problems, and the ones it does cover are not always high frequency ones.

56.5.2 Qualitative Approaches to Coding Usability Problems

Quantitative measures can be seductive, so it is important to approach them critically. Even if simple scores for thoroughness or validity could be reliably calculated (and to be clear, they cannot), identical scores could hide major differences in UIM performance (Woolrych and Cockton 2000). For example, two UIMs could have identical thoroughness scores, but one could systematically miss most severe problems, which has been shown to be true for HE (Cockton and Woolrych 2001) by *coding* successful predictions and missed problems for *discoverability*. The easiest problems to discover are *perceivable*: these can be seen at a glance. Next comes *actionable* problems: these can be discovered after a few simple actions (e.g., a mouse click). Hardest to find are *constructable* problems, which require complex task scenarios to reveal them. 80% of problems missed by evaluators using HE were constructable, as opposed to 7% of successful predictions. HE's limited use of task knowledge resources is responsible for missing usability problems that only arise in interaction sequences longer than a few simple actions.

Discoverability is a *qualitative* measure, requiring UIM assessors to code a problem as perceivable, actionable, or constructable. Useful codes delve below the surface of superficial quantitative measures to reveal the impact of a UIM's (lack of) evaluation resources. However, the ability to code for a specific measure depends on the contents of the reporting formats for usability problems. In an experiment to establish common ground for method assessment, Cockton and Woolrych (2009) analyzed eight multilingual usability report problem sets from various evaluation methods (HE, EC, user testing, expert inspection) in a variety of formats (e.g., research problem set, consultancy report). The problem reports were inspected for common elements that could be a basis for comparison through problem coding, including the following:

- Description of the usability problem
- The context in which the problem was discovered
- Evidence of how the usability problem was discovered
- Actual or predicted user difficulties relevant to the problem
- Evidence of the frequency of the problem
- Any suggested solutions to the problem

The only common element in all of the problem report sets was a problem description! The context of problem discovery was quite common in most (but not all) problem sets, but often within a problem description. Thus comparing UIMs on the basis of qualitative measures requires appropriate problem reporting formats. Identification of DCRs in research by the first two authors, and analysis of interactions between them, depended on the ability to code problem reports for the use of a range of evaluation resources and the ability to distinguish their separate use on discovery and analysis, which was not always possible. Severity codings were used in early studies of HE by the first two authors to reveal the interaction between appropriateness of heuristic use of the impact of actual problems. This suggested that appropriate heuristic use was a form of confirmation bias arising when considering predictions that turned out to have low frequency and/or severity in the set of actual problems revealed through falsification testing (Cockton and Woolrych 2001).

56.5.3 Why Comparisons of Usability Inspection Methods Fail to Produce Reliable Results

Initially, problems in comparing UIMs were attributed to poor experimental design. Gray and Salzman (1998) reviewed the validity of five major studies in the literature that compared the performance of different evaluation methods. They based their review on Cook and Campbell's (1979) four main types of validity: statistical conclusion validity, internal validity, construct validity, and external validity. They added a fifth type: conclusion validity. Gray and Salzman found validity problems with each study reviewed. For example, Jeffries et al. (1991) compared CW, expert inspection (but called HE), guidelines, and user testing and found expert inspection to be superior. However, the study used few evaluators and thus it is not clear if the effects of the study (e.g., the superiority of expert review) occurred by chance and lacked *statistical conclusion validity.*

Internal validity is threatened when the effect supposedly caused by a variable under manipulation is actually caused by a confounding variable. One study where expert review was shown to be superior may, however, suffer from internal validity because the experts were given a 2-week period at their own pace to complete the evaluation, whereas evaluators in the other conditions had far less time. The worst performing methods were used by software engineers with less usability expertise than the HE group. Here, *time* is revealed as an evaluation resource as well as additional DCRs that usability experts bring to evaluations.

Nielsen (1992) investigated the effects of evaluator expertise on the number of problems identified using HE and claims that "usability specialists were much better than those without usability expertise by finding usability problems with heuristic evaluation." Gray and Salzman claim this study lacks *conclusion validity* because it is not clear what the effect of HE was on the evaluator's ability to find usability problems or how many problems evaluators would find through expert review without recourse to HE's evaluation resources. They suggest the data supported the more modest claim that "experts named more problems than non-experts."

Gray and Salzman found that many studies presented conclusions that were not supported by the data. They do not argue against presenting advice based on experience rather than experimental evidence, but argue that the source of such advice should be made explicit. Since their critique, our knowledge of the range of evaluation resources that influences evaluator performance has significantly increased, both through attempts to avoid the methodological flaws identified by Gray and Salzman and by more recent realistic case studies of usability work. The former research tactics (avoiding methodological flaws) have exposed the impact of problem reporting formats, matching and merging procedures, and task selection resources on UIM performance. As only HW provides any such resources (task selection), no UIM can be assessed in isolation. It must be supplemented by other evaluation resources, which may themselves have a major impact on evaluator performance (as in Cockton et al. 2003). Studies of usability work have revealed an even wider range of evaluation resources that have far more impact on evaluation outcomes than resources provided by UIMs. Usability work requires evaluation resources that are rarely provided by UIMs, which thus cannot be compared by comparing the outcomes of evaluations, since these will be confounded by many evaluation resources in the study context. However, it is possible to manipulate a single resource such as a problem report format and hold other evaluation resources fairly constant (through randomization). Such focused studies, rather than crude comparisons of UIMs, are one important way forward in HCI research on evaluation methods. The methodological challenges identified by Gray and Salzman simply cannot be overcome, but there have been some useful spin offs from continued attempts to rigorously compare UIMs.

56.6 CHOOSING AND USING USABILITY INSPECTION METHODS

Based on the discussion so far, it should be clear that choosing, combining, and using UIMs are creative processes; simply picking an inspection method because it is easy to use or applicable early in a project is insufficient and likely to fail. Next we provide some guidance on planning usability inspections, but temper this with an overview of the need to select resources that can (and will) be provided by a specific project.

56.6.1 Planning Usability Inspections

The DCRs identified as a result of exploring the DARe model do not simply enumerate the groups of resources used in usability inspection; DCRs are also a checklist for things to think through when preparing for an inspection. For instance, many usability inspections fail because evaluators know too little about the product, users' tasks, and the domain to be supported. Many studies have documented how knowledge about these things may improve inspection, to the extent that some evaluation approaches successfully trade in the need for knowledge about interaction and technical issues for domain knowledge (e.g., Følstad 2007). In planning inspections, usability evaluators need to consider whether knowledge resources concerning products, users' tasks, and the domain are available and sufficient for the inspection. Ideally, project managers and usability specialists need to plan support for inspections from the project outset to ensure that the necessary resources are in place to support high quality inspection. Such resources have multiple uses beyond supporting usability inspection. They also support planning of participant recruitment and selection of tasks (when appropriate) for user testing and also design activities such as authoring personas and scenarios. Planning for usability inspections should not start just before inspections are scheduled. Instead, resources required for all user-centered design activities need to be identified early in a project and sourced in good time. Otherwise, it is unreasonable to expect usability inspection to have high *downstream utility* (John and Marks 1997), which would be achieved by correcting, identifying, and understanding problems and recommending appropriate design change recommendations on this basis. Downstream utility cannot compensate for *upstream futility;* if evaluators are not adequately supported, then poor quality inspections result. In this sense, the tactics underlying *discount methods* are misguided. While a UIM can be reduced to 10 heuristics, advice on using multiple evaluators and a very rough two pass procedure, the effectiveness of UIMs such as HE is substantially compromised by deficiencies across all DCRs.

The DCRs revealed via the DARe model indicate that many different resources enter usability inspection. This is in agreement with the recommendation that multiple analysts may improve inspection method thoroughness (Nielsen and Landauer 1993). The DARe model explains why multiple evaluators find more problems when the UIM and environment remain the same. Quite simply, as more evaluators are added, more problem discovery resources are added to the inspection, hence more problems are found. However, the DARe model also leads us to considering the impact of multiple evaluators on analysis resources. If evaluators are inclined to not reject problems at all or if they are unduly confident in confirming problems, then multiple evaluators will not only be collectively more thorough, and thus find more problems, but they will also be collectively less valid and thus predict more false positives (Cockton and Woolrych 2002).

The more recent focus on *usability work* has greatly extended DCRs with a broader understanding of project-specific resources, as discussed earlier. These too provide another checklist for planning evaluation support within software and hardware development projects. For instance, the *goal* of the evaluation is a consideration too frequently stepped over in planning. The goal may be a formative or a summative evaluation; a global evaluation or a targeted assessment of a feature; negotiated among stakeholders or relatively open; and to identify solutions or pinpoint difficulties. Being explicit about the goal and configuring usability work to reflect it is crucial: it especially supports the logical phases of confirmation or elimination of candidate problems and problem reporting. Furthermore, the goals of evaluation need to focus on design purpose (Cockton 2005). This can be encouraged by report formats that include a focus on business impact or other forms of design purpose (e.g., social or personal impact), as illustrated by Hornbæk and Frøkjær (2008b). As already noted, reporting formats and merging and matching procedures should also be considered. Again, when planning an inspection, considering these and other resources would provide useful input to planning. Throwing evaluation resources together in a rush is a recipe for ineffective poor quality inspections

Planning for usability inspection is thus best considered as one aspect of overall project management. While usability inspections can be "slipped in" at short notice into a project schedule and will always deliver some value, it is better to plan for them within an overall user-focused process, balancing other concerns such as business impact (e.g., for e-commerce sites) as appropriate. DCRs, including project-specific resources identified above, provide a checklist that can support planning. Advance planning allows time for careful consideration of heuristic sets, with project-specific amendments and extensions as necessary. It also allows time for careful consideration of severity scales, which must be closely related to design purpose. The severity of a usability problem is directly related to its impact on achieving the intended purpose for an interactive system or device. Severity problems increase as usability problems progressively degrade the value or worth that either users can gain from interaction or the achievable worth for other stakeholders such as website owners or other project. Without project-specific severity scales in place, evaluators must use *ad hoc* generic scales that are close to meaningless.

56.6.2 Matching Approach Resources to Project Resources

Project planning and resourcing will always be constrained by a range of internal and external considerations. For example, client needs and expectations will control what can and cannot be considered as evaluation resources. The first two authors have worked on a range of usability consultancies where the client insisted on exclusive use of user testing, even where it was clear from a brief "guerilla" inspection that much better value would arise for user testing if an inspection was followed by a set of design changes first. However, many clients find inspection methods too subjective and unscientific, even when evaluators can offer decades of combined usability expertise. This mirrors trends from surveys of usability professionals. HE was the most used usability method in a paper questionnaire-based survey of 111 usability professionals in 1999 (Rosenbaum, Rohn, and Humburg 2000). However, a more recent web survey of 83 usability professionals, with a detailed follow up for 16 respondents (Venturi, Troost, and Jokela 2006), now ranks inspection methods (38% of respondents use during design) well below discount user testing (quick and dirty usability tests used by 53%—in contrast to 70% and 65%, respectively, in the 1999 survey). Although surveys must be compared with great caution, UIMs may no longer be the predominant method in usability practice. User-based methods are increasingly preferred because, once selected and briefed, individual test participants generate many complete usage scenarios. Hence, user testing can expose problems through user behaviors that are very hard to anticipate. However, testing only reveals a wide possible range of usability problems if users stress the system with complex interactions across all features. It is thus possible to anticipate user difficulties that may not emerge during testing, unless specific efforts are made to flush out all predicted problems (Woolrych, Cockton, and Hindmarch 2004). However, UIMs are still in widespread use, sometimes because the cost and logistical challenges of recruiting test participants leads some clients to rule out user testing, placing the whole usability evaluation load on UIMs (including expert inspection).

One of the most important resources for evaluation is a clear sense of design purpose and project vision. Such a resource can be frustratingly rare, but without it makes it very difficult to devise adequate severity scales, nor is there a sound basis for prioritizing design changes on the basis of well grounded criteria. For commercial systems, it is important to relate purpose and priorities to the business context. Without such resources, there is limited support for considering business impact during usability inspections. As with other key evaluation resources, in the absence of information and/or adequate project leadership, usability specialists need to find ways to compensate for lack of support from project management. Even when there is clear vision and good project leadership, not all recommended resources for UIMs can be provided. For example, multiple evaluators have been shown to improve thoroughness for HE and other UIMs, but these evaluators have to be sourced, and finding 5–8 expert evaluators with HCI expertise will not be possible for most projects. However, usability leads may be able to provide some training in UIMs for other development staff. Alternatively, a Pluralistic Walkthrough (PW) can be chosen, with specialists with roles such as marketing, training, accessibility, support, or documentation providing alternative complementary expertise to the usability specialist.

Inspections need to take place as soon as any aspect of a design can be evaluated. UIMs provide their best value early in the development cycle. The longer design choices are adhered to, the harder it is to make changes as a result of an inspection, which is sometimes why clients require user testing, since more credible but more costly data may be needed to establish the need to undo existing expensively implemented design decisions. A common exception here are those web sites (e.g., e-commerce websites) that are often redesigned at set intervals, with a corresponding expectation that most existing design decisions can be revisited and revised if necessary.

56.7 FUTURE OF USABILITY INSPECTIONS: MAKING DIFFERENCES TO USABILITY WORK

UIMs are approaches that offer bundles of resources that can be adapted and complemented to support usability work. Thus, while there is much evidence of difficulties in UIM use, especially as regards evaluation quality, most problems associated with the use of UIM resources such as heuristics and walkthrough procedures are avoidable. Our view remains that, used with care, UIMs remain key approaches in the usability toolbox: "The challenge is to improve all HCI methods, so that discount methods are less discounted and 'full strength' methods can be applied in more contexts" (Cockton and Woolrych 2002, p. 29). The most appropriate use of UIMs is to drive design iterations, rather than use for summative evaluation, benchmarking, or competitor analysis. UIMs are cheap to apply and are seen as low cost and low skill (but more resources and expertise can greatly improve evaluation performance). They have been applied to many commercial designs by practitioners. UIMs can be used before a testable prototype has been implemented and can be iterated without exhausting or biasing a group of test participants. UIMs can also be a planning resource for user testing, which can be designed to focus on predicted problems. Development resources may rule out user testing, leaving UIMs as the only possible approach, and some usability is always better than no usability.

UIMs remain important and their weaknesses can be mitigated. The main risks are missing serious usability problems and wasting development effort through poor fixes to mispredicted nonproblems (false positives). Different business models make different demands; thus, UIM errors are more costly in some development contexts than others are. In some contexts, successful predictions may always be worthwhile despite a flood of false positives, as fixed problems translate into savings on support costs and attractive new features. When users buy software, most must struggle on, unlike visitors to free e-commerce sites, yet mainstream UIMs do not cover their complete user experience, especially for affective issues such as trust, comfort, and brand image. Hence, user testing is vital to eliminate any severe problems; otherwise, money will be lost.

Novice evaluators should learn how to configure and augment UIMs before practice on familiar systems and usage contexts to establish quickly their scopes and accuracies. No UIM provides contextual information or understandings of users and tasks (Cockton and Woolrych 2002). Fortunately, HCI professionals apply contextual research (Venturi, Troost, and Jokela 2006) even though some may not accept that contextual resources are not part of UIMs (Manning 2002). Novice UIM users need to be coached to properly augment UIM resources with an appropriate complement of DCRs and make full use of available project resources. In particular, evaluators must know about and understand the system they are inspecting. Some UIM developers disagree, preferring to keep analysts in untainted ignorance. They aim to induce user empathy, but this can only be truly grounded in contextual resources. Ungrounded beliefs about users and usage contexts can be very unreliable (and often insult real users' intelligence). If evaluators begin inspection ignorant of both the usage context and the system being evaluated, then the result is not better empathy with the user but incorrect claims that features are missing or beyond users. While there may be evidence of usability problems in such evaluator errors, they are still errors. Properly informed evaluators are more likely to note that a feature is hard to find (rather than absent) or that a design rationale has overlooked some contextual criteria. Such problem predictions are far preferable to bogus ones, which are major risks in UIM usage. In short, evaluator preparation is crucial to successful UIM usage.

By properly configuring and augmenting UIMs, evaluators can improve the quality of discovery and analysis resources. Knowledge of expected contexts of use, human capabilities, and key properties of HCI are critical. For example, knowledge of display-based interaction may eliminate possible problems that overlook users' abilities to discover information and to explore interactive behaviors. Knowledge of human capabilities such as visual attention may either confirm possible problems (e.g., key information in the wrong place) or eliminate them (e.g., misleading information in the wrong place).

Evaluators thus need to be expected to work to make UIMs work. However, in the next few years, we expect to see a growth of in-depth case studies of evaluation practices and outcomes in the HCI literature. Usability specialists will be able to draw on these case studies to improve their practice. Note here that the aim of HCI research on UIMs is moving away from method assessment and comparison towards studies of usability work. The aim is less to improve UIMs per se, but instead to improve their usage and to do so by improving evaluators through improved intelligence on the inspection process. At some point, a critical mass of well designed and well executed case studies will support derivation of complex system models of usability work, from which hypotheses can be derived. Well focused experimental studies can then be designed to test these hypotheses. At this point, the scientific knowledge sought in initial comparisons of UIMs will be more likely, but it will not take the form of simple rankings of UIMs, but instead deep understandings of the impact on evaluation performance of specific configurations and combinations of evaluation resources. Until then, expertise in usability inspection is primarily the responsibility of evaluators. UIMs themselves cannot be sufficiently improved to guarantee success. However, imaginative use of specific resources such as report formats and specialized heuristics can have disproportionate impacts. The core knowledge for usability inspection does not, thus, concern "methods" but resources. Evaluators need to understand the bases for quality for each evaluation resource and put this knowledge to the best effect when configuring and combining resources for usability inspection.

We expect the next few years to open up new research approaches for UIMs (Woolrych, Hornbæk, Frøkjær and Cockton 2012), which will feed through into education and practice. These new approaches will firstly focus within methods on different types of resource (e.g., knowledge, scoping, procedural, analytic) and the impact of variations for a single resource, and secondly above the method level on usability *work activities*. Methods are simply the wrong unit of analysis for understanding evaluation practice. By focusing on methods, research has not paid enough attention to variations within use of the same method, and has thus attributed specific impacts to methods that are actually impacts of specific resources. The impact of different formats and content for problem report formats has clearly demonstrated that specific resources can have disproportionate impacts on evaluation performance. Also, by focusing on individual evaluation methods, research has not paid enough attention to how sets of methods are selected, adapted and combined during usability work. What matters in usability work are the outcomes of specialist investigations and advice, and that is the result of complex interactions within a mix of contextual factors. Methods, or rather the bundling of resources into approaches, are only aspect of this mix. Methods have to be related to the big picture in interaction design work. We expect that this big picture will be a major focus of HCI research in the current decade, resulting in a much more sophisticated understanding of usability work and the role of methods within this.

57 Model-Based Evaluation

David Kieras

CONTENTS

57.1 INTRODUCTION

57.1.1 What Is Model-Based Evaluation?

Model-based evaluation is using a *model* of how a human would use a proposed system to obtain predicted usability measures by calculation or simulation. These predictions can replace or supplement empirical measurements obtained by user testing. In addition, the content of the model itself conveys useful information about the relationship between the user's task and the system design.

57.1.2 Organization of This Chapter

This chapter will first argue that model-based evaluation is a valuable supplement to conventional usability evaluation and then survey the current approaches for performing model-based evaluation. Because of the considerable technical detail involved in applying model-based evaluation techniques, this chapter cannot include "how to" guides on the specific modeling methods, but they are all well documented elsewhere. Instead, this chapter will present several high-level issues in constructing and using models for interface evaluation and comment on the current approaches in the context of those issues. This will assist the reader in deciding whether to apply a model-based technique, which one to use, what problems to avoid, and what benefits to expect. Somewhat more detail will be presented about one form of model-based evaluation, Goals, Operators, Methods, and Selection rules (GOMS) models, which is a well developed, relatively simple, and "ready to use" methodology applicable to many interface design problems. A set of concluding recommendations will summarize the practical advice.

57.1.3 Why Use Model-Based Evaluation?

Model-based evaluation can be best viewed as an alternative way to implement an iterative process for developing a usable system. This section will summarize the standard usability process and contrast it with a process using model-based evaluation.

57.1.3.1 Standard Usability Design Process

In simplified and idealized form, the standard process for developing a usable system centers on user testing of prototypes that seeks to compare user performance to a specification or identify problems that impair learning or performance. After performing a task analysis and choosing a set of benchmark tasks, an interface design is specified based on intuition and guidelines both for the platform/application style and usability. A prototype of some sort is implemented and then a sample of representative users attempts to complete the benchmark tasks with the prototype. Usability problems are noted, such as excessive task completion time or errors, being unable to complete a task, or confusion over what to do next. If the problems are serious enough, the prototype is revised and a new user test is conducted. At some point, the process is terminated and the product is completed, either because no more serious problems have been detected or because there is not enough time or money for further development. See Dumas (this volume) for a complete presentation of this iterative user-testing methodology.

The standard process is a straightforward, well-documented methodology with a proven record of success (Landauer 1995). The guidelines for user interface design, together with knowledge possessed by those experienced in interface design and user testing, add up to a substantial accumulation of wisdom on developing usable systems. There is no doubt that if this process were applied more widely and thoroughly, the result would be a tremendous improvement in software quality. User testing has always been considered the "gold standard" for usability assessment. However, it has some serious limitations—some practical and others theoretical.

57.1.3.2 Practical Limitations of User Testing

A major practical problem is that user testing can be too slow and expensive to be compatible with current software development schedules, and so a focus of human–computer interaction (HCI) research for many years has been a way to tighten the iterative design loop. For example, better prototyping tools allow prototypes to be developed and modified more rapidly. Clever use of paper mockups or other early user input techniques allows important issues to be addressed before making the substantial investment in programming a prototype. The so-called inspection evaluation methods seek to replace user testing with other forms of evaluation, such as expert surveys of the design or techniques such as cognitive walkthroughs (Cockton et al. this volume).

If user testing is really the best method for usability assessment, then it is necessary to come to terms with the unavoidable time and cost demands of collecting behavioral data and analyzing it, even in the rather informal manner that normally suffices for user testing. For example, if the system design were substantially altered on iteration, it would be necessary to retest the design with a new set of test users. While it is hoped that the testing process finds fewer important problems with each iteration, the process does not get any faster with each iteration—the same adequate number of test users must perform the same adequate number of representative tasks and their performance assessed.

The cost of user testing is especially pronounced in expert-use domains, where the user is somebody like a physician, a petroleum geologist, or an engineer. Such users are few and their time is valuable. This may make relying on user testing too costly to adequately refine an interface. A related problem is evaluating software that is intended to serve experienced users especially well. Assessing the quality of the interface requires a very complete prototype that can be used in a realistic way for an extended period of time so that the test users can become experienced. This drives up the cost of each iteration, because the new version of the highly functional prototype must be developed and the lengthy training process has to be repeated. Other design goals can also make user testing problematic: consider developing a pair of products for which skill is supposed to transfer from one to the other. Assessing such transfer requires prototyping both products fully enough to train users on the first and then training them on the second, to see if the savings in training time are adequate. Any design change in either of the products might affect the transfer, and thus require a repeat test of the two systems. This double-dose of development and testing effort is probably impractical except in critical domains, where the additional problem of testing with expert users will probably appear.

57.1.3.3 Theoretical Limitations of User Testing

From the perspective of scientific psychology, the user testing approach takes very little advantage of what is known about human psychology, and thus lacks grounding in psychological theory. Although scientific psychology has been underway since the late 1800s, the only concepts relied on by user testing are a few basic concepts of how to collect behavioral data. Surely more is known about human psychology than this! The fact is that user testing methodology would work even if there was no systematic scientific knowledge of human psychology at all—as long as the designer's intuition leads in a reasonable direction on each iteration, it suffices merely to revise and retest until no more problems are found. While this is undoubtedly an advantage, it does suggest that user testing may be a relatively inefficient way to develop a good interface.

This lack of grounding in psychological principles is related to the most profound limitation of user testing: it lacks a systematic and explicit representation of the knowledge developed during the design experience; such a representation could allow design knowledge to be accumulated, documented, and systematically reused. After a successful user testing process, there is no representation of how the design "works" psychologically to ensure usability—there is only the final design itself, as described in specifications or in the implementation code. These descriptions normally have no theoretical relationship to the user's task or the psychological characteristics of the user. Any change to the design, or to the user's tasks, might produce a new and different usability situation, but there is no way to tell what aspects of the design are still relevant or valid. The information on why the design is good, or how it works for users, resides only in the intuitions of the designers. While designers often have outstanding intuitions, we know from the history of creations such as the medieval cathedrals that intuitive design is capable of producing magnificent results, but is also routinely guilty of costly over-engineering or disastrous failures. We now know that medieval structures benefitted from the happy accident that building in stone is relatively fool-proof; intuitive design proved dangerous with more modern materials (Gordon 1978). Perhaps, because of the complex and rapidly developing nature of computer software, the experience of the usability field seems to be that the ordinary software developer's intuition is quite unreliable, and so the only widely accepted recipe for avoiding design failure is slow and expensive iterative design based on user testing.

57.1.3.4 Model-Based Approach

The goal of model-based evaluation is to get some usability results before implementing a prototype or testing with human subjects. The approach uses a *model* of the HCI situation to represent the interface design and produce predicted measurements of the usability of the interface. Such models are also termed *engineering models* or *analytic models* for usability. The model is based on a detailed description of the proposed design and a detailed task analysis; it explains how the users will accomplish the tasks by interacting with the proposed interface and uses psychological theory and parametric data to generate the predicted usability metrics. Once the model is built, the usability predictions can be quickly and easily obtained by calculation or by running a simulation. Moreover, the implications of variations on the design can be quickly explored by making the corresponding changes in the model. Since most variations are relatively small, a circuit around the revise/evaluate iterative design loop is typically quite fast once the initial model-building investment is made. Thus, unlike user testing, iterations generally get faster and easier as the design is refined.

In addition, the model itself summarizes the design and can be inspected for insight into how the design supports (or fails to support) the user in performing the tasks. Depending on the type of model, components of it may be reusable not in just different versions of the system under development, but in other systems as well. Such a reusable model component captures a stable feature of human performance, task structures, or interaction techniques; characterizing them contributes to our scientific understanding of HCI.

The basic scheme for using model-based evaluation in the overall design process is that iterative design is done first using the model and then by user testing. In this way, many design decisions can be worked out before investing in prototype construction or user testing. The final user testing process is required for two reasons. First, the available modeling methods only cover certain aspects of usability; at this time, they are limited to predicting the sequence of actions, the time required executing the task, and certain aspects of the time required to learn how to use the system. Thus, user testing is required to cover the remaining aspects. Second, since the modeling process is necessarily imperfect, user testing is required to ensure that some critical issue has not been overlooked. If the user testing reveals major problems along the lines of a fundamental error in the basic concept of the interface, it will be necessary to go back and reconsider the entire design; again model-based iterations can help address some of the issues quickly. Thus, the purpose of the model-based evaluation is to perform some of the design iterations in a lower-cost, higher-speed mode before the relatively slow and expensive user testing.

57.1.3.5 What "Interface Engineering" Should Be

Model-based evaluation is not the dominant approach to user interface development; most practitioners and academics seem to favor some combination of user testing and inspection methods. Some have tagged this majority approach as a form of "engineering." However, even a cursory comparison to established engineering disciplines (e.g., in an engineering handbook such as Merritt, Loftin, and Ricketts 1996) makes it clear that conventional approaches to user interface design and evaluation has little resemblance to an engineering discipline. In fact, model-based evaluation is a deliberate attempt to develop and apply true engineering methods for user interface design. The following somewhat extended analogy will help clarify the distinction and explain the need for further research in modeling techniques.

If civil engineering were done with iterative empirical testing, bridges would be built by erecting a bridge according to an intuitively appealing design and then driving heavy trucks over it to see if it cracks or collapses. If it does, it would be rebuilt in a new version (e.g., with thicker girders) and the trial repeated; the iterative process continues with additional guesses until a satisfactory result is obtained. Over time, experienced bridge-builders would develop an intuitive feel for good designs and how strong the structural members need to be, and so will often guess right. However, time and cost pressures will probably lead to cutting the process short by favoring conservative designs that are likely to work, even though they might be unnecessarily clumsy and costly.

Although very early bridge-building undoubtedly proceeded in this fashion, modern civil engineers do not build bridges by iterative testing of trial structures. Rather, in the early 1800s under the combined stimulus of developing mathematics, new materials, more challenging applications, and design failures (Beckett 1984; Buchanan 1989; Gordon 1978; Petrosky 1985; Pugsley 1976), engineering researchers and practitioners began to develop a body of scientific theory on the behaviors of structures and forces and a body of principles and parametric data on the strengths and limitations of bridge-building materials. By the mid-1800s, important bridges were designed based on mathematical models with extensive calculations; the models for new design concepts were sometimes verified using physical models of sub-components of the overall structure. From this theory and data, civil engineers can quickly construct models in the form of equations or computer simulations that allow them to evaluate the quality of a proposed design without having to physically construct a bridge (e.g., see Merrit, Loftin, and Ricketts 1996). Modeling is a central part of the design process.

The bridge is not built until the design has been tested and evaluated based on the models, and the models themselves checked for correctness, and the new bridge almost always performs correctly; enough so that final testing of the completed structure is not routinely done. When final testing has been done, it has served as final verification of a successful design, not as an iteration along the way to a final design. It is fair to say that starting in the mid-1800s bridges were routinely and successfully built in a single physical iteration!

Thus, an investment in theory development and measurement enables engineers to replace an empirical iterative process with a theoretical iterative process that is much faster and cheaper per iteration. Of course, the modeling process is fallible, and so designers include conservative safety factors in the analysis to cover errors or defects in materials and maintenance and occasionally make mistakes that result in incorrect designs. More importantly, occasionally the model for a new design is found to be seriously inaccurate—such as missing an important factor relevant to an innovative design—and a spectacular and deadly design failure is the result. While the failures are prominent, relative to the number of bridges built, design failures have been rare in the last century.

The claim is not that using engineering models is perfect or infallible, only that it saves time and money and thus allows designs to be more highly refined. In short, more design iterations results in better designs, and more iterations are possible if some of them can be done very cheaply using models.

Moreover, the theory and the model summarize the design and explain why the design works well or poorly. The theoretical analysis identifies the weak and strong points of the design, giving guidance to the designer where intuition can be applied to improve the design; a new analysis can then test whether the design has actually been improved. Engineering analysis does not result in simply static repetition of proven ideas. Rather, it enables more creativity because it is now possible to cheaply and quickly determine whether a new concept will work. Thus, novel and creative concepts for bridge structures have steadily appeared once the engineering models were developed—as was seen even in the nineteenth century and continue today.

Correspondingly, model-based evaluation of user interfaces is simply the rigorous and science-based techniques for how to evaluate user interfaces without user testing; it likewise relies on a body of theory and parametric data to generate predictions of the performance of an engineered artifact and explain why the artifact behaves as it does. While true interface engineering is nowhere as advanced as bridge engineering, useful techniques have been available for some time and should be more widely used. As model-based evaluation becomes more developed, it will become possible to rely on true engineering methods to handle most of the routine problems in user interface design, with considerable savings in cost and time and with reliably higher quality. As has happened in other branches of engineering, the availability of powerful analysis tools means that the designer's energy and creativity can be unleashed to explore fundamentally new applications and design concepts.

The fact that these methods are not as widely used as they could be should not be taken as evidence against their utility. Even in bridge engineering, the mathematical analyses were considered very difficult when first introduced, and many prominent engineers deprecated them in favor of more intuitive "practical" approaches (Gordon 1978; Buchanan 1989). Only as the design problems became more difficult did the value of mathematical methods become compelling, and after several decades, they became standard in engineering training and practice. Thus, we can expect that true user interface engineering methodology will take some time to be adopted, even as research continues.

57.1.4 Three Current Approaches

Research in HCI and allied fields has resulted in many models of HCI at many levels of analysis. This chapter restricts attention to approaches that have developed to the point that they have some claim, either practical or scientific, to being suitable for actual application in design problems. This section identifies three current approaches to modeling human performance that are the most relevant to model-based evaluation for system and interface design. These are task network models, cognitive architecture models, and GOMS models.

57.1.4.1 Task Network Models

In task network models, task performance is modeled in terms of a PERT-chart-like network of processes. Each process starts when its prerequisite processes have been completed and has an assumed distribution of completion times. This basic model can be augmented with arbitrary computations to determine the completion time and what its symbolic or numeric inputs and outputs should be. Note that the processes are usually termed “tasks,” but they need not be human-performed at all, but can be machine processes instead. In addition, other information, such as workload or resource parameters can be attached to each process. Performance predictions are obtained by running a Monte-Carlo simulation of the model activity, in which the triggering input events are generated either by random variables or by task scenarios. A variety of statistical results, including aggregations of workload or resource usage, values can be readily produced. The classic SAINT (Chubb 1981) and the commercial MicroSaint tool (Laughery 1989) are prime examples. These systems originated in applied human factors and systems engineering and are heavily used in system design, especially for military systems.

57.1.4.2 Cognitive Architecture Models

Cognitive architecture systems are surveyed by Byrne (this volume). These systems consist of a set of hypothetical interacting perceptual, cognitive, and motor components assumed to be present in the human and whose properties are based on empirical and theoretical results from scientific research in psychology and allied fields. The functioning of the components and their interactions are typically simulated with a computer program, which in effect produces a *simulated human* performing in a *simulated task environment* that supplies inputs (stimuli) to the simulated human, and reacts to the outputs (responses) produced by the simulated human. Tasks are modeled primarily by programming the cognitive component according to a task analysis, and then performance predictions are obtained by running the simulation using selected scenarios to generate the input events in the task. Because these systems are serious attempts to represent a theory of human psychological functions, they tend to be rather complex and are primarily used in basic research projects; there has been very limited experience in using them in actual design settings.

57.1.4.3 GOMS Models

GOMS models are the original approach to model-based evaluation in the computer user interface field; both the model-based evaluation approach and GOMS models were presented as methods for user interface design in the seminal Card, Moran, and Newell (1983) presentation of the psychology of HCI. They based the GOMS concept on the theory of human problem-solving and skill acquisition. In brief, GOMS models describe the knowledge of procedures that a user must have to operate a system, The acronym and the approach can be summarized as follows: the user can accomplish certain goals (G) with the system; operators (O) are the basic actions that can be performed on the system such as striking a key or finding an icon on the screen; methods (M) are sequences of operators that when executed accomplish a goal; selection rules (S) describe which method should be used in which situation to accomplish a goal, if there is more than one available. Constructing a GOMS model involves writing out the methods for accomplishing the task goals of interest and then calculating predicted usability metrics from the method representation.

There are different forms of GOMS models, systematized by John and Kieras (1996a,b), which represent the methods at different levels of detail and whose calculations can range in complexity from simple hand calculations to full-fledged simulations. John and Kieras pointed out that the different forms can be viewed as being based on different simplified cognitive architectures that make the models easy to apply to typical interface design problems and insulate the model-builder from many difficult theoretical issues. More so than any other model-based approach, GOMS models have a long and well-established track record of success in user interface design, although they are not used as widely as their simplicity and record would justify. Although still under development by researchers, GOMS models are emphasized in this chapter because in some forms they are a “ready to use” modeling methodology. Section 57.4 will describe their rationale more completely, but the reader is referred to John and Kieras (1996a,b) for a thorough discussion.

57.2 THEORETICAL BASIS FOR CHOOSING A MODEL-BASED EVALUATION TECHNIQUE

This section presents several key issues concerning the theoretical foundations of model-based evaluation, concerning the basic sources of information and applicability of the modeling approach. When choosing or evaluating a technique for model-based evaluation, the potential user should consider these issues; the techniques differ widely in how well they handle certain fundamental questions. The next section will focus on the practical problems of applying a modeling technique once it has been chosen. In both sections, the three basic approaches to model-based evaluation are commented on as appropriate. Advice is given to both the user of model-based evaluation and the developer of model-based techniques.

57.2.1 Psychological Constraints Are Essential

The concept of model-based evaluation in system design has a long history and many different proposed methods (for early surveys, see Pew et al. 1977; McMillan et al. 1989; Elkind et al. 1989). However, the necessary scientific basis for genuinely powerful models has been slow to develop. The key requirement for model-based evaluation is that building a model to evaluate a design must be a routine, production, or engineering activity and not a piece of basic scientific research on how human psychological factors are involved in a particular computer usage situation. This means that the relevant psychological science must not only be developed first, but also then systematized and encapsulated in the modeling methodology itself. That is, a modeling methodology must provide *constraints* on the content and form of the model, and these constraints must provide the psychological validity of the model as a predictor of human performance. In other words, if the model builder can do essentially anything in the modeling system, then the only way the resulting model can be psychologically valid is if the model builder does all the work to construct a valid psychological theory of human cognition and behavior in the task and then ensure that the constructed model accurately reflects this theory.

Of course, it takes tremendous time, effort, and training to construct original psychological theory, far more than should be necessary for most interface design situations. Although the decisions in truly novel or critical design situations might require some fundamental psychological research, most interface design situations are rather routine: the problem is to match a computer system to the user's tasks using known interface design concepts and techniques. It should not be necessary to be an expert researcher in human cognition and performance to carry this out.

Thus, the key role of a modeling system is to provide constraints based on the psychological science, so that a model constructed within the system has a useful degree of predictive validity. In essence, simply by using the modeling system according to its rules, the designer must be able to construct a scientifically plausible and usefully accurate model "automatically."

A simple series of examples will help make the point: computer user interfaces involve typing of arbitrary strings of text on the keyboard and pointing with a mouse. The time required to type on the keyboard and to point with a mouse is fairly well documented. If task execution times are of interest, an acceptable modeling system should include these human performance parameters so that the interface designer does not have to collect them or guess them.

Furthermore, because both hands are involved in typing strings of text, users cannot type at the same time as they move the mouse cursor; these operations must be performed sequentially, taking rather more time than if they could be done simultaneously. A modeling system should make it impossible to construct a model of an interface that overzealously optimizes execution speed by assuming that the user could type strings and point simultaneously; the sequential constraint should be enforced automatically. A high-quality modeling system would not only enforce this constraint, but also automatically include the time costs of switching between typing and pointing, such as the time to move the hand between the mouse and the keyboard. There are many such constraints on human performance, some of them quite obvious, as in these examples, and some very subtle. A good modeling system will represent these constraints in such a way that they are automatically taken into account in how the model can be constructed and used. Because of the subtleties involved, computational tools are especially valuable for constructing and using models because they can help enforce the psychological constraints and make it easier for the model-builder to work within them.

57.2.2 Brief History of Constraints in Modern Psychological Theory

Theoretical constraints are not easy to represent or incorporate; a coherent and rigorous theoretical foundation is required to serve as the substrate for the network of constraints, and suitable foundations were not constructed until fairly recently. Through most of second half of the twentieth century, psychological theory was mired in a rather crude form of information-processing theory, in which human activity was divided into information-processing stages, such as perception, memory, decision making, and action, usually depicted as a flowchart with a box for each stage, various connections between the boxes, and perhaps with some fairly simple equations that described the time required for each stage or the accuracy of its processing. However, there was little constraint on the possible data contained in each box or the operations performed there; a box could be of arbitrary complexity, and no actual explicit mechanism had to be provided for any of them. Such models were little more than a "visual aid" for theories posed in the dominant forms of informal verbal statements or rather abstract mathematical equations. Later, many researchers began to construct computer simulations of these "box models," which provided more flexibility than traditional mathematical models and also contributed more explicitness and rigor than traditional verbal models. But still the operations performed in each box were generally unstructured and arbitrary.

An early effort at model-based evaluation in this theoretical mode appears in the famous human operator simulator (HOS) system (see Wherry 1976; Pew et al. 1977; Strieb and Wherry 1979; Lane et al. 1981; Glenn, Zaklad, and Wherry 1982; and Harris, Iavecchia, and Bittner 1988; Harris, Iavecchia, and Dick 1989). HOS contained a set of *micromodels* for low-level perceptual, cognitive, and motor activities, invoked by task-specific programs written in a special-purpose procedural programming language called HOPROC (human operator procedures language). The micromodels included such things as Hick's and Fitts' Law, formulas for visual recognition time, a model of short-term memory retention, and formulas for calculating the time required for various motor actions such as pushing buttons and walking. The effort was ambitious and the results impressive, but in a real sense, HOS was ahead of its time. The problem was that psychological theory was not well enough developed at the time to provide a sound foundation for such a tool; the developers were basically trying to invent a cognitive architecture good enough for practical application before the concept had been developed in the scientific community. Interestingly, the spirit of the HOPROC language lives on in the independently developed notations for some forms of GOMS models. In addition, the scientific base for the micromodels was in fact very sparse at the time, and many of them are currently out of date empirically and theoretically. HOS appears to have been subsumed into some commercial modeling systems; for example, a task network version of HOS is available from Micro Analysis and Design, Inc. (http://www.maad.com/), and its micromodels are used in their integrated performance modeling environment (IPME), as well as CHI System's COGNET/IGEN (http://www.chiinc.com/).

The task network models also originated in this box-model mode of psychology theory and show it in their lack of psychological constraints; their very generality means they contribute little built-in psychological validity. Even if the HOS micromodels are used, the flexibility of the modeling system means that model-builders themselves must identify the psychological processes and constraints involved in the task being modeled and program them into the model explicitly.

Led by Anderson (1983) and Newell (1990), researchers in human cognition and performance began to construct models using a *cognitive architecture* (see Byrne, this volume). Cognitive architecture parallels the concept of computer architecture: a cognitive architecture specifies a set of fixed mechanisms, the "hardware," that comprise the human mind. To construct a model for a specific task, the researcher "programs" the architecture by specifying a psychological strategy for doing the task, the "software" (specifying parameter value settings and information in memory might be involved as well.) The architecture provides the coherent theoretical framework within which the processes and constraints can be proposed and given an explicit and rigorous definition. Several proposed cognitive architectures exist in the form of computer simulation packages in which programming the architecture is done in the form of production systems, collections of modular if-then rules, which have proved to be an especially good theoretical model of human procedural knowledge. Developing these architectures, and demonstrating their utility, is a continuing research activity (see Byrne, this volume). Not surprisingly, they all have a long way to go before they accurately incorporate even a subset of the human abilities and limitations that appear in an HCI design context.

The psychological validity of a model constructed with a cognitive architecture depends on the validity of both the architecture and the task-specific programming, and so it can be difficult to assign credit or blame for success or failure in modeling an individual task. However, the fixed architecture and its associated parameters are supposed to be based on fundamental psychological mechanisms that are required to be invariant across all tasks, while the task-specific programming is free to vary with a particular modeled task. To the extent that the architecture is correct, one should be able to model any task simply by programming the architecture using only task-analytic information and supplying a few task-specific parameters. The value of such architectures lies in this clear division between universal and task-specific features of human cognition; the model builder should be free to focus solely on the specific task and system under design and let the architecture handle the psychology.

A key property of most current architectures is the insistence on a small number of fundamental mechanisms that provide a comprehensive and coherent system. For example, several of the scientifically successful cognitive architectures require that all cognitive processing must be expressed in the form of production rules that can include only certain things in their conditions and actions. These rules control all the other components in the architecture, which in turn have strictly defined and highly limited capabilities. These highly constrained systems have been successful in a wide range of modeling problems, showing that to be useful in both scientific and practical prediction, the possible models must be constrained—too many possibilities are not helpful, but harmful.

Achieving this goal in psychological research is a daunting challenge. What about the practical sphere? In fact, the role of architectural constraints in some of the extant commercial modeling systems is problematic. The task network models basically have such an abstract representation that there is no straightforward way for architectural assumptions to constrain the modeling system. Once one has opted for representing human activity as a set of arbitrary interconnected task processes, there is no easy way to somehow impose more constrained structure and mechanism on the system. Attempting to do so simply creates more complexity in the modeling problem—the modeler must figure out how to *underuse* the *over-general* capabilities of the system in just the right way.

At the other extreme, a modeling system that attempts to cover the higher aspects of human cognition by providing complex architectures, such as COGNET/IGEN (see Zachary et al. 2000, for a relatively complete description) can have the form of a cognitive architecture, but as argued more below, as a practical matter, it is difficult to analyze these aspects in a routine interface design problem. From the point of view of cognitive architectures and the constraints supplied by the architecture, the modeling approaches described in this chapter, as currently implemented, span the range from little or no architectural content or constraints (the task network systems) to considerable architectural complexity and constraints (the cognitive-architecture systems). GOMS models occupy an intermediate position: they assume a simplified, but definitely constraining, cognitive architecture that allows them to be applied easily by interface designers and still produce usefully accurate results. But at the same time, they are less flexible than the modeling systems at the other extremes.

57.2.3 Modeling Cognitive versus Perceptual-Motor Aspects of a Design

As pointed out by Byrne (this volume), cognitive architectures have lately begun to incorporate not just proposed cognitive mechanisms, but also proposals for perceptual and motor mechanisms that act as additional sources of constraint on performance. Calling these a "cognitive" architecture is something of a misnomer, since perceptual and motor mechanisms are normally distinguished from cognitive ones. However, including perceptual and motor constraints is actually a critical requirement for modeling user interfaces; this follows from the traditional characterization of HCI in terms of the interactive cycle (Norman 1986). The user sees something on the screen if they are looking in the right place and can sense and recognize it, involving the perceptual system and associated motor processes such as eye movements. The user decides what to do, an exclusively cognitive activity, and then carries out the decision by performing motor actions that are determined by the physical interaction devices that are present and may also involve the perceptual system, such as visual guidance for mouse pointing.

Occasionally, the cognitive processes of deciding what to do next can dominate the perceptual and motor activities. For example, one mouse click might bring up a screen containing a single number, such as a stock price, and the user might think about it for many minutes before simply clicking on a "buy" or "sell" button. But in many user interface settings, users engage in a stream of routine activities that require only relatively simple cognitive processing, and so the perceptual and motor actions take up most of the time and determine most of the task structure. Two implications follow from this thumbnail analysis.

57.2.3.1 Modeling Purely Cognitive Tasks Is Generally Impractical

Trying to model purely cognitive tasks such as human problem-solving, reasoning, or decision-making processes is extremely difficult because they are so open-ended and unconstrained (see also Landauer 1995). For example, there are a myriad possible ways in which people could decide to buy or sell a stock, and the nature of the task does not set any substantial or observable constraints on how people might make such decisions—stock decisions are based on everything from gut feel to transient financial situations, to detailed long-term analysis of market trends, and to individual corporate strategies. Trying to identify the strategy that a user population will follow in such tasks is not a routine interface design problem, but a scientific research problem, or at least a very difficult task analysis problem. Fortunately, a routine task analysis may produce enough information to allow the designer to *finesse* the problem, that is, side-step it or avoid having to confront it. For example, if one could determine what information the stock-trader needs to make the decisions and then make that information available in an effective and usable manner, the result will be a highly useful and usable system without having to understand exactly how users make their decisions.

57.2.3.2 Modeling Perceptual-Motor Activities Is Critical

A good modeling approach at a minimum must explicitly represent the perceptual and motor operations involved in a task. For most systems, the perceptual and motor activities involved in interacting with a computer take relatively well-defined amounts of time, are heavily determined by the system design, and frequently dominate the user's activity; leaving them out of the picture means that the resulting model is likely to be seriously inaccurate. For example, if two interface designs differ in how many visual searches or mouse points they logically require to complete a task, the one requiring fewer is almost certainly going to be faster to execute and will probably have a simpler task structure as well, meaning it will probably be easier to learn and less error-prone. Since perceptual-motor activities are relatively easy to model, it can be easy to get fairly reliable and robust model-based evaluation information in many cases. This means that any modeling approach that represents the basic timing and the structure of perceptual and motor activity entailed by an interface is likely to provide a good approximation to the basic usability characteristics of the interface. One reason why GOMS models work so well is that they allow the modeler to easily represent perceptual-motor activity.

57.2.4 Science Base Must Be Visible

Even though the modeling methodology encapsulates the constraints provided by psychological theory, it is critical that the psychological assumptions be accessible, justified, and intelligible. An architecture is the best way to do this, because the psychological assumptions are either hard-wired into the modeling system architecture or are explicitly stated in the task-specific programming supplied by the modeler. The basis for the task-specific programming is the task analysis obtained during the overall design process, and the basis for the architecture is a documented synthesis of the scientific literature.

The importance of the documented synthesis of the scientific literature cannot be overstated. The science of human cognition and performance that is relevant to system design is not at all "finished"; important new results are constantly appearing, and many long-documented phenomena are incompletely understood (e.g., Kieras 2009). Thus, any modeling system will have to be updated repeatedly as these theoretical and empirical issues are thrashed out, and it will have to be kept clear which results it incorporates and which it does not.

The commercial modeling tools have seriously lagged behind the scientific literature; while some conservatism would be desirable to damp out some of the volatility in scientific work, the problem is not just conservatism, but rather obsolescence, as in the case of the micromodels inherited from HOS. Perhaps these systems would still be adequate for practical work but, unfortunately, it is very difficult to get a scientific perspective on their adequacy because they have been neither described nor tested in forums and under ground rules similar to those used for mainstream scientific work in human cognition and performance. Thus, they have not been subject to the full presentation, strict review, criticism, and evolution that are characteristic of the cognitive architecture and GOMS model work. The practitioner should, therefore, greet the claims of commercial modeling system with healthy skepticism and developers of modeling systems should participate more completely in the open scientific process.

57.2.5 Value of Generativity

It is useful if a modeling method is *generative*, meaning that a single model can *generate* predicted human behavior for a whole class of scenarios, where a scenario is defined solely in terms of the sequence of input events or the specifications for a task situation, neither of which specifies the behavior the user is expected to produce. Many familiar modeling methods, including the Keystroke-Level type of GOMS model, are nongenerative, in that they start with a specific scenario in which the model builder has specified, usually manually, what the user's actions are supposed to be for the specified inputs. A nongenerative model predicts metrics defined only over this particular input–output sequence. To see what the results would be for a different scenario, a whole new model must be constructed (though parts might be duplicated). Since nongenerative modeling methods are typically labor intensive, involving a manual assignment of user actions to each input–output event, they tend to sharply limit how many scenarios are considered, which can be very risky in complex or critical design problems. Modern computer-based analytic tools can help overcome this limitation by making it easy to reuse parts of scenario, as in CogTool, described later.

An example of a sophisticated nongenerative modeling method is the CPM-GOMS models developed by Gray, John, and Atwood (1993) to model telephone operator tasks. These models decomposed each task scenario into a set of operations performed by perceptual, cognitive, and motor processors likes those proposed in the Card, Moran, and Newell (1983) model human processor. The sequential dependencies and time durations of these operations were represented with a PERT chart, which then specified the total task time and whose critical path revealed the processing bottlenecks in task performance. Such models are nongenerative in that a different scenario with a different pattern of events requires a different PERT chart to represent the different set of process dependencies. Since there is a chart for each scenario, predicting the time for a new scenario, or different interface design, requires creating a new chart to fit the new sequence of events. However, a new chart can often be assembled from templates or portions of previous charts, saving considerable effort (see John and Kieras 1996a,b for more detail).

However, if a model is generative, a single model can produce predicted usability results for any relevant scenario, just like a computer program for calculating the mean of a set of numbers can be applied to any specific set of values. A typical hierarchical task analysis (HTA) (see Annett et al. 1971; Kirwan and Ainsworth 1992) results in a generative representation, in that the HTA chart can be followed to perform the task in any subsumed situation. The forms of GOMS models that explicitly represent methods (see John and Kieras 1996a,b) are also generative. The typical cognitive-architecture model is generative in that it is programmed to perform the cognitive processes necessary to decide how to respond appropriately to any possible input that might occur in the task. In essence, the model programming expresses the general procedural knowledge required to perform the task, and the architecture, when executing this procedural knowledge, supplies all the details; the result is that the model responds with a different specific time sequence of actions to different specific situations.

For example, Kieras, Wood, and Meyer (1997) used a cognitive architecture to construct a production-rule model of some of the telephone operator tasks studied by Gray, John, and Atwood (1993). Because the model consisted of a general "program" for doing the tasks, it would behave differently depending on the details of the input events; for example, greeting a customer differently depending on information on the display and punching function keys and entering data depending on what the customer says and requires. Thus, the specific behavior and its time course of the model depend on the specific inputs, in a way expressed by a single set of general procedures.

A generative model is typically more difficult to construct initially, but because it is not bound to a specific scenario, it can be directly applied to a large selection of scenarios to provide a comprehensive analysis of complex tasks. The technique is especially powerful if the model runs as a computer simulation in which there is a *simulated device* that represents how the scenario data results in specific display events and governs how the system will respond to the user and the *simulated human*, which is the model of how the user will perform the task. The different scenarios are just the input data for the simulation, which produces the predicted behavior for each one. Furthermore, because generative models represent the procedural knowledge of the user explicitly, they readily satisfy the desirable property of models described earlier: the content of a generative model can be inspected to see how a design "works" and what procedures the user must know and execute.

57.2.6 Role of Detail

In the initial presentation above, the reader may have noticed the emphasis on the role of detailed description, both of the user's task and the proposed interface design. Modeling has sometimes been criticized because it appears to be unduly labor intensive. Building a model and using it to obtain predictions may indeed involve substantial detail work. However, working out the details about the user's task and the interface design is, or should be, a necessary part of any interface design approach; the usability lies in the details, not the generalities (Whiteside et al. 1985). If the user's task has not been described in detail, chances are that the task analysis is inadequate and a successful interface will be more difficult to achieve; extra design iterations may be required to discover and correct deficiencies in the original understanding of the user's needs. If the interface designer has not worked out the interface design in detail, the prospects of success are especially poor. The final form of an interface reflects a mass of detailed design decisions; these should have been explicitly made by an interface designer whose focus is on the user, rather than the programmers who happen to write the interface code. So the designer has to develop this detail as part of any successful design effort. In short, using model-based evaluation does not require any more detail than should be available anyway; it just requires that this detail be developed more explicitly and earlier than is often the case. Tools such as CogTool, described below, are promising because they evnable UI designers to easily explore alternative design prototypes in detail and also calculate usability metrics based on these details.

57.2.6.1 Cognitive Architectures Are Committed to Detail

Cognitive architecture systems are primarily research systems dedicated to synthesizing and testing basic psychological theory. Because they have a heavy commitment to characterizing the human cognitive architecture in detail, they naturally work at an extremely detailed level. The current cognitive architecture systems differ widely in the extent to which they incorporate the most potent source of practical constraints, namely perceptual-motor constraints, but at the same time, they are committed to enabling the representation of a comprehensive range of very complex cognitive processes, ranging from multitask performance to problem-solving and learning. Thus, these systems are generally very flexible in what cognitive processes they can represent within their otherwise very constrained architectures.

However, the detail has a downside. Cognitive architectures are typically difficult to program, even for simple tasks, and have the further drawback that, as a consequence of their detail, currently unresolved psychological issues can become exposed to the modeler for resolution. For example, the nature of visual short-term memory is rather poorly understood at this time, and no current architecture has an empirically sound representation of it. Using one of the current architectures to model a task in which visual short-term memory appears to be prominent might require many detailed assumptions about how it works and is used in the task, and these assumptions typically cannot be tested within the modeling project itself. One reason is the difficulty discussed below of getting high-precision data for complex tasks. But the more serious reason is that, in a design context, data to test the model is normally not available because there is not yet a system to collect the data with! Less detailed modeling approaches such as GOMS may not be any more accurate, but they at least have the virtue of not side-tracking the modeler into time-consuming detailed guesswork or speculation about fundamental issues. See Kieras (2005b) for more discussion.

57.2.6.2 Task Networks Can Be Used before Detailed Design

Although model-based evaluation works best for detailed designs, the task network modeling techniques were developed to assist in design stages before detailed design, especially for complex military systems. For example, task network modeling was used to determine how many human operators would be required to properly man a new combat helicopter. Too many operators drastically increase the cost and size of the aircraft; too few means the helicopter could not be operated successfully or safely. Thus, questions at these stages of design are what capacity (in terms of the number of people or machines) is needed to handle the workload and what kinds of work need to be performed by the each person or machine.

In outline, these early design stages involve first selecting a *mission profile*, essentially a high-level scenario that describes what the system and its operators must accomplish in a typical mission, then developing a basic *functional analysis* that determines the functions (large-scale operations) that must be performed to accomplish the mission and what their interactions and dependencies are. Then the candidate high-level design consists of a tentative *function allocation* to determine which human operator or machine will perform each function (see Beevis et al. 1992). The task network model can then be set up to include the tasks and their dependencies, and simulations run to determine execution times and compute workload metrics based on the workload characteristics of each task.

Clearly, entertaining detailed designs for each operator's controls or workstation is pointless until such a high-level analysis determines how many operators there will be and what tasks they are responsible for. Note that the cognitive-architecture and GOMS models are inherently limited to predicting performance in detailed designs, because their basic logic is to use the exact sequence of activities required in a task to determine the sequence of primitive operations. However, as will be discussed later, recent work with *high-level GOMS models* suggests an alternative approach in which a GOMS model using abstract or high-level operators to interact with the device can be developed first and then elaborated into a model for a specific interface as the design takes shape. But at this time, for high-level design modeling, the task-network models appear to be the best, or only, choice.

However, there are limitations that must be clearly understood. The ability of the task network models to represent a design at these earliest stages is a direct consequence of the fact that these modeling methods do not have any detailed mechanisms or constraints for representing human cognition and performance. Recall that the tasks in the network can consist of any arbitrary process whose execution characteristics can follow any desired distribution. Thus, the tasks and their parameters can be freely chosen without any regard to how a human will be actually doing them in the final version of the system. Hence this early-design capability is a result of a lack of theoretical content in the modeling system itself.

While the choice of tasks in a network model is based on a task analysis, the time distribution parameters are more problematic—how does one estimate the time required for a human to perform a process specified only in the most general terms? One way is to rely on empirical measurements of similar tasks performed in similar systems, but this requires that the new system must be similar to a previous system not only at the task-function level, but at least roughly at the level of design details.

Given the difficulty of arriving at task parameter estimates rigorously, a commonly applied technique is to ask a subject matter expert to supply *subjective estimates* of task time means and standard deviations and workload parameters. When used in this way, a task-network model is essentially a mathematically straightforward way to start with estimates of individual subtask performance, with no restrictions on the origin or quality of these estimates and then to combine them to arrive at performance estimates for the entire task and system.

Clearly, basing major design decisions on an aggregation of mere subjective estimates is hardly ideal, but as long as a detailed design or preexisting system is not available, there is really no alternative to guide early design. In the absence of such analyses, system developers would have to choose an early design based on "gut feel" about the entire design, which is surely more dangerous.

Note that if there is a detailed design available, the task-network modeler could decompose the task structure down to a fine enough level to make use of basic human performance parameters, similar to those used in the cognitive-architecture and GOMS models. For example, some commercial tools allow using the HOS micromodels to produce fine-grained task time predictions. However, it is hard to see the advantage in using task network models for detailed design. The networks and their supplementary executable code would seem to be less suitable to the design process than the conceptually simple task procedure descriptions used in GOMS models or the highly flexible and modular structure of production systems current popular in cognitive architectures.

Another option would be to construct GOMS or cognitive architecture models to produce time estimates for the individual tasks and use these in the network model instead of subjective estimates. This might be useful if only part of the design has been detailed, but otherwise, staying with a single modeling approach would surely be simpler. If one believes that interface usability is mostly a matter of getting the details right, along the lines originally argued by Whiteside et al. (1985) and verified by many experiences in user testing, modeling approaches that naturally and conveniently work at a detailed design level will be especially valuable.

57.3 PRACTICAL ISSUES IN APPLYING A MODEL-BASED EVALUATION TECHNIQUE

Once a model-based evaluation technique is chosen, there are some practical issues that arise in seeking to apply the technique to a particular user interface design situation. This section presents several of these issues.

57.3.1 Creating the Simulated Device

As mentioned earlier, the basic structure of a model used for evaluation is that a simulated human representing the user is interacting with a simulated device that represents the system under design. In parallel with Norman's interactive cycle, the simulated human receives simulated visual and auditory input from the simulated device and responds with simulated actions that provide input to the simulated device, which can then respond with different visual and auditory inputs to the human. Depending on the level of generativity and fidelity of the model, the simulated device can range from being a dummy device that does nothing in response to the simulated human interaction to a highly detailed simulation of the device interface and functionality. An example of a dummy device is the device that is assumed in the Keystroke-Level Model, which is not at all explicitly defined; the modeler simply assumes that a specific sequence of user actions will result in the device doing the correct thing. At the other extreme are models such as the ones used by Kieras and Santoro (2004), which actually implemented significant portions of the logical functionality of a complex radar workstation and the domain of moving aircraft and ships. In modeling situations where a generative model is called for, namely a complex task domain with multiple or lengthy detailed scenarios, a fully simulated device is the most convenient way to ensure that a simulated human is in fact performing the task correctly and to easily work with more than one scenario for the task situation.

It is important to realize that the simulated device does not have to implement the actual interface whose design is being evaluated. Rather, it suffices to produce abstract psychological inputs to the simulated human. For example, if a red circle is supposed to appear on the screen, the simulated device can merely signal the simulated human with an abstract description that an object has appeared at certain (x, y) coordinates that has a "shape" of "circle" and a "color" of "red." It is not at all necessary for the simulated device to actually produce a human-viewable graphical display containing a circular red area at a certain position.

A lesson learned by Kieras and Santoro (2004) was that the effort required to construct even such an abstract simulated device in a complex domain is a major part of the modeling effort and is more difficult in some ways than constructing the models of the simulated users! Clearly, to some extent, this effort is redundant with the effort required to develop the actual system and so can undermine the rationale for modeling early in the design and development process.

A common response to this problem is to seek to connect the cognitive architecture directly to an intact application or system prototype that plays the role of the simulated device, in short, replacing the simulated device with an actual device. Work such as St. Amant and Reidl (2001) provides a pathway for interfacing to an intact application: the technique is basically to use the existing API of the application platform (e.g. Windows) to capture the screen bitmap and run visual object recognition algorithms on it to produce the description of the visual inputs to the simulated human, and outputs from the simulated human can be directly supplied to the platform to produce keyboard input or to control the cursor position. Even for the limited domain of Windows applications using the standard GUI objects, this is technically challenging, but quite feasible.

A less ambitious approach is to instrument a prototype version of the interface, so that for example, when the prototype causes a certain object to appear on the screen, the simulated human is supplied with the visual input description. Given the considerable variety in how GUIs are implemented, this solution is not very general, but does have interesting solutions if the application prototype is programmed in Java, HTML, or similar cross-platform languages or general-purpose tools that can be used for prototyping.

However, both these methods of coupling a user model to an application suffer from an easily overlooked limitation: The time when modeling is most useful is *early* in design, *before* the system has been prototyped. Thus, because coupling to a prototype or an application can only happen late in the development process or after development, these approaches come too late to provide the most benefit of model-based evaluation.

Thus, multiple approaches for creating the simulated device are both possible and needed: if the design questions can be answered with evaluation techniques such as the Keystroke-Level Model, then no simulated device is needed at all. If the model is for an existing application, coupling to the intact application is clearly the best solution. If a prototype is going to be constructed at this point in the design process anyway, using it as the simulated device is the best solution. But in the potentially most useful case, the simulated device must be created before any prototype or final application, making the fewest possible commitments to prototyping or coding effort; this requires constructing a simulated device from scratch, stripped down to the bare minimum necessary to allow a candidate design to interact with the simulated user. The next section provides some advice on this process.

57.3.1.1 How to Simplify the Simulated Device

Distinguish between device behavior that is relevant to the modeling effort and that which is not. Basically, if the simulated human will not use or respond to certain behaviors of the simulated device, then the simulated device does not need to produce those behaviors. A similar argument applies to the amount of detail in the behavior. Of course, as the interface design is elaborated, the simulated device may need to cover more aspects of the task. Good programming techniques will make it easy to extend the simulated device as needed; a good programmer on the project is a definite asset.

Distinguish between what the simulated device has to provide to the simulated human and what would be a convenience to the modeler. That is, while the device can supply abstract descriptions to the simulated user, an actual graphical display of what the simulated device is displaying can be a very useful tool for the modeler in monitoring, debugging, or demonstrating the model. A very crude general-purpose display module that shows what the simulated human "sees" will suffice and can be reasonably easy to provide in a form that is reusable for a variety of simulation projects. However, developing this handy display should be recognized as an optional convenience, rather than an essential part of the simulated device.

Since programming the simulated device can be a significant programming effort, an attractive simplification would be a programming language that is specialized for describing abstract device behavior. Clearly, using such a language could be valuable if the modeling system already provides it and it is adequate for the purpose, especially if the device programming language can generate a prototype for the interface that can be directly coupled to the simulated human, moving the whole process along rapidly. An extensive project involving many different but similar interface designs would profit, especially if the language matches the problem domain well.

However, in less than ideal situations, a specialized device language is unlikely to be an advantage. The reason is that to cover the full span of devices that might need to be simulated, the device programming language will have to include a full set of general programming language facilities. For example, to handle the Kieras and Santoro (2004) domain, trigonometric functions are needed to calculate courses and trajectories and containers of complex objects are required to keep track of the separate aircraft and their properties. Thus, specialized languages will inevitably have to include most of the same feature set as general-purpose programming languages, meaning that the developers of modeling systems will have to develop, document, maintain, and support with editors and debuggers a full-fledged programming language. This takes effort away from the functions that are unique to human performance modeling systems, such as ensuring that the psychology is correctly represented. In addition, the modeler will also have to expend the time and effort necessary to learn a specialized language whose complexity is similar to a general-purpose programming language, also taking effort away from unique aspects of the modeling effort.

A better choice would be to provide for the device to be programmed easily in a standard general-purpose programming language that modelers can (or should) know anyway, allowing reuse of not just the modeler's skills, but existing programming tools and education resources as well. A well-designed modeling system can ensure that a minimum of system-specific knowledge must be acquired before coding can begin.

57.3.2 Identifying the Task Strategy

57.3.2.1 Task Analysis Does Not Necessarily Specify a Task Strategy

Human performance in a task is determined by (1) the logical requirements of the task—what the human is supposed to accomplish, as determined by a task analysis; (2) the human cognitive architecture—the basic mechanisms available to produce behavior; and (3) a specific strategy for doing the task—given the task requirements and the architecture, what should be done in what order and at what time to complete the task. Thus, to construct a model for doing the task, one must first understand the task, then choose an architecture, and then choose a strategy to specify how the architecture will be used to accomplish the task. Identifying this strategy is the critical prerequisite for constructing a model.

Normal task analysis methods, such as those described in sources such as Kirwan and Ainsworth (1992), Beevis et al. (1992), and Diaper and Stanton (2004), do not necessarily identify the exact sequence of actions to perform with the interface under design, and they rarely specify the timing of actions. For example, anyone who has made coffee with a home coffee maker knows that there are certain constraints that must be met, but there is still considerable variation in the sequence and time in which the individual required steps could be performed. In fact, there can be variation on how the activity is organized; for example, one strategy is to use the visible state of the coffee maker as an external memory to determine which actions should be performed next (Larkin 1989). A normal task analysis will not identify these variations. But even further, task analysis will not necessarily identify how any trade-offs should be decided, even as basic as speed versus accuracy, much less more global problems such as managing workload, dealing with multiple task priorities, and so forth.

Thus, to model a human performing in such situations, some additional information beyond a normal task analysis has to be added, namely the specific task strategies that are used to accomplish the tasks. Conversely, the performance that a human can produce in a task can vary over a wide range depending on the specific strategy that is used, and this is true over the range of tasks from elementary psychology laboratory tasks to highly complex real-world tasks (Kieras and Meyer 2000). This raises a general problem: Given that we have a model that predicts performance on an interface design, how do we distinguish the effects of the interface design from the effects of the particular strategy for using the interface? Not only does this apply to the model performance, but also to the human's performance. It has always been clear that clever and experienced users can get a lot out of a poorly designed system, and even a reasonably well-designed powerful system can be seriously under-used (Bhavnani and John 1996). How can we predict performance without knowing the actual task strategy, and how does our model's task strategy relate to the actual user's task strategy?

57.3.2.2 Difficulties in Identifying Task Strategy

The state of the art in cognitive modeling research for identifying a task strategy is to choose a candidate intuitively, build the model using the strategy, evaluate the goodness of fit to data, and then choose a better strategy and repeat until a satisfactory fit is obtained. If there is adequate detail in the data, such as the sequence of activities, it might be possible to make good initial guesses at the task strategy and then revise these through the modeling process. This iterative refinement process is known to be very slow, but more seriously, in system design we normally do not have data to fit a model to—this is what the modeling is supposed to replace. The task strategy has to be chosen in the absence of such data.

Another approach is to get the task strategy by knowledge engineering techniques with existing task performers or other sources such as training materials. As will be argued below, it is especially important to identify the best (or at least a good) strategy for doing the task. But a good strategy for doing a task is often not obvious, even to experts. Even highly experienced people do not always know or use the best procedures; even the trainers may not know them, and it is common to discover that procedural training materials present suboptimal methods. Finally, and again most importantly, if the system is new, there are no experts or training materials to consult to see how it is used.

57.3.2.3 A Heuristic: Model What Users Should Do

Given the obstacles to identifying task strategies, how do we find out what strategies users will follow in using the system under development? The short answer is that it is too hard to find out within the constraints of a design process. Instead, start from the design goals that the system is supposed to meet and assume that *users will be using the system like it is supposed to be used*. For example, if the system provides a feature that is supposed to allow the user to perform a certain task easily, assume that the simulated user will use that feature in the intended fashion. This is essentially a best-case analysis of the ability of the user to make use of the interface design. If the usability under these conditions is too low, then it would certainly be inadequate when used by actual users! It is a separate issue whether the users can or will use the system in this intended way and the failures can be dramatic and serious (Bhavnani and John 1996). Whether users use a system in the intended way depends on several factors: problems in the learnability of the design, which some models (see John and Kieras 1996a,b) can predict; the quality of the training materials, which also can be improved with modeling (see John and Kieras 1996a,b); and perhaps most importantly, matters beyond the scope of model-based evaluation, such as whether users have the opportunity or incentive to take full advantage of the system. Finally, there is no point in trying to improve a system under the assumption that users will ignore the capabilities that it provides! This is why, in choosing a task strategy to model for design evaluation, the most effective approach is to assume that *the design will be used as intended*. Not only will this strategy be the easiest to identify and implement, but it is also most directly relevant to evaluating the design!

Within this basic strategy, there is another range of variation, which is whether the user attempts to perform at the highest possible level or simply satisfices by performing at some adequate level. That is, people can use clever low-level strategies (what Gray and Boehm-Davis [2000] termed microstrategies) to greatly improve performance. For example, if the task is to classify "blips" on a radar display, the user can speed up considerably by looking for the next blip to inspect while still hitting the keys to respond to the previous one (Hornof, Zhang, and Halverson 2010). On the other hand, the user is performing reasonably if they finish each blip before going on to the next one. Kieras and Meyer (2000) pointed out that in a variety of even elementary laboratory tasks, subjects do not always adopt high-performance strategies, even when large improvements would result; they are optional, not mandatory. So even if we are willing to assume that the design will be used as intended, how do we know whether the actual users will be going "all out" with a clever strategy versus just "getting the job done?" Again, the short answer is that it is too difficult to find out, especially in a design process where the system does not yet exist.

In response to this quandary, Kieras and Meyer (2000) proposed the *bracketing heuristic*. Construct a base model in which the user performs the task in a straightforward way using the interface as designed, but without any special strategic optimizations, a *slowest-reasonable* model. Derive from this a *fastest-possible* model that performs the task at the maximum performance level allowed by the cognitive architecture used for the model. The two models should bracket the actual user's future performance. If both models produce adequate performance, then the design should be adequate; if both produce inadequate performance, then the design needs to be improved. If the slowest-reasonable model is inadequate, but the fastest-possible model is acceptable, boosting the level of training or perhaps motivation of the user might result in satisfactory performance, although clearly improving the design would be a more robust solution.

There has been recent work devoted to automatic construction of the optimum strategy corresponding to the fastest-possible model. The concept is that a cognitive architecture and task demands can be specified as a set of constraints. Procedures or task strategies can then be computationally generated from these constraints and their performance compared (John et al. 2002; Vera et al. 2004; Howes, Lewis, and Vera 2009). Thus, it is possible to algorithmically explore the space of all possible strategies and then choose the strategy that maximizes task performance. This approach takes much of the guess-work out of model-building, at least for the fastest/best-possible model. While very promising, it is not yet clear whether the technique can be practically scaled to evaluate realistically complex interfaces and tasks, or whether the slowest-reasonable model or its equivalent can be similarly automatically constructed.

57.3.3 Concerns over Model Validity

57.3.3.1 Can You Believe the Model?

Suppose a model implies critical design choices. Should you follow them? A poor response is to build and test prototypes just as if no modeling had been done. It could be argued that the modeling might have clarified the situation, but the purpose of model-based evaluation is to reduce the amount of prototyping and user testing required for refining a design. So this response under-utilizes the approach.

A better response to the situation is to understand how the model implies the design choices—what aspects of the model are contributing to the outcome? This can be done by profiling the model processing and analyzing the model structure. If the critical aspects of the model are known to be valid and appear to be properly represented, then the model results should be accepted. For example, perhaps one design is slower than the other simply because it turns out that more navigation through menus is required; the model processes involved are relatively simple and adequately validated in the literature. However, if the relevant aspects of the model are problematic, the result needs further study. For example, suppose the model for the better of two designs differs from the poorer design in assuming that the user can remember all the information about previously inspected screen objects and so does not need to search the screen again when the information is needed later. Because the bounds on visual memory are unclear, as discussed above, the modeling architecture might not enforce any bounds. Thus, the modeling result is suspicious for this reason, and the true bounds might be much smaller than the model assumes. The modeler could then perform a sensitivity analysis to reveal how much the design choice might be affected by the problematic assumption. For example, the model could be modified to vary the number of previous inspected objects that could be remembered. At what value does this parameter change which design is predicted to be better? If the decision is not very sensitive to this parameter (e.g., because the effects are minor compared to the total time involved or there are other improvements in the better design), then choosing the better design is a reasonably safe decision.

If the decision turns out to be sensitive to the problematic model assumption, then the situation becomes quite difficult. One possible solution is to remove the problematic aspect of the model by changing it in the direction of less human capability; this is a conservative strategy and might be appropriate if the user will be under stress as well. But if data or theory that resolves the issue is available, the modeler can go beyond the normal model-based process and modify the model or architecture to incorporate the more accurate psychological information.

57.3.3.2 Should You Validate the Model?

Remember that testing with real users must be done sometime in the development process, because the models do not cover all the design issues, are only approximate where they do apply, and like any analytic method, can be misapplied.

The model can thus be validated after use by comparing the final user test results to the model predictions; this will reveal problems in the accuracy of the model and its application to the design; any modeling mistakes and design errors can then be corrected for the future.

However, should special data to validate the model be collected prior to using it to guide the design? While it would seem to be a good idea to validate a model before using it, the answer really should be *no* because validation is not supposed to be a normal part of using a predictive model of human performance. The whole idea of model-based evaluation is to avoid data collection during design. Only the developers of the modeling methodology are supposed to be concerned about the validity, not the user of the methodology.

There are a couple of special cases about data collection that need discussion. One is data collection to provide basic parameter values required for modeling, such as how long it takes the user to input characters with a novel device. If the parameters concern low-level processes, the data collection is independent of a specific design and will be generally useful for many different modeling applications. The second special case is data collection to support modeling how an *existing* system is *actually* being used. Such a model cannot be constructed a priori, but rather must be based on data about how actual users interact with the actual system. Because of the uncertainties involved in constructing a model based on human behavior, the model will have to be validated with a suitably complete and reliable data set before it can be taken as a usefully accurate model. This purpose of modeling is very different from the model-based evaluation approach presented in this chapter: instead of serving as a guide for designing a new system and a surrogate for user testing, the model is an explanation and characterization of observed behavior; it might serve as a guide for a new design, but only in the sense of characterizing the current situation that we want to improve upon. The model itself will not directly apply to the new design. In short, modeling the actual use of an existing system has very different methods, goals, and applications from modeling the usage of a system being designed.

But if in spite of all the above considerations, the validity of the model is in question, it is critical to realize that a data set adequate for a scientifically sound test of validity must be much more controlled and detailed than normal user testing data and can be very difficult to collect in the context of a development project, due to the practical difficulties that appear in both applied and basic research. Despite the usually considerable effort and expense to collect it, data on actual real-world task performance is often lacking in detail, scenario coverage, and adequate sample sizes. Even in the laboratory, collecting highly precise, detailed, and complete data about task performance is quite difficult, and researchers are typically trapped into using tasks that are artificial, performed by nonexpert subjects, or trivial relative to actual tasks, and even so, the data collection, analysis, and interpretation process can take years to complete.

To elaborate on the difficulty of collecting adequate validation data, while all would agree that a model is almost certainly incorrect at some level, it is often mistakenly assumed that collecting empirical data on human performance in complex tasks is a royal road to certainty. Rather, as pointed out in Kieras and Santoro (2004), complex real-world tasks involve subtle user strategies, team interactions, influences of background knowledge, and the specifics of the scenarios. Such experiments are extremely slow and expensive to conduct, even with small samples, where the reliability of the results then comes into question. Clearly, it is not practical to run experiments using many scenarios, every reasonable design variation, every candidate team organization, and ample numbers of subjects. Furthermore, even for a well-chosen subset of these possibilities, it may be difficult to understand why people did what they did in the tasks—asking them is usually ambiguous at best and their strategies might be idiosyncratic. Thus, the reliability, generalizability, and even the meaning of the data can be difficult to determine. In fact, it can be difficult to ensure that the model and the experiment are even relevant to each other. For example (see Kieras and Santoro 2004), if the model is based on what users *should* do in the task and the test users do not follow the strategy that the model follows, then the failure of the model to behave the same way as the test users is actually irrelevant—it might be said that the data is "wrong," not the model! Thus, even if deemed appropriate, attempting to validate a model of a complex task is likely to be impractically difficult for a normal development process.

A final point on data collection is as follows: if the resources are available to do extensive data collection and analysis before the final stages of development, what function is served by modeling? If the model validity would be in doubt, would not the data collection resources be better devoted to user testing?

57.3.3.3 Summary: Assessing Model Validity

Instead of collecting data to validate the model, assess its validity in terms of whether it meets the following basic requirements: (1) Is the model strategy based on an analysis of what users *should* do? If not, it is a poor choice to inform the design of a new system. (2) Is it likely that users can or will follow the same strategy as the model? If not, then the model is irrelevant—either the model was misconstructed or the design is fundamentally wrong. (3) Are the assumptions about human abilities in the model plausible? If not, see the earlier suggestions. If the answer to all three questions is yes, then the model results can be accepted as useful guidance for the design decisions without special validation efforts. Of course, it needs to be kept in mind that the model might be seriously incorrect, but modeling is not supposed to be perfect; it suffices merely that it help a design process.

57.4 GOMS MODELS: READY-TO-USE APPROACH

As summarized earlier, GOMS is an approach to describing the knowledge of procedures that a user must have to operate a system. The different types of GOMS models differ in the specifics of how the methods and sequences of operators are represented. The aforementioned CPM-GOMS model represents a specific sequence of activity in terms of the cognitive, perceptual, and motor operators performed in the context of a simple model of human information processing. At the other extreme of detail, the Keystroke-Level Model (Card, Moran, and Newell 1980) is likewise based on a specific sequence of activities, but these are limited to the overt *keystroke-level* operators (i.e., easily observable actions at the level of keystrokes, mouse moves, finding something on the screen, turning a page, and so forth). The task execution time can be predicted by simply looking up a standardized time estimate for each operator and then summing the times. The Keystroke-Level Model has a long string of successes to its credit (see John and Kieras 1996a). Without a doubt, if the design question involves which alternative design is faster in fairly simple situations, there is no excuse for measuring or guessing when a few simple calculations will produce a usefully accurate answer.

However, the Keystroke-Level Model is tedious to calculate for realistic applications and requires training and practice to apply uniformly, and in its bare form does not fit well into traditional user interface development processes. A good solution, CogTool, has been developed by John and co-workers (John et al. 2004) (see http://cogtool.hcii.cs.cmu.edu/). CogTool takes advantage of the *storyboard* technique, the most common interface design technique in which illustrations of the sequence of displays show how the user moves through a task. These storyboards can be in the form of simple hand-drawn sketches or more elaborate mockups in the form of PowerPoint slides or HTML pages. The tool allows the user to bring in these storyboard images, annotate them with "hot-spots" for the buttons if needed, and then easily demonstrate the sequence of user actions that accomplish the task. The tool then automatically calculates the Keystroke-Level Model time predictions for each task. One result is that the tool greatly improves the reliability of the modeling—different tool users produce very similar modeling results (John 2010). But more importantly, CogTool provides a simple and effective storyboard-level prototyping tool that also provides basic task time predictions as a "bonus," making it much more tempting to the developer community. This approach is an important step in making model-based evaluation more practical and accepted.

It is easy to generalize the Keystroke-Level Model somewhat to apply to more than one specific sequence of operators. For example, if the scenario calls for typing in some variable number of strings of text, the model can be parameterized by the number of strings and their length. However, if the situation calls for complex branching or iteration and clearly involves some kind of hierarchy of task procedures, such sequence-based models become quite awkward and a more generative form of model is required.

The generative forms of GOMS models are those in which the procedural knowledge is represented in a form resembling an ordinary computer programming language and are written in a fairly general sort of way. This form of GOMS model can be applied to many conventional desktop computing interface design situations. It was originally presented in Card, Moran, and Newell (1983, Chapter 5) and further developed by Kieras, Polson, and Bovair (Kieras and Polson 1985; Polson 1987; Bovair, Kieras, and Polson 1990), who provided a translation between GOMS models and the production-rule representations popular in several cognitive architectures and demonstrated how these models could be used to predict learning and execution times. Kieras (1988, 1997) proposed a structured-natural-language notation, NGOMSL ("Natural" GOMS language), which preserved the empirical content of the production-rule representation, but resembled a conventional procedural programming language. This notation was later formalized into a fully executable form, GOMSL (GOMS language), for use in computer simulation tools that implement a simplified cognitive architecture (Kieras et al. 1995; Kieras 2005a). This tool has been applied to modeling team tasks (e.g. Kieras and Santoro 2004) and extended to provide analysis of error recovery methods supported by error-source heuristics (Wood 2000). St. Amant, Horton, and Ritter (2007) provide a useful comparison of a GOMS model with a cognitive-architectural model, showing how the GOMS model can provide results comparable to the more complex model much more easily.

Continuing the analogy with conventional computer programming languages, in generative GOMS models, the operators are like the primitive operations in a programming language; methods are like functions or subroutines that are called to accomplish a particular goal, with individual steps or statements containing the operators, which are executed one at a time, as in a conventional programming language. Methods can assert a sub-goal, which amounts to a call of a sub-method, in a conventional hierarchical flow of control. When procedural knowledge is represented explicitly in this way and in a format that enforces a uniform "grain size" of the operators and steps in a method, then there are characteristics of the representation that relate to usability metrics in straightforward ways.

For example, the collection of methods represents "how to use the system" to accomplish goals. If a system requires a large number of lengthy methods, then it will be hard to learn; there is literally more required knowledge than for a system with a smaller number of methods or simpler methods. If the methods for similar goals are similar, or in fact the same method can be used to accomplish different, but similar, goals, then the system is "consistent" in a certain, easily characterized sense: in a procedurally consistent system, fewer methods, or unique steps in methods, must be learned to cover a set of goals compared to an inconsistent system, and so it is easier to learn. One can literally count the amount of overlap between the methods to measure procedural consistency.

Finally, by starting with a goal and the information about the specific situation, one can follow the sequence of operators specified by the methods and sub-methods to accomplish the goal. This generates the sequence of operators required to accomplish the goal under that specific situation; if the methods were written to be adequately general, they should suffice to generate the correct sequence of operators for any relevant task situation. The times for the operators in the trace can be summed, as in the Keystroke-Level Model, to obtain a predicted execution time. Details of the timing can be examined or "profiled" to see where the processing bottlenecks are.

See Baumeister, John, and Byrne (2000) for a survey of computer tools for GOMS modeling.

57.4.1 Why GOMS Models Work

The reasons why GOMS models have useful predictive and heuristic power in interface design can be summarized under three principles: The *rationality principle* (cf. Card, Moran, and Newell 1983) asserts that humans attempt to be efficient given the constraints on their knowledge, ability, and the task situation. Generally, when people attempt to accomplish a goal with a computer system, they do not engage in behavior that they know is irrelevant or superfluous—they are focused on getting the job done. Although they might perform suboptimally due to poor training (see Bhavnani and John 1996), they generally try to work as efficiently as they know how, given the system they are working with. How they accomplish a goal depends on the design of the system and its interface—for example, in a word-processing system, there are only a certain number of sensible ways to delete a word and the user has some basis for choosing between these that minimizes effort along some dimension. Between these two sets of constraints—the user's desire to get the job done easily and efficiently and the computer system's design—there is considerable constraint on the possible user actions. This means that we can predict user behavior and performance at a useful level of accuracy *just from the design of the system and an analysis of the user's task goals and situation*. A GOMS model is one way of combining this information to produce predicted performance.

Procedural primacy is the claim that regardless of what else is involved in using a system, at some level the user must infer, learn, and execute procedures to accomplish goals using the system. That is, computers are not used purely passively—the user has to do something with them, and this activity takes the form of a procedure that the user must acquire and execute. Note that even display-only systems still require some procedural knowledge for visual search—for example, making use of the flight status displays at an airport requires choosing and following some procedure for finding one's flight and extracting the desired information—different airlines use different display organizations, some of which are probably more usable than others. Because the user must always acquire and follow procedures, the complexity of the procedures entailed by an interface design is therefore related to the difficulty of using the interface. While other aspects of usability are important, the procedural aspect is always present. Therefore, analyzing the procedural requirements of an interface design with a technique such as GOMS will provide critical information on the usability of the design.

Explicit representation refers to the fact that any attempt to assess something benefits from being explicit and clear and relying on some form of written formalized expression. Thus, all task analysis techniques (Kirwan and Ainsworth 1992; Beevis et al. 1992; Diaper and Stanton 2004) involve formalized descriptions of a user's task. Likewise, capturing the procedural implications of an interface design will benefit from representing the procedures explicitly in a form that allows them to be inspected and manipulated. Because GOMS models involve writing out user procedures in a complete, accurate, and detailed format, it becomes possible to define metrics over the representation (e.g., counting the number of statements) that can be calibrated against empirical measurements to provide predictions of usability. Moreover, by making user procedures explicit, the designer can then apply the same kinds of intuition and heuristics used in the design of software: clumsy, convoluted, inconsistent, and "ugly" user procedures can often be spotted and corrected just like poorly written computer code. Thus, by writing out user procedures in a notation like GOMS, the designer can often detect and correct usability problems without even performing the calculations.

A related developing concept that uses an explicit representation of user procedures is the application of *model-checking* methodology developed in computer science for formal verification. Briefly, if the possible states and state transitions of a system can be formally characterized, then it is possible to enumerate all the possible transitions in a system and verify that, for example, the system will not enter into an unsafe state. This has begun to be applied to systems with user interfaces (e.g., Bolton and Bass 2009) to verify their efficacy and safety. While this method does not provide a way for predicting task performance, it may provide a way for verifying the overall functionality and safety of a system.

User procedure representations derived from a task analysis can help choose the functionality behind the interface. The approach can be formalized with *high-level GOMS models* (Kieras 2004), in which the operators refer to invocations of system functions rather than keystroke-level interface actions. GOMSL and GLEAN (see Kieras 2005b) currently contain high-level GOMS operators to directly support a "seamless" transition of computational modeling from the task and functionality level of analysis down to detailed design. Butler et al. (2007) argue that the *top-level routine* that describes how a user and machine cooperate to get work done is usually not deliberately designed, but rather is left up to users to infer from haphazardly chosen functionality. The top-level routine, and the choice of functionality to simplify it and make it more effective, can in fact be designed using techniques based on task and domain analysis, and candidates can be compared and evaluated with high-level GOMS models and potentially verified with model-checking. This combination of techniques would comprise a valuable engineering toolbox for system design.

57.4.2 Limitations of GOMS Models

GOMS models address only the procedural aspects of a computer interface design. This means that they do not address a variety of nonprocedural aspects of usability, such as the readability of displayed text, the discriminability of color codes, or memorability of command strings. Fortunately, these properties of usability are directly addressed by standard methods in human factors.

Within the procedural aspect, user activity can be divided into the open-ended "creative" parts of the task, such as composing the content of a document or thinking of the concept for the design of an electronic circuit, on the one hand, and the routine parts of the task, on the other, which consist of simply manipulating the computer to accept the information that the user has created and then to supply new information that the user needs. For example, the creator of a document has to input specific strings of words in the computer, rearrange them, format them, spell check them, and then print them out. The creator of an electronic device design has to specify the circuit and its components to a CAD system and then obtain measures of its performance. If the user is reasonably skilled, these activities take the form of executing routine procedures involving little or no creativity.

The bulk of time spent working with a computer is in this routine activity, and the goal of computer system design should be to minimize the difficulty and time cost of this routine activity so as to free up time and energy for the creative activity. GOMS models are easy to construct for the routine parts of a task, because, as described earlier, the user's procedures are constrained by the task requirements and the design of the system, and these models can then be used to improve the ability of the system to support the user. However, the creative parts of task activity are purely cognitive tasks and, as discussed above, attempting to formulate a GOMS model for them is highly speculative at best and would generally be impractical. Applying GOMS thus takes some task analysis skill to identify and separate the creative and routine procedural portions of the user's overall task situation.

Finally, it is important to recognize that while a GOMS model is often a useful way to express the results of a task analysis, similar to the popular HTA technique (Annett et al. 1971; Kirwan and Ainsworth 1992), building a GOMS model does not "do" a task analysis. The designer must first engage in task analysis work to understand the user's task before a GOMS model for the task can be constructed. In particular, identifying the top-level goals of the user and selecting relevant task scenarios are all logically prior to constructing a GOMS model.

57.5 CONCLUDING RECOMMENDATIONS

- If you need to predict the performance of a system prior to detailed design when overall system structure and functions are being considered, use a task network model.
- If you are developing a detailed design and want immediate intuitive feedback on how well it supports the user's tasks, write out and inspect a high-level or informal GOMS model for the user procedures while you are making the design decisions.
- If your design criterion is the execution speed for a discrete selected task, use a Keystroke-Level model.
- If your design criteria include the learnability, consistency, or execution speed of a whole set of task procedures, use a generative GOMS model. If numerous or complex task scenarios must be modeled, use a GOMS model simulation system.
- If the design issues hinge on understanding detailed or subtle interactions of human cognitive, perceptual, and motor processing and their effect on execution speed and only a few scenarios need to be analyzed, use a CPM-GOMS model.
- If the resources for a research-level activity are available and a detailed analysis is needed of the cognitive, perceptual, and motor interactions for a complex task or many task scenarios, use a model built with the simplest cognitive architecture that incorporates the relevant scientific phenomena.

58 Spreadsheet Tool for Simple Cost-Benefit Analyses of User Experience Engineering

Deborah J. Mayhew

CONTENTS

58.1 INTRODUCTION

This chapter offers and explains a free spreadsheet-based tool developed to help estimate the *potential return on investment (ROI)* of an investment in *user experience (UX) resources and activities* on software or website development projects. The spreadsheet-based tool is provided as a free download on my website (Mayhew 2009). The tool is a multi-worksheet Microsoft Excel file in .xls format. Table and page numbers referred to in this chapter as well as in the tool worksheets are references to table and page numbers in the book *Cost-Justifying Usability—An Update for the Internet Age* (Bias and Mayhew 2005)—a reference for much more detail on cost justifying UX efforts.

While the tool is general purpose and offers assistance for cost justifying UX resources in many different development contexts (e.g., internal desktop applications, commercial software, websites of various kinds), in this chapter, I explain the tool and how to use it in the context of cost justifying UX efforts when developing websites in particular.

Any cost-benefit analysis must start with estimating the *cost* of an investment, followed by predicting the potential *benefits*, so as to determine whether, and to what extent, the benefits might be expected to exceed the costs, that is, the extent to which an ROI will be realized. To estimate the costs of a UX engineering investment, one must have a plan for UX resources and activities as a part of the overall software or website design and development plan. My book *The Usability*

Engineering Lifecycle (Mayhew 1999) describes and explains a generic approach to usability engineering, which has since come to be more commonly referred to as UX engineering. It is this lifecycle that is the basis of estimating the cost side in the cost justification tool described and explained in this chapter. The usability engineering lifecycle is a general framework that is relevant to cost justifying a UX effort when developing any kind of software application, from commodity trading to an eCommerce website. The next section provides an overview of the usability engineering lifecycle, although wording has been slightly changed to reflect the use of the broader term "user experience" and the context of website development.

58.2 USER EXPERIENCE ENGINEERING LIFECYCLE—AN OVERVIEW

The first step in cost justifying a UX engineering effort on a website development project is to lay out a UX engineering plan for that project. This section provides a very high level synopsis of such a plan, based on *The Usability Engineering Lifecycle* (Mayhew 1999).

The UX engineering lifecycle consists of a set of UX tasks applied in a particular order at specific points in an overall website development lifecycle.

Several types of tasks are included in the UX engineering lifecycle:

- Structured UX requirements analysis tasks
- An explicit UX goal-setting task, driven directly from requirements analysis data
- Tasks supporting a structured, top-down approach to UX design that is driven directly from UX goals and other requirements data
- Objective UX evaluation tasks for iterating design toward UX goals

Figure 58.1 represents in summary, visual form, the usability (or UX) engineering lifecycle. The lifecycle is cast in three phases: requirements analysis, design/testing/development, and installation. Specific UX tasks within each phase are presented in boxes, and arrows show the basic order in which tasks should be carried out. Much of the sequencing of tasks is iterative, and the specific places where iterations would most typically occur are illustrated by arrows returning to earlier points in the lifecycle. Brief descriptions of each lifecycle task follow, again with slight wording changes relative to the chart in Figure 58.1 to reflect website development in particular.

58.2.1 Phase 1: Requirements Analysis

58.2.1.1 User Profile

A description of specific user characteristics relevant to UX design (e.g., level of general computer and/or web literacy, expected frequency of use, level of familiarity with tasks supported by the website) is obtained for the intended user population. This will drive tailored UX design decisions and also identify major user categories for study in the Task Analysis task.

58.2.1.2 Task Analysis

A study of users' natural task flow patterns, informational needs, and conceptual frameworks is conducted, resulting in an understanding and specification of underlying user goals. These will be used to set UX goals and drive information architecture design (previously referred to as work reengineering) and UX design.

58.2.1.3 Platform Capabilities/Constraints

The UX design capabilities and constraints inherent in the technology platform chosen for the product (e.g., browsers and browser versions, screen sizes and resolutions) are determined and documented. These will define the scope of possibilities for UX design.

58.2.1.4 General Design Guidelines

Relevant general UX design guidelines available in the UX engineering literature are gathered and reviewed. They will be applied during the design process to come, along with all other project-specific information gathered in the previous tasks.

58.2.1.5 User Experience Goals

Specific *qualitative* goals reflecting UX requirements are developed, extracted from the user profile and task analysis work products. In addition, *quantitative* goals (based on a subset of high-priority qualitative goals) may be developed, defining minimal acceptable user performance and satisfaction criteria. These UX goals focus later design efforts and form the basis for later iterative UX evaluation.

58.2.2 Phase 2: Design/Testing/Development

58.2.2.1 Level 1 Design

58.2.2.1.1 Information Architecture

In this task (previously referred to as work reengineering) based on all requirements analysis data and the UX goals extracted from them, user tasks are redesigned at the level of organization and workflow to streamline user tasks and exploit the capabilities of automation. No *visual* UX design is involved in this task, just abstract organization of functionality and workflow design. The information architecture defines how users will navigate through the information and/or functionality of the application.

58.2.2.1.2 Conceptual Model Design

Based on all the previous tasks, a set of design conventions are generated for visually presenting the different levels in the (usually hierarchical) information architecture and for interactions for navigating through it. Page design detail is *not* addressed at this design level.

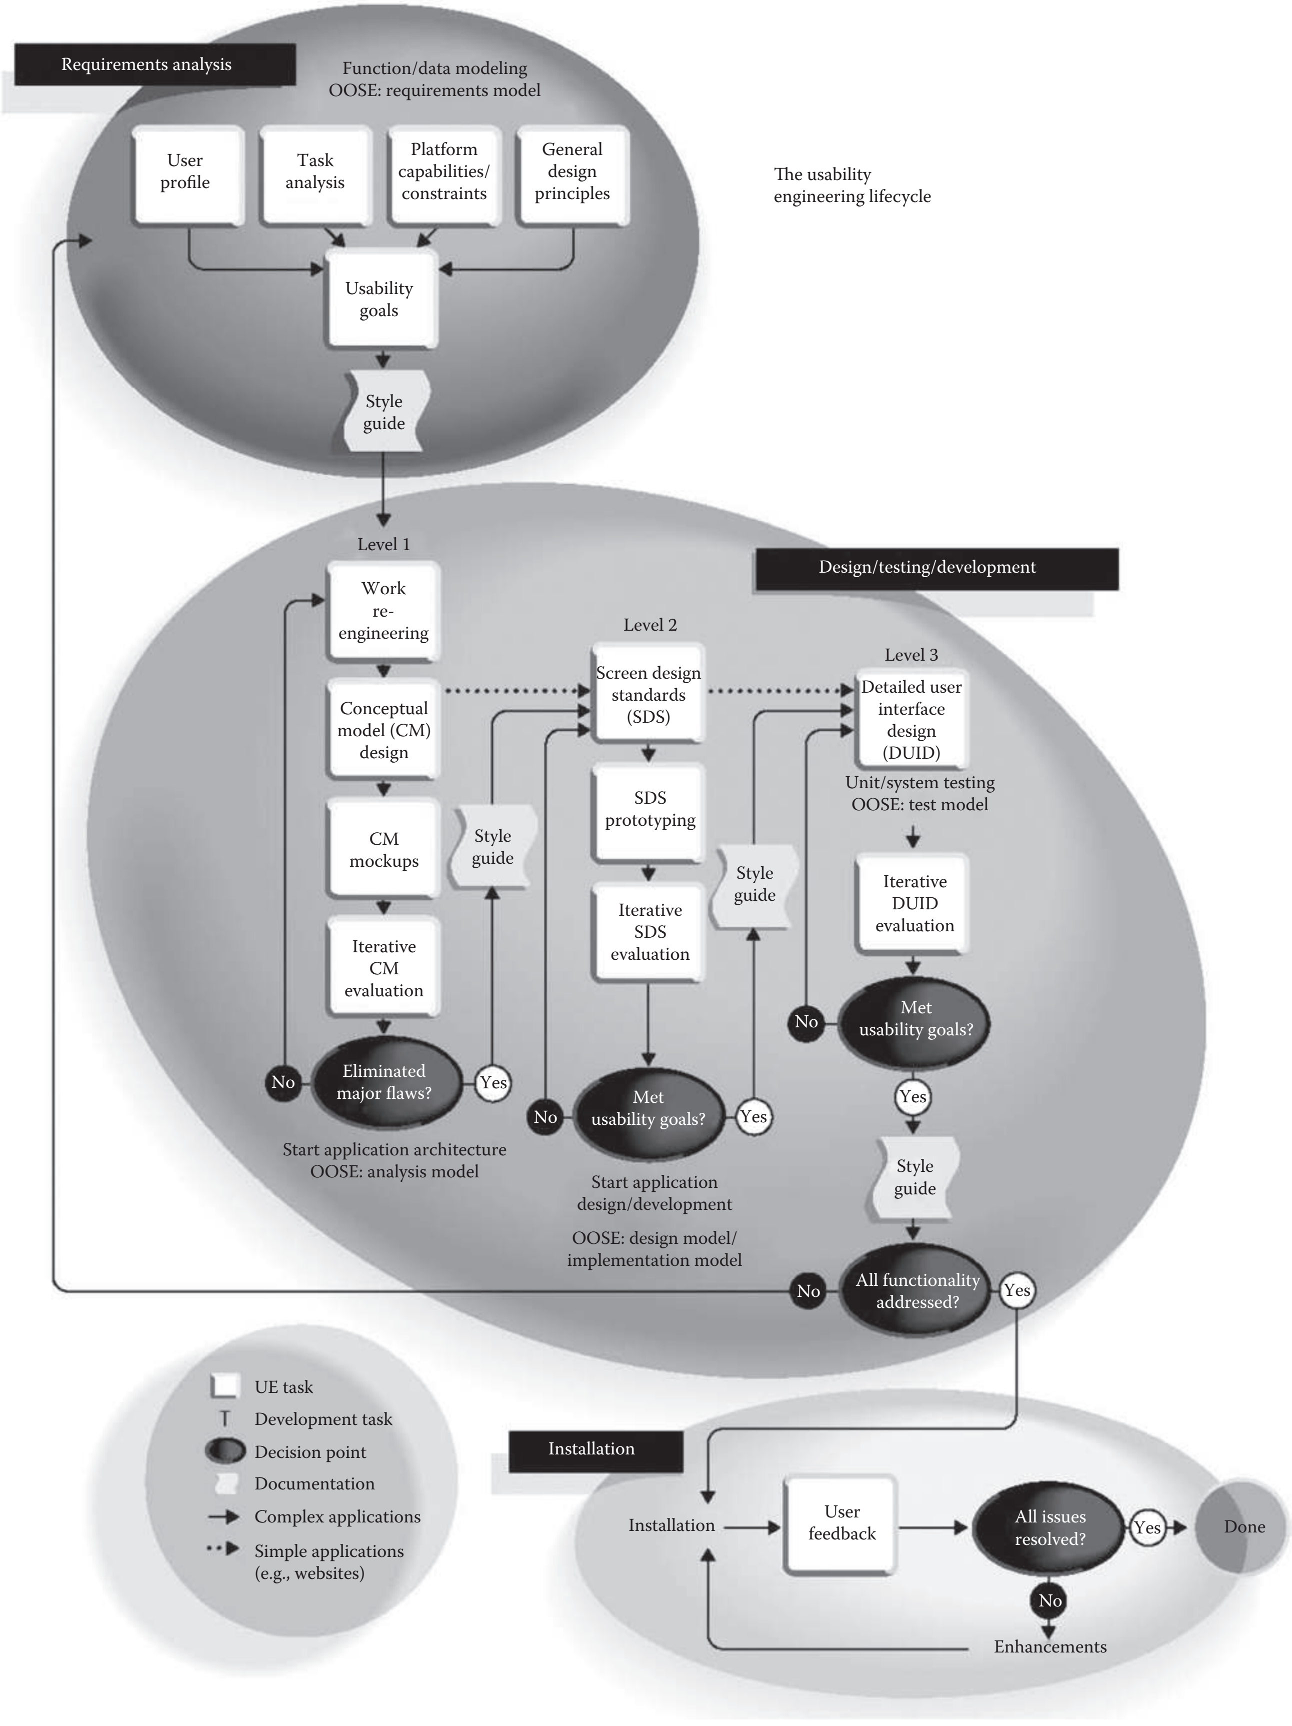

FIGURE 58.1 The usability engineering lifecycle. (From Mayhew, D. J. 1999. *The Usability Engineering Lifecycle*. San Francisco, CA: Morgan Kaufmann Publishers.)

58.2.2.1.3 Conceptual Model Mockups

Paper-and-pencil or live prototype mockups of high-level design ideas generated in the conceptual model design task are prepared, representing ideas about high-level functional organization and conceptual model design. Detailed page design and complete functional design are *not* in focus here.

58.2.2.1.4 Iterative Conceptual Model Evaluation

The mockups are evaluated and modified through iterative evaluation techniques such as formal UX testing, in which real, representative end users attempt to perform real, representative tasks with minimal training and intervention, imagining that the mockups are a real website UX design. This and the previous two tasks are conducted in iterative cycles until all major UX "bugs" are identified and engineered out of Level 1 (i.e., Conceptual Model) Design. Once a conceptual model is relatively stable, system architecture design can commence.

58.2.2.2 Level 2 Design

58.2.2.2.1 Page Design Standards

A set of website-specific standards and conventions for all aspects of detailed page design is developed, based on any corporate standards that have been mandated, the data generated in the requirements analysis phase, and the product-unique conceptual model design arrived at during Level 1 Design. Page design standards will ensure another level of coherence and consistency—the foundations of usability—across the website UX.

58.2.2.2.2 Page Design Standards Prototyping

The page design standards (as well as the conceptual model design) are applied to design the detailed UX to selected subsets of website functionality. This design is implemented as a running prototype.

58.2.2.2.3 Page Design Standards Evaluation

An evaluation technique such as formal UX testing is carried out on the page design standards prototype and then redesign/re-evaluation iterations are performed to refine and validate a robust set of page design standards. Iterations are continued until all major UX "bugs" are eliminated and UX goals seem within reach.

58.2.2.2.4 Style Guide

At the end of the design/evaluate iterations in design levels 1 and 2, you have a validated and stabilized conceptual model design and a validated and stabilized set of standards and conventions for all aspects of detailed page design. These are captured in a document called a style guide (and ultimately in the CSS style sheets in the website code), which already documents the results of requirements analysis tasks. During detailed UX design, which comes next, following the conceptual model design and page design standards in the website style guide will ensure quality, coherence, and consistency—the foundations of a good UX design.

58.2.2.3 Level 3 Design

58.2.2.3.1 Detailed UX Design

Detailed design of the complete website UX is carried out based on the refined and validated information architecture, conceptual model design, and page design standards documented in the website style guide. This design then drives website development.

58.2.2.3.2 Iterative Detailed User Experience Design Evaluation

An evaluation technique such as formal UX testing is continued during website development to expand evaluation to previously unassessed subsets of functionality and categories of users and also to continue to refine the UX and validate it against UX goals.

58.2.3 Phase 3: Installation

58.2.3.1 User Feedback

After the website has been launched and in production for some time, feedback is gathered to feed into design enhancements, design of new pages, and/or design of new but related websites.

58.3 GENERAL APPROACH TO COST-BENEFIT ANALYSIS OF USER EXPERIENCE ENGINEERING

To cost justify a proposed UX engineering plan, you simply adapt a very generic and widely used cost-benefit analysis technique. Having laid out a detailed UX engineering project plan based on The Usability Engineering Lifecycle (see above, and Mayhew 1999), it is a fairly straightforward matter to calculate the costs of that plan. Then you need to calculate the predicted benefits. This is a little trickier, and it is where the adaptation of the generic cost justification analysis comes into play. Then, you simply compare costs to benefits to find out if, when and to what extent, the benefits are predicted to outweigh the costs. If they do to a satisfactory extent, then you have cost justified the planned UX engineering effort. If they do not, then you will need to rethink your UX engineering plan.

More specifically, first a UX engineering plan is laid out. The plan specifies particular techniques to use for each UX engineering task in the lifecycle, breaks the techniques down into steps, and specifies the personnel hours and equipment costs for each step. The *cost* of each task is then calculated by multiplying the total number of hours for each type of personnel (e.g., UX professionals, developers, test participants) by their effective hourly wage (fully loaded, i.e., including salary, benefits, office space, equipment, utilities, and other facilities) and adding up personnel costs across types. Sometimes it is hard to get data on fully loaded wages for an organization. In this case, I use a rule of thumb I have heard informally to simply double the before-tax annual salary and then divide by the typical number of hours a full time worker is paid for in a year, usually about 2000. Even if my audience is unwilling or unable to give me actual figures for fully loaded wages, they can contest—or not—my ballpark figure based on this rule of thumb. Then the costs from all tasks are summed to arrive at a total estimated cost for the plan.

Next, the overall *benefits* of the specific UX engineering plan are predicted by selecting relevant benefit categories, calculating expected benefits by plugging project-specific parameters and assumptions into benefit formulas, and summing benefits across categories.

The potential benefit categories relevant to a particular cost-benefit analysis will depend on the basic business model of the software being developed. Benefit categories potentially relevant to different types of software applications and websites are summarized in Figure 58.2 and in the Benefits Categories worksheet of the spreadsheet tool (see also Table 3.1 on page 58 of Bias and Mayhew 2005). This would be a good time to download and open the spreadsheet tool (Mayhew 2011).

Note that the relevant benefit categories for different types of applications/websites vary somewhat. In a cost-benefit analysis, one wants to focus attention on the potential benefits that are *of most relevance to the bottom line business goals for an application or website*, either short term or long term or both.

Note also that these benefits represent just a sample of those that might be relevant for the types of software applications and websites listed. Other benefits relevant to these particular types of projects might be included as appropriate, given the business goals of the application or website stakeholders and the primary concerns of the audience, and could be calculated in a similar fashion within the spreadsheet tool as those described later. And of course, very different kinds of automation projects exist that may have very different kinds of expected benefits, for example, lives and equipment saved and wars won in a military context. The general cost justification approach can be applied in these latter types of

	Application/Site Type							
Benefits	**Internal Application**	**Commercial Product**	**E-Commerce Site**	**E-Services Site**	**Site Funded by Advertising**	**Product Information Site**	**Customer Service Site**	**Intranets**
Increased buy-to-look ratios			✓					
Decreased abandoned shopping carts			✓					
Increased number of visits					✓			
Increased return visits			✓		✓			
Increased length of visits					✓			
Decreased failed searches			✓		✓			
Decreased costs of other sales channels			✓

Decreased costs of traditional customer service channels		✓		✓			✓	
Decreased training costs	✓	✓						✓
Increased user productivity	✓							✓
Decreased user errors	✓							✓

FIGURE 58.2 Benefit categories by application/site type.

situations, but the spreadsheet tool would have to be significantly modified to address them.

Finally, overall predicted benefits are compared to overall estimated costs to see if, and to what extent, the overall UX engineering plan is justified as an investment.

When UX practitioners are invited to participate in application or website development projects already in progress, which is often the case, it may be difficult to include all tasks and to influence overall schedules and budgets. They are likely to have to live within already-committed-to schedules, assumed platforms and system architectures, use shortcut techniques for lifecycle tasks, and minimally impact budgets. Nevertheless, it is almost always possible to create a UX engineering plan that will make a significant contribution to an application or website development project, even when one comes in relatively late. And, you can use the cost-benefit analysis technique to prepare and support even plans that involve only parts of the overall lifecycle and only shortcut techniques for tasks within it.

58.4 EXAMPLE OF COST-BENEFIT ANALYSIS

In this section, I provide both a concrete example of conducting a cost-benefit analysis of a UX engineering plan for a website and introduce and explain the use of my spreadsheet-based cost justification tool, available as a free download from my website (Mayhew 2009). The example I use involves the development of an eCommerce website.

58.4.1 An eCommerce Website Development Project

First, let us look at the overall results of the cost-benefit analysis for this example, both in the spreadsheet tool and the book if you have it (Bias and Mayhew 2005). We will assume the UX project plan with its associated cost that is shown in Figure 58.3 and presented in the Total Costs worksheet of the spreadsheet tool (see also Table 3.2 on page 61 of Bias and Mayhew 2005).

In this example, the project UX engineer estimated that in the case of this project, the UX engineering plan shown in Figure 58.3 would produce an eCommerce website with the *expected benefits* summarized in Figure 58.4 and in the eCommerce worksheet in the spreadsheet tool (see also Table 3.26 on page 87 of Bias and Mayhew 2005).

Comparing these benefits and costs, the UX engineer argued that the proposed UX engineering plan would more than pay for itself in the first year after launch, as shown in Figure 58.5 and in the eCommerce worksheet in the spreadsheet tool (see also Table 3.27 on page 87 of Bias and Mayhew 2005).

Manager fully loaded hourly wage:	$200
Customer support fully loaded hourly wage:	$50
Usability lab:	In place

FIGURE 58.6 Analysis parameters for an eCommerce website.

Note that the simple analyses offered in this example and in the spreadsheet-based tool do not consider the time value of money, that is, the money for the costs is spent at one point in time, whereas the benefits come later in time, and this is *not* taken into account in this simple analysis. Also, if the money was *not* spent on these costs, but instead was invested in some other way, this money would likely increase in value and this is not addressed either. In my experience, usually the predicted benefits of UX engineering are so dramatic that these more sophisticated financial considerations are not necessary to convince the audience for the analysis. However, if needed, these more sophisticated calculations based on the time value of money and other factors are explained in Chapter 7 of Bias and Mayhew (2005).

The project UX engineer expected the UX engineering plan in this example to be approved on the basis of the cost justification in this example. Now let us see exactly how this net benefit was calculated, using the spreadsheet tool.

58.4.1.1 Start with the User Experience Engineering Plan

This is the first step in conducting a cost-benefit analysis. The UX engineering plan identifies which UX engineering lifecycle tasks and techniques (see above and also Mayhew 1999) will be used and breaks them down into required staff and hours. Costs can then be computed for these tasks in the next two steps below.

In this example, we start with the assumed plan represented in Figure 58.3 and in the Total Costs worksheet of the spreadsheet tool (see also Table 3.2 on page 61 of Bias and Mayhew 2005). Note that almost all the cells in this worksheet have a *pink* (gray dotted in the illustrations in this chapter) background. This indicates that the values in these cells are computed according to *formulas* that reference cells in other worksheets. Thus, when using the tool, you should *not* directly edit any of the pink (gray dotted) cells in the worksheets. Cells you *should* edit to reflect your particular project will appear with a *green* background in worksheets (solid gray in the illustrations in this chapter). For this stage in the analysis process, we are really just focused on the first two columns of this table, which lay out the UX engineering plan.

It is important to note that there is never one correct UX plan. This, as much else, is something that will vary across projects. The choice of technique for carrying out each task in the UX engineering lifecycle will depend on project budget and schedules as well as application/website complexity. Thus the example plan presented here should not be assumed. A project-unique plan must be designed around the parameters of a specific project.

58.4.1.2 Establish Analysis Parameters

Most of the calculations for both estimated costs and predicted benefits are based on project-specific parameters. These should be researched, established, and documented before proceeding with the analysis. Analysis parameters for this example are presented in Figure 58.6 and in the eCommerce worksheet of the spreadsheet tool (see also Table 3.28 on page 88 of Bias and Mayhew 2005).

In this example, we assume there is an existing website with known parameters, and the project involves a redesign, a common scenario for web development today.

It should be emphasized that when using the general cost-benefit analysis technique illustrated here, the particular parameters and parameter *values* used in this example should *not* be assumed. Both the particular parameters themselves and the parameter values of *your* project and organization should be substituted for those in Figure 58.6 and in the eCommerce worksheet (as well as all other worksheets) of the spreadsheet tool (see also Table 3.28 on page 88 of Bias and Mayhew 2005). For example, your current website traffic will be totally different, and the fully loaded hourly wage (the costs of salary plus benefits, office space, equipment, utilities, and other facilities) of your personnel may be significantly lower or higher than those assumed in these sample analyses. See also other worksheets in the spreadsheet tool for examples of relevant parameters for other types of development projects.

Note that in general, certain parameters in a cost-benefit analysis have a major impact on the magnitude of potential benefits. For example, when considering eCommerce websites as in this example, the critical parameters are the current average visitors per month and the average profit margin of a sale. When there is a high volume of site traffic and the average profit margin of a sale is high, even very small increases in conversion rates in an optimized website UX will add up quickly to significant overall benefits. On the other hand, where there is light traffic and/or a low profit margin per sale, benefits may not add up to anything very significant.

For example, consider the following two scenarios. First, imagine a case where average visitors per month are 10,000 and the average profit margin of a sale is $100. Even a conversion rate 1% higher than the current rate in this case adds up:

$$\begin{aligned}&10{,}000 \text{ visitors per month} * \text{conversion rate increase of } 1\% *\\ &\quad \$100 \text{ per sale } = \$10{,}000 \text{ more in profit, per month}\end{aligned}$$

This is a pretty dramatic benefit for a small improvement on the conversion rate.

On the other hand, if there were only 1000 visitors per month and the average profit margin per sale was $10, even if a 1% increase in conversion rate could be realized, the overall benefit would only be

$$\begin{aligned}&1{,}000 \text{ visitors per month} * \text{conversion rate increase of } 1\% *\\ &\quad \$10 \text{ per sale } = \$100 \text{ more profit, per month}\end{aligned}$$

Thus, in the case of eCommerce websites, costs associated with optimizing the UX are more likely to pay off when both traffic and the average profit margin per sale are high.

58.4.1.3 Calculate the Cost of Each User Experience Engineering Lifecycle Task in the User Experience Engineering Plan

The cost of each individual task/technique listed in Figure 58.3 and in the Total Costs worksheet of the spreadsheet tool (see also Table 3.2 on page 61 of Bias and Mayhew 2005) was estimated by breaking the task/technique down into small steps, estimating the number of hours required for each step by different types of personnel and multiplying these hours by the known fully loaded hourly wage of each type of personnel (if outside consultants or contractors are used, their simple hourly rate plus travel expenses would apply, and if external users are recruited to participate, they will be paid at some simple hourly rate or flat fee).

In our example, the project UX engineer used the task cost calculations, as shown in the User Profile through DUID worksheets of the spreadsheet tool. One example of these task cost calculations can be seen in Figure 58.7 (see also Tables 3.6 through 3.18 on pages 66–72 in Bias and Mayhew 2005).

These task cost calculations show the derivation of the numbers summarized in Figure 58.3 and in the Total Costs worksheet of the spreadsheet tool (see also Table 3.2 on page 61 of Bias and Mayhew 2005).

User Profile (Questionnaire)	Usability Engineers	Developers	Managers	Users	
Step	**Hours**	**Hours**	**Hours**	**Hours**	
Needs finding	4		2	2	
Draft questionnaire	6				
Management feedback	2		2	2	
Revise questionnaire	4				
Pilot questionnaire	4			4	
Revise questionnaire	2				
Select user sample	4				
Distribute questionnaire/ respond	8			25	
Data analysis	8				
Data interpretation/presentation	20				
Total hours	62	0	4	33	
Times hourly rate	$175	$175	$200	$25	
Equals	$10,850 plus	$0 plus	$800 plus	$825	= $12,475

FIGURE 58.7 Cost of user profile (Questionnaire).

Developer	$175
Usability engineer (UE)	$175
User	$25
Manager	$200
Customer support	$50
Trainer	$50

FIGURE 58.8 Fully loaded hourly rates.

One of the parameters used in the calculations of cost is fully loaded hourly wage of involved personnel. Fully loaded hourly wages are calculated by adding together the cost of salary, benefits, office space, equipment, and any other relevant overhead for a type of personnel and dividing this by the number of hours paid for each year by that personnel type. The hourly rate used here for UX staff is based on an informal average of typical current salaries of senior level internal UX staff and external consultants (see UPA website 2009 for the most recent salary survey of usability practitioners). The hourly rate of developers was similarly estimated (see, e.g., Payscale website 2011). However, the fully loaded hourly rate figures used to generate this and the other sample cost-benefit analyses in the spreadsheet tool and Bias and Mayhew (2005) are just examples, and you would have to substitute the actual hourly rates of personnel in your own organization in an actual analysis. Additional costs, such as equipment and supplies, could also be estimated and added into the total cost of each task/technique, although that was not done in this example for simplicity's sake.

In the spreadsheet tool, you would start by plugging in your fully loaded hourly wage parameters in the Fully Loaded Hourly Rate worksheet, as shown in Figure 58.8.

Then, for each table in the User Profile through the DUID Evaluation worksheets, you would enter your planned level of effort for each task, as for example in Figure 58.7 (see also Tables 3.6 through 3.18 on pages 66–72 in Bias and Mayhew 2005). *For any task that is not included in your plan, it is important to enter zeroes in all gray (green) cells* in the worksheet for that task. Similarly, if you plan to conduct a given task but not every listed step in it, simply enter zeroes in the gray (green) cells of any steps you do not plan to conduct.

Once you have entered your unique project parameters in the hourly wage and tasks worksheets, you can look back at the Total Costs worksheet to see the total estimated cost of your plan.

58.4.1.4 Select Relevant Benefit Categories

Since our example is a redesign of an *eCommerce website*, only certain benefit categories are of relevance to the business goals of the project, as shown in Figure 58.2 and the Benefits Categories worksheet in the spreadsheet tool (see also Table 3.1 on page 58 in Bias and Mayhew 2005). These include the following:

- Increased buy-to-look ratio
- Decreased abandoned shopping carts
- Decreased usage of "call back" button

As discussed earlier, the best benefit categories to include in a cost-benefit analysis will depend on the type of project and the intended audience for the analysis.

In this example, as compared to the existing site design, the UX engineer anticipated that in the course of redesign, the UX engineering effort would decrease abandoned shopping carts by insuring that the checkout process is clear, efficient, provides all the right information at the right time, and does not bother users with tedious data entry of information they do not want or need to provide. She/he expected to improve the buy-to-look ratio by insuring that the right product information is contained on the site and that navigation to find products is efficient and always successful. She/he expected to decrease the use of the "call back" button by insuring that the information architecture matched users' expectations and by designing and validating a clear conceptual model, so that navigation of and interactions with the site are intuitively obvious. Accomplishing all these things depends upon conducting the requirements analysis and testing activities in the proposed plan, as well as on applying general UX design expertise.

Figure 58.4 and the eCommerce worksheet in the spreadsheet tool (see also Table 3.26 on page 87 in Bias and Mayhew 2005) summarize the predicted magnitude of each of these benefit categories and then sums across them to predict a total benefit.

When selecting benefit categories to use in your own cost justification analysis of a UX engineering plan for an eCommerce website development project, you can use the benefits assumptions table in the eCommerce worksheet in the spreadsheet tool (also shown in Figure 58.9) to make your benefit assumptions. You can use all three of the benefit categories in that table, or choose to use any combination of them, or even others that are relevant to your situation. Simply enter zeroes in the cells representing assumption values for benefit categories you do not wish to include.

What follows is an explanation of how benefit predictions in each category were derived from project-specific parameters and assumptions.

58.4.1.5 Predict Benefits

In this step, the project UX engineer predicted the magnitude of the benefits that would be realized—*relative to the current website,* which is being redesigned—*if* the UX engineering plan (with its associated costs) was implemented. Benefits were predicted in each selected benefit category by doing some simple arithmetic based on project-specific analysis parameters and some simple project-specific assumptions.

Note that while at this point in the process of your own analysis, you have already filled in your project-unique parameters, you now need to consider your project-unique benefits assumptions and modify the values for them in the benefits assumptions table in the spreadsheet tool. The project *parameters* for this example are laid out in Figure 58.6 and in the eCommerce worksheet in the spreadsheet tool (see also Table 3.28 on page 88 in Bias and Mayhew 2005). The benefits *assumptions* are given in Figure 58.9 and in the eCommerce worksheet in the spreadsheet tool (see also Table 3.29 on page 90 in Bias and Mayhew 2005).

In the case of calculating predicted buy-to-look ratio benefits, the relevant *parameters* are from Figure 58.6 and in the eCommerce worksheet in the spreadsheet tool (see also Table 3.28 on page 88 in Bias and Mayhew 2005):

- Current average visitors per month
- Profit margin per unit

The *assumption* made regarding increased buy-to-look ratio in our example (see Figure 58.9 and the eCommerce worksheet in the spreadsheet tool) is the following:

- There will be a 1% increase in visitors who decide to buy (and check out successfully)

Benefit assumptions are the crux of the whole cost-benefit analysis. While *costs* can be calculated with a high degree of confidence based on past experience, and all the *parameters* fed into the analysis are known facts, the *assumptions* made are just that—assumptions, predictions, rather than known facts or guaranteed outcomes. The audience for the analysis is asked to accept that these assumptions are reasonable ones and they must to be convinced by the overall analysis.

It should be pointed out that *any* cost-benefit analysis for *any* purpose must ultimately include some assumptions that are really only predictions of the likely outcome of investments of various sorts. The whole point of a cost-benefit analysis is to try to evaluate in advance, in a situation in which there is some element of uncertainty, the likelihood that an investment will pay off. The trick is basing the prediction of ROI on a firm foundation of known facts and reasonable assumptions. In the case of a cost-benefit analysis of a UX engineering effort, there are several foundations upon which to formulate sound assumptions regarding predicted benefits, including the following:

- References to the general UX literature documenting impacts of certain types of design approaches on user performance
- References to after-the-fact case studies of benefits achieved through UX engineering
- Anecdotes from colleagues
- One's own past experiences as a UX engineer
- One's own past experience working with a particular design/development organization

See Bias and Mayhew (2005) for more in-depth discussion of making and supporting analysis assumptions.

In general, it is usually wise to make very conservative benefit assumptions, for several reasons. First, any cost-benefit analysis has an intended audience, who must be convinced that benefits will in fact outweigh costs. Assumptions that are very conservative are less likely to be challenged by the relevant audience, thus increasing the likelihood of acceptance of the analysis conclusions. In addition, conservative benefit assumptions help to manage expectations. It is always better to achieve a greater benefit than was predicted in the cost-benefit analysis, than to achieve a lesser benefit, even if it still outweighs the costs. Having underestimated benefits will likely make future cost-benefit analyses more credible and more readily accepted. Also, it is important to realize that some validly predicted benefits may be cancelled out by other non-UX-related changes, such as decreases in user morale and motivation, decreased system reliability or response time, and so on. Having made conservative benefit predictions decreases the possibility that other factors will completely wipe out any benefits due to improved usability.

Returning to the explanation of the derivation of benefit predictions in our example, we see the benefit assumptions for each benefit category given in Figure 58.9 and in the eCommerce worksheet in the spreadsheet tool (see also Table 3.29 on page 90 in Bias and Mayhew 2005). The UX engineer based the benefit assumptions in this analysis on statistics available in the literature. In particular, she/he began with the often quoted average eCommerce website buy-to-look ratio of 2%–3% (Sonderegger 1998; Souza 2000, Fireclick 2010). She/he then based the assumption that she/he could improve this rate by a minimum of 2% (1% from improving the product search process and 1% from improving the checkout process) through UX engineering techniques, on a variety of statistics available in the literature.

Benefit Assumptions	
Increased Buy-to-Look Ratio	
Increase in visitors who decide to buy (and checkout successfully), relative to total monthly visitors	1%
Decreased Abandoned Shopping Carts	
Increase in visitors who have already decided to buy but who also now checkout successfully, relative to total monthly visitors	1%
Decreased Usage of "call back" button	
Decrease in number of visitors using "call back" button, relative to total monthly visitors	1%

FIGURE 58.9 Benefits assumptions for an eCommerce website.

For example, Souza (2001) suggests that it is typical for as much as 5% of online shoppers to fail to find the product and offer they are looking for and cites one study in which 65% of shopping attempts at a set of prominent eCommerce sites ended in failure. Sonderegger (1998) suggests sales under perform on eCommerce sites by as much as 50% or more due to poor site usability. GVU (1999) survey data suggests that almost 50% of website users cannot find the information they are looking for and that over 80% web shoppers have left one site for another when they had dissatisfying experiences with site usability. Souza (2001) also notes that companies spend between $100,000 and $1,000,000 on site redesigns, but few have any sense of which specific design changes might pay off.

The project UX engineer based the assumption of reduced usage of the "call back" button by 1% on statistics, suggesting that as much as 20% of eCommerce site users typically call in to get more information (Souza 2001).

Most of us have experienced all these problems—difficulty finding products, difficulty checking out, and need to use a "call back" button to complete transactions—and would have little argument with the idea that they are typical even in 2012. Given all the dramatic statistics cited, the modest assumptions made in this analysis seem very conservative indeed. And given the fact that companies typically spend a great deal of money on redesign with no process in place that can insure improvements in the site UX, the notion of a highly structured and goal-oriented UX process starts to make a lot of sense.

Figure 58.10 and the eCommerce worksheet in the spreadsheet tool (see also Table 3.30 on page 91 in Bias and Mayhew 2005) show the calculation of the total predicted benefit in each benefit category, based on parameters and assumptions in Figures 58.6 and 58.9.

The sum of predicted benefits in these three separate benefits categories is given in Figure 58.4—a monthly benefit of $28,125.

When conducting your own project-specific cost-benefit analysis, note that while you need to enter values for some parameters and for assumptions in the project type worksheet in the spreadsheet tool, all tables to the right of those two in that worksheet are based on calculations involving previously entered values in other tables and worksheets, indicated by the dotted gray (pink) background in those cells. You will not edit those tables at all. Also recall that you will want to enter zeroes for any parameter or assumption you do not wish to use in your analysis.

58.4.1.6 Compare Costs to Benefits

Having calculated the costs of a particular UX engineering plan and predicted the total benefits to result from executing that plan as compared to not executing it, the next step is simply to compare the total costs to the total benefits to arrive at a net benefit. In this example, this calculation is shown in Figure 58.5 and in the eCommerce worksheet in the spreadsheet tool (see also Table 3.27 on page 87 in Bias and Mayhew 2005). The analysis predicts a clear and substantial net benefit ($111,575) in the first year. After that, additional benefits of $28,125 per month are predicted to continue to accrue assuming all else (e.g., the economy) remains constant.

Our UX engineer's initial UX engineering plan appeared to be well justified. It was a fairly aggressive plan, in that it included all lifecycle tasks, and the most reliable and thorough techniques for each task. Given the very clear net benefit, the UX engineer would have been wise to stick with this aggressive plan and submit it to project management for approval and funding.

If the net benefit had been marginal or if there had in fact been a net cost, then it would have been well-advised to go back and rethink the proposed UX engineering plan, scaling back to shortcut techniques for some tasks. Perhaps, for example, the UX engineer should have planned to do only a shortcut user profile by interviewing sales and marketing personnel, a shortcut task analysis consisting of just a few rounds of contextual observations/interviews with users, and do just one iterative cycle of UX testing on a complete detailed design, to catch major flaws and be sure the predicted benefits have been achieved. Of course, this would make the predictions more risky and call for an even more conservative analysis.

Individual Benefit Calculations				
Increased Buy-to-Look Ratio				
Current monthly visitors ×	Rate of increase in buyers ×	Profit margin per unit =		
125,000	1%	$10		$12,500.00
Decreased Abandoned Shopping Carts				
Current monthly visitors ×	Rate of increase in buyers ×	Profit margin per unit =		
125,000	1%	$10		$12,500.00
Decreased Usage of "call back" button				
Current monthly visitors ×	Rate of decrease in use of "call back" button ×	Hours saved per call eliminated ×	Customer support hourly rate =	
125,000	1%	0.050000	$50	$3,125.00

FIGURE 58.10 Benefits calculations for an eCommerce website.

As explained earlier, to plan the budget for a UX engineering program, it makes sense to start out by calculating the costs of the most aggressive UX engineering plan that you would like to implement, including the more reliable and thorough techniques for most if not all lifecycle tasks. If predicted benefits outweigh costs dramatically, as they usually will when critical parameters are favorable, then you can easily make a good argument for even the most aggressive UX engineering plan, because only the most conservative claims concerning potential benefits have been made, and as such can be defended easily.

If, however, costs and benefits in the initial calculation seem to match up fairly closely, then you might want to consider scaling back the planned UX engineering plan, maybe even to just a bare-bones plan, with more shortcut techniques applied for each lifecycle task.

To illustrate this planning strategy, consider the following two scenarios. First, revisit our example analysis, which involved an eCommerce website. A fairly conservative assumption was made concerning benefits: a 1% increase in conversion rate. Even with this fairly conservative assumption, the fairly aggressive UX engineering plan was predicted to pay off in the first year, with net benefits continuing to accrue dramatically after that.

In fact, if you had made the more aggressive and yet still realistic benefits assumption of a 3% increase in conversion rate (rather than by 1%), the net benefits would have summed to $411,575 in the first year alone, with benefits of $53,125 per month continuing to accrue after that. Thus, one could argue that while even the most conservative assumptions predict a fairly dramatic payoff of a comprehensive UX engineering plan, the likelihood is that the payoff will be higher still. Please note that this calculation is performed for you by the spreadsheet tool by simply changing a single cell—changing the benefit assumption of increased buy-to-look ratio from 1% to 3%.

In contrast, suppose you again started out by costing out a comprehensive UX engineering plan at $225,925. In this case, however, suppose that there are only 25,000 average visitors per month rather than 125,000. In this case, calculations using the original more conservative benefits assumptions would show a loss until well into the fourth year (try changing this single number in the parameters table in the worksheet and then inspecting the bottom line results in the last table to the right in the worksheet).

Even though the benefits assumptions were conservative, while a loss in the first few years is not necessarily a bad thing, it still seems risky to make an aggressive investment that, based on conservative assumptions, really does not show a significant payoff even over the course of four years. In this case, one would want to scale back the planned usability engineering program and its associated costs. Because the benefits assumptions made were so conservative, it is likely that they will be achieved even with a minimal usability effort. In this way, you can use the spreadsheet-based cost-benefit analysis tool to “what if” to plan a level of UX engineering effort that is most likely to pay off—or to decide to spend your limited UX dollars on a different project altogether that is more likely to pay off.

58.5 SUMMARY

The cost-benefit analysis example offered in this chapter is based on a simple subset of all actual costs and potential benefits and very simple and basic assumptions regarding the value of money over time. More complex and sophisticated analyses can be calculated (see Karat, Chapter 4 in Bias and Mayhew 2005). However, often a simple and straightforward analysis of the type offered in the example above will be sufficient for the purpose of winning funding for UX engineering investments during software application or website development in general or for planning appropriate UX engineering plans for specific development projects.

The example analysis offered here suggests that it is usually fairly easy to justify a significant investment of time and money in UX engineering during the development of eCommerce websites. The framework and example presented in this chapter, along with the free spreadsheet tool available from my website, should help you demonstrate that this is the case for your development projects.

59 Technology Transfer

Kevin M. Schofield

CONTENTS

59.1 INTRODUCTION

This chapter is intended to provide guidance on how to approach technology transfer of HCI-related research. Admittedly, there are many different perspectives one could take in looking at this often-difficult problem: researcher versus practitioner, industry versus government versus academia. There is also the extra, added dimension of whether the transfer is within the boundaries of a corporation or across corporate lines.

In this chapter, we will discuss tech transfer both internal and external to a company and then discuss commonalities across the two processes. Primarily, we will look at it from the perspective of the researcher, because in practice the burden is more on the researcher to justify the transfer and to make it work. Practitioners, however, will also gain value from reading this, as it will help them to understand the role of the researcher in technology transfer.

Although any technology transfer has its challenges, HCI tends to be a particularly difficult one. This is due to many factors, but the two main factors are that it is often more about abstract ideas than specific implementations and because we in the HCI community are still fighting the (wrong) impression that HCI is an afterthought and not the "real meat" of research and development efforts.

59.2 NEW FACE OF TECHNOLOGY TRANSFER

The last few decades have seen dramatic boom-and-bust cycles in the technology industry that, for a number of reasons, has changed the face of business, commerce, and information flow. Probably, the most earthshaking of those changes has been within the high-tech industry itself, as fitting for such a rabid consumer of its own technologies and ideologies.

The Internet, through its nearly ubiquitous connectivity to information and other people, has reshaped organizational patterns and forged a brand new set of relationships between researchers, designers, developers, manufacturers, marketers, and the other people involved in business and commerce. Those new organizations and relationships respect neither national nor corporate borders and bring us one step closer to the "friction-free" economy that was trumpeted in the mid-1990s.

Technology transfer is not what it used to be, largely because research and development is also not what it used to be. As Friedman (2005) pointed out, the world has flattened, and increasingly research and development can be done anywhere, with anyone, and for anyone. In lockstep, the relationships between corporate and academic R&D have also evolved; there are fewer and smaller standalone corporate research laboratories as many companies have chosen to "outsource" their basic research to academia. Even those companies that continue to invest in basic research are realizing that with fewer barriers to communication and collaboration, an "open innovation" model of joint R&D, as suggested by Chesbrough (2003), often makes sense to maximize the impact of internally generated ideas as well as to take full advantage of the most relevant externally generated ideas.

Government research, and funding, is also changing. Some of this is due to economic cycles; much is due to shifting political priorities. In Europe, for example, the Lisbon Agenda defines the European Union's desire to make Europe the most innovative economy in the world by 2009, and this drives their investment in research and development. In contrast, in the United States, despite a wide recognition that IT is driving economic advances, the major funding agencies (NSF, DARPA, and NIST) have reduced their support for academic research in computer science, with a built-in assumption that private industry should and will take up the slack. Somewhere in the middle, many countries (e.g., Canada, Australia) have programs where academic researchers who are funded by private companies can apply to the government for matching funding.

Still, as the National Research Council (2003) observed, successful technology transfer is usually a marathon, not a sprint, and may require years to reach completion. It also reflects a complex partnership between government, industry, and academia. What should we take away from this? That, clearly there is no one model for technology transfer from research into industry—there exists a whole spectrum. As mentioned previously, some governments fund research, while others do not, and some are in the middle. Likewise, some companies do their own basic research, while others outsource it, and some are in the middle. Some universities keep a death grip on their faculty's intellectual property; others, such as University of Wisconsin and University of Waterloo, have a policy that IP belongs to the inventor. Many are in the middle.

Consequently, there is no "playbook" that will explain exactly how to transfer a research result. Both researchers and practitioners will need to be very flexible and willing to adjust to the situation in which they find themselves. Tech transfer is, in the end, a business, and the best way to succeed at it is to think like a businessperson.

59.3 INTERNAL TECHNOLOGY TRANSFER

I am constantly surprised by the number of people who believe that technology transfer is some sort of Rube Goldberg machine,* where technology is inserted in one end of the contraption, strange things happen in the middle that usually involve people in uncomfortable and contorted positions, and then magically it pops out on the other end. Countless books and articles have been written (Lesko, Nicolai, and Steve 1998; Mock, Kenkeremath, and Janis 1993) in an attempt to document the perfect mechanical process for technology transfer. And yet, despite the fact that nearly everyone has had painful experiences trying to define a mechanical process for technology transfer, they still try to do it and complain bitterly when it fails (Butler 1990; Hiltzik 1999; Isaacs and Tang 1996; Singh 1993).

59.4 TECHNOLOGY TRANSFER AS A SOCIAL PROCESS

Tech transfer is not a mechanical or logistical process; it is fundamentally a social process. It succeeds when people build a relationship between the provider and the recipient that fosters trust and communication. Manning (1974) recognized that successful technology transfer centers on viewpoints and perspectives and fundamentally on communications. Foley (1996) spoke to this point most directly, that technology transfer is a "full-contact sport" that centers on the people.

Successful product organizations understand that risk is their mortal enemy. They work hard to proactively manage the risk in their development process or to remove the risk factors altogether. One of the most prevalent and difficult-to-manage risk factors is an external dependency, and let us be honest: an external dependency from a research organization looks about as risky as it gets. As long as your counterparts in product organizations think of a research organization that way, technology transfer is difficult at best and often outright impossible.

To succeed with technology transfer, we need to mitigate the risk or at least the perceived risk in the minds of the people we wish to receive our technology.

Up to this point, none of this is particularly controversial, but this is where the paths diverge. Many people will tell you that you succeed in mitigating the risk by creating well-defined, step-by-step processes through which you and your industry partner will enact the technology transfer. I argue that this approach fails more often than it succeeds, for two main reasons:

- The only experience that people in industry have with external dependencies is the occasional dependence on an external contractor or supplier to deliver a finished component ready for integration. They inevitably use this as the model for defining their tech-transfer process from research, and it is fundamentally incompatible. Research technologies are not finished components, and any product organization that expects a research group to deliver a finished component fundamentally misunderstands the role, expertise, and hiring practices of a research organization. Research groups almost never understand the development and test practices of a commercial product organization; even if they did, those practices vary so widely between organizations that past

* For those in the United Kingdom, that would be "Heath Robinson machine."

experience does not guarantee that they could successfully deliver a finished component. Moreover, it is not the goal of a research organization to develop technologies into finished components; its goal is to discover and prove solutions to previously unsolved problems. To do so, a research organization requires different skills and expertise and frankly different development and testing methodologies. Both research and product organizations need to understand this fundamental difference and embrace it as a way to complement each other's strengths, rather than ignore it and delude them about a theoretical capability that, practically speaking, is not there.

- People who do not understand each other cannot communicate and do not trust each other and cannot be expected to work cooperatively toward a shared goal, even within the best-defined process. The trust and communication must come first. If the two people on opposite sides of a table trust each other, then the two of them can accomplish anything; if they do not, they will never accomplish anything of value.

59.5 BUILDING TRUST IN STEPS

So then comes the catch: how does one build trust? By working side by side, of course! This means that one must start with the kind of activities that are initially low in risk, but high in communication, and build on one's successes to build more trust and overcome successively higher levels of risk.

Step 1 is to establish trust that one is an expert in the domain. Technical people, whether in research or in industry, are almost universally avid readers and understand the importance of staying up to date in their fields. But we all suffer from a lack of time to weed through the volumes of less-than-useful information to find the truly valuable nuggets of wisdom. If someone in a product organization expresses an interest in one's field, an offer to forward them a set of papers, articles, and books that represent the seminal reading is a great first response. Granted, doing a literature search is not glamorous work, but it fundamentally demonstrates a working knowledge of the domain and an ability to provide guidance. Equally important, it shows a healthy respect for the people's intellect and a flattering assumption that they will be able to read and digest the material. One of two things will happen. Either they will actually read the materials sent to them, in which case they have not only made an initial investment in seeing a technology transfer happen but have also been provided with great topics for further conversation, or they will not read the material and most likely conclude that it is simply easier to rely on the researcher as their expert rather than to become experts themselves. Either way, it is a foot in the door. They will ask endless questions as they try to decide for themselves what is within the realm of possibility and, more importantly, practicality. It is essential to ask them just as many questions to understand as completely as possible their constraints and to make clear recommendations on what they can expect to build.

Step 2 is to move from simply giving domain guidance on the state of the art to provide feedback on product-design plans. This involves offering to review specifications and providing timely feedback. Timeliness is critical—schedules are the rules of the game, and an ability to stay within their stated schedule reflects an understanding of the rules, an appreciation for their importance, and a commitment to the success of their project. This is also a critical test of a researcher's ability to think practically; in their distrust, they might expect suggestions of wildly impractical things that would have a negative impact on their schedule or require resources out of proportion the relative importance of the technology to the overall product. It is the researcher's job to show once again an understanding of their constraints and the value added to their team effort. Success will be apparent when a subtle but important shift happens: instead of the researcher asking to review their design documents, they will ask the researcher to review them.

Step 3 is a significant one indeed: when the clients ask the researcher to help write the specification for the product. Do not expect this to happen until there has been a clear success at Step 2 that has established credibility. But when it does happen, the product organization is making a loud and unambiguous statement that they now think of the researcher as part of the product team. This is an enormous step for a product group to take in their relationship, and it is a heavy responsibility to take on. At first, they will probably only delegate small parts, and often they might ask the researcher to co-write design documents. But regardless of the size of the assignment, the key to success is the same: whatever is designed must be easily buildable and testable. If there is any significant disagreement on whether the design can be built or tested, the product organization will not take the risk. Development organizations (at least the successful ones) are inherently conservative and will overstate the costs to build new technologies.* This is not only another test of whether the researcher understands their constraints but also equally whether he or she understands their development process. I encourage "aiming low" initially and looking for indications from the team that they would like to work together to design something more aggressive. If there is success in co-designing components, they will loosen the reins and delegate more responsibility (with more autonomy).

Step 4 is where one (finally) gets involved in implementation. It has taken enormous patience on the part of the researcher to get here, and there are still landmines everywhere. No two development organizations are alike; they all have different practices for creating, documenting, integrating, accepting, testing, and deploying new products. It is impossible to understand all of their processes, and it is

* Ironically, it has been my experience that development organizations tend to estimate incorrectly not in the new technologies, but rather in the incremental improvements to legacy components, and particularly in the "integration" work in making multiple components work together.

very unlikely that they will all be written down; yet, every one of them has an opportunity to break form and cause a rift. I would encourage asking the group manager how they bring a new employee into the group and what training and mentoring that person would go through; further, see if there are opportunities to take advantage of such a process to help to get up to speed. If one has made it this far, the product team wants to see a success as much as the researcher does. Because one's success is the other's success, the product team will be very reasonable about doing things to help themselves be understood by the researcher, especially if it is clear to them that that is the goal. All development groups fall in love with their own processes, and one can earn their cooperation by showing equal respect for those processes, no matter how silly they might seem to an outsider.

The key to success in a development process is to realistically promise and over deliver. Set rational expectations; they should think that you can carry your own weight, but not that you are God's gift to engineering. Be honest about the readiness of your technology in as crisp terms as possible; Speser (2006) suggests terminology for Technology Readiness Levels that represent how far away from market introduction the technology is currently. Promise metrics for work and for the technologies created that are achievable but not overly aggressive, and then exceed those metrics. By doing that, it is possible to fully gain their trust and move on to discuss with them more aggressive technology transfers.

It is important to note that in this "pyramid" of sorts that we are building with increasing levels of risk and corresponding trust, it is possible to peak at any level. For instance, if the researcher does not have the development skills to co-develop components with a real product team, then do not try to do it! By all measures, every step in this process can be considered technology transfer. Product organizations need knowledge, understanding, and ideas about technology just as much as they need finished technology components; they need to understand what cannot be built just as much as what can. And, most importantly, they need researchers to tell them honestly what they are and are not capable of doing for them. Even without ever delivering a finished component to a product organization, one can still have a litany of technology-transfer successes for which the product organization will sing praises. It is more important to proceed in measured steps built upon past successes and build the trust and the lines of communication that will guarantee future successes.

59.6 THINKING FOR THE FUTURE

It is also important to be thinking to the future—to be thinking about what comes next. There is always a desire to simply throw a technology over the wall and then to move on to the next research project, but this is unrealistic. It never really works that way, and even if it did, "throwing it over the wall" would end the relationship and any opportunities for future technology transfer; the ongoing relationship after the transfer is an opportunity to carry on a dialogue about the next great technology.

From the product–organization perspective, there is rarely a "clean" way to integrate a component. The overwhelming majority of development work is revisions to existing products; very rarely are new products started. Revision work means that new components need to be integrated into an existing legacy framework; this usually requires development work on both sides of the integration to ensure the optimal match.

59.7 CONSIDERING HCI IN THE TECH TRANSFER PROCESS

As if this was not difficult enough, applying this approach to HCI-related technology transfer introduces its own challenges. One can read The Psychology of Human–Computer Interaction (Card, Moran, and Newell 1983) and learn that at a very fundamental level, a set of scientific principles holds very broadly. However, we in the HCI community have also learned that interactive systems must be designed within the context of a particular task and human and that this very fact makes it tricky at best, and misleading or impossible at worst, to try to generalize specific designs to other contexts. Even with the best of intentions and the most thorough usability testing, there are no clear guidelines about how much of an HCI-related research technology can actually be transferred and particularly for integration into an existing product. So "throwing over the wall" is especially difficult, as it calls for potential redesign, as well as further development and integration, test, localization, support, and operations (it is increasingly a service world, after all).

In the traditional view of technology transfer, lack of a clean handoff would be fatal. In the "relationship" view, however, this is an opportunity to build a working model that lets you overcome the challenges and work side-by-side with a product organization to guide the transfer of your work.

Beyond simply moving up the pyramid, one can do other important things to deepen the relationship. Scheduling regular "maintenance" conversations can help to maintain communication channels and to keep abreast of activity in the product organization; it is also an opportunity to continue to update them on progress on new work. The relationship can also be used to improve the researcher's own work by learning about critical real-world issues. Good product organizations have a wealth of information about their customers; by using their access to real customers (and aggregate information about them), the relevance of research activities can be improved. It is an opportunity to ask key questions, learn about critical product strategic direction, conduct user studies, and find out what difficult HCI and technical issues are about to become critical issues for real customers. This is the golden opportunity to get out of the ivory tower.

As an aside, it is worth pointing out that HCI has its own value-add in the tech transfer process helping to quantify improvements. Often it is important, when there are competing technologies, to demonstrate the superiority of your technology. HCI's processes to measure quantitative differences in ease of use and "time on task" can be very helpful in these cases.

59.8 EXTERNAL TECHNOLOGY TRANSFER

Technology transfers outside the boundaries of a legal entity, regardless of whether they originate in a government agency, academia, or an industrial lab, are almost by definition cleaner types of transfers. This means that one will be participating in a transaction involving the sale or licensing of technology, or contracting to provide some service, or both. So, the first order of business is negotiating the "deal."

59.9 KNOW WHAT YOU ARE SELLING

It is critical to know and understand what is being sold: outright ownership of intellectual property or a license to it? Is it a complete solution that has been developed or just pieces? Those pieces might include any or all of the following:

- User interface design
- System specifications
- A working prototype
- An actual implementation, tested to some level of quality
- The source code for a software implementation
- Copyrights
- Patents
- Working time as a commitment to support ongoing productization
- A running service that you host

59.10 KNOW WHAT YOU ARE NOT SELLING

It is equally important to know what is not being sold. If one would like to continue this work, he or she will need to make sure to preserve rights and ownership to continue that work. Otherwise, one could very well put oneself out of business by selling complete ownership to a valuable asset or by signing an exclusive license, which precludes licenses with any other company.

59.11 KNOW THE PEOPLE INVOLVED

Deals inevitably involve lawyers as well as what are known as "business development" people: those whose job are to negotiate deals that further the business interests of their employers. One can assume that the company negotiating will have both business development people and lawyers; it makes good sense for the researcher to have them too. This is a situation where we need to put our pride and high-minded notions about doing business "on a handshake" aside. While the overwhelming majority of companies are not in the business of stealing from people like us, and will not try to do so, to get the most value in return for what is being offered one needs someone on his or her side who understands what is customary in intellectual property deals and how to negotiate for it. Even a brilliant and excellent debater who does not know what to reasonably ask for is at a serious disadvantage. The bottom line: find someone with good business development skills and experience to negotiate the deal.

Likewise, once the terms of a deal have been negotiated, one needs a lawyer to write it up and make it legally binding. Do not even think about self-representation in the drafting of an intellectual property agreement; the laws are changing too quickly (which is not the fault of the lawyers) for a researcher to understand which ones apply to the situation and should be factored into the drafting of an agreement. Mock, Kenkeremath, and Janis (1993) set out the basics of existing laws and how they relate to technology transfer, though the details have changed substantially since then. Many good books exist to help one to get educated on current intellectual property laws, although that is a poor substitute for a competent attorney skilled in the current practice. The Association of University Technology Managers (http://www.autm.net) also provides a wealth of resources to its members on a number of issues related to technology transfer and intellectual property.

The key to success is to understand the defined role of each of the three people on a negotiating team: oneself, the business-development person, and the lawyer. The researcher's role is to be the technical expert and to place a value on the work as well as what the people on the other side of the table are offering in return; one's role as "client" is to decide what is needed to be successful and what additionally is desired but negotiable. The role of the business development person is to take the articulated needs and desires and try to structure the terms of an agreement that will work for both parties. He or she understands business risks and will help the team members to understand them and make informed decisions about how much risk can be tolerated. The role of the lawyer is to take the terms and write them down in words that both parties understand and that can be interpreted under the law to protect the client's interests. The lawyer also understands and can articulate the legal risks; laws are often subtle and ambiguous things that can be interpreted in many ways (in fact, nations have an entire branch of government that does nothing but interpret the laws). Any contractual obligation runs the risk of being interpreted in a way other than how it was intended, and a lawyer can help the team members to understand how likely that is, based on the language of the law and similar previous cases where the law has been interpreted by the courts. Just as there is always business risk, there is always legal risk, and in the end, it will fall upon the researcher to make the decision as to whether the risk is acceptable.

It is also important to understand who plays these roles on the "buying" team. Speser argues that the most important role to understand (and in particular who is playing that role) is that of the decision maker, who at the end of the day will actually decide whether to go ahead and acquire a technology. It most likely will not be someone in the legal department or someone in their internal research department, who might even see you as unwanted competition. It most likely will be the person in the development team who actually plans to use the technology, as that person is the one who will need to find the money to purchase it as a part of running their business.

Where do deals go wrong? In my personal experience, they often go wrong when these three roles become confused and when the business development person and the lawyer start to make the key decisions. The researcher must live with the result of the deal, not them. On one end of the spectrum, there is no such thing as a risk-free deal; on the other end, even a high-risk deal could be worth doing if the reward is also high enough. Those decisions are the client's, not theirs, and the researcher as client should insist on making them.

There are many good sources for both business development people and lawyers. Venture capitalists will often have a "short list" of ones they trust to do their business transactions. The Chamber of Commerce for a local area can also provide recommendations and often will track complaints registered against specific ones. Many regions also have associations of entrepreneurs, inventors, and small-business owners, with great resources to draw from.

Of course, if one already works in a research lab, the institution most likely has a technology-licensing office that will negotiate and draft deals on the researcher's behalf (and are likely required to do so if the researcher's employment agreement assigns ownership of inventions to the employer). In that case, one will still need to stay involved to make sure that the researcher's needs are met in whatever deal is negotiated.

59.12 CRAFTING A DEAL

The most difficult process of negotiating a deal is crafting an arrangement that meets the needs of both sides. I have seen that many negotiations take much longer to conclude, and in many cases fail to conclude successfully, because either or both sides did not bother to try to understand the other side's business needs. Business partnerships are always about finding a way to help both parties be more successful. Speser goes as far as to suggest that deal making is the search for a Nash equilibrium whereby all parties have more incentive to stay with the deal than to change their tactics. The best way to do that is to understand what one's prospective partner's business is about and likewise to share enough information about one's own business, openly and honestly, so that together a combination can be found that works for both sides. Find out everything available about a partner's current business situation:

- Their revenues and profits
- Their competition
- Their most important customers
- What customers are saying about their product
- Where they say they want to take their business in the future
- The problems and challenges they are facing

This essential information will guide you to deeper insights on how to offer terms that will be seen as valuable to a potential buyer or licensee. Steinberg (1998) described his experiences in negotiating deals and his own well-known and well-respected philosophy for how to structure deals makes good business sense for all parties.

Companies will pay for the value that can be delivered to them. They will pay a certain amount of money to make an even larger reduction in their costs (because in the end they save money). They will of course pay to help themselves make even more money. Finally, they will pay if one solves a problem for them. As a deal is structured, try to cast it in terms of what it does for them; those are terms that they can understand and, more importantly, quantify in a valuation.

Take it further. Help the buyers in any way possible to place a value on what is brought to the table. For example, conduct a user study on their existing product and another showing how the technology being offered will improve their product (if it happens to address a key customer complaint, all the better, and that should definitely be brought to their attention). During the negotiations, show them a smart, effective professional who can work with them. This does not mean that you need to negotiate hard to the very last item; contrary to popular belief, the tough negotiators are not always the most respected, and in fact, they are often the ones that create their own reputation for being difficult to work with. It is much more important to demonstrate an understanding of the buyers and an ability to speak their language, as well as willingness to help them make the case to the decision makers in their organization's senior management.

59.13 CONFIDENTIALITY AND NDAs

One large challenge in negotiating deals is the issue of confidentiality, which usually rears its head first in the often-dreaded nondisclosure agreement. Nondisclosure agreements are signed before revealing confidential information to ensure that the information would not be disclosed to competitors. That part is a good business and a natural, noncontroversial part of good-faith bargaining—we all need to be able to keep secrets. The difficult part of nondisclosures is the issue of residuals: by looking at confidential information, I learn things and then I carry that learning around in my head for the rest of my career. What am I allowed to do with that information in my head, and who in fact owns it? From the discloser's point of view, one wants to make sure that someone cannot use his or her own confidential information to compete. From the other side, it is impossible to know exactly what will be disclosed, or what business opportunities are going to come one's way tomorrow, so it is deeply problematic to sign away the ability to enter certain businesses simply for the privilege of looking at confidential information. Both sides sound very reasonable, and they are, which is why NDAs are no trivial matter and often become the stopping point in negotiations.

Whenever possible, try to complete as much of the negotiations as possible without entering into an NDA, because it simplifies matters and prevents the trust issues from rising to the surface too early. The downside is that this makes the early negotiations a precarious dance, where a researcher needs to show the other party enough to convince them that the technology is real and solves their problem, without giving away key secrets. There are things that still can be done: tell them "what" it does, instead of "how" it does it, and show them the system working. The goal is to make them crave it enough that they will want to sign an NDA under the researcher's terms to complete the technical due-diligence required for them to close the deal.

It is critical to think this all through before getting to the negotiation table—these are never decisions to make under time and social pressure. It is also critical to realize that the whole issue of confidentiality and NDAs is one more business risk; admit it and decide for yourself whether (and when) the potential reward outweighs the risk. This is one of the clear cases in which a lawyer will be extremely conservative and protective and describe in great detail everything that could be lost by entering into an NDA (or by showing technology without an NDA). But, in the end, the decision is the researcher's.

59.14 GOING TO THE NEGOTIATING TABLE

Negotiating a deal is probably the most hyped and feared part of this whole process; perhaps, we have all had too many nightmares about slick car salesmen tricking us into paying too much for too little in return. The reason we fear car salesmen is that the salesman has all the information about what the car is really worth and shares none of it with us; we are forced to blindly trust him, and many of us do not.

Steinberg (1998) once again shared his wisdom on a sound and ethical approach to negotiation in his "twelve essential rules for negotiating." Not nearly as ambitious as Steinberg, I have only three basic rules for negotiating:

1. I obtain as much information about each side's position as possible before arriving at the table.
2. I have a list of what I really need to succeed and a separate list of what I want to have in addition. I hold firm on my needs, and I am willing to compromise on my wants.
3. I always negotiate a deal in which both sides win.

Understanding a potential business partner's position is critical to negotiating success for a number of reasons. First, it tells what they are looking for. Ask the same list of questions we discussed with internal technology transfer: Who are their customers? What are those customers saying about their products? Who are their competitors? What is the company looking for that will help them to be more successful? What are their strengths and weaknesses? Second, and very much related, it tells how the buyer will value what they are offered. Successful business deals involve an exchange of value that both sides view as fair and equitable, but value is of course relative to the company and its context. Understand that in order to find an equal trade. Reading the company's annual report is an excellent source of information about a company (if it is a publicly traded company). Reading news articles and competitive reviews also provides invaluable information about the business pressures the company is under, as well as the assets that they bring to the table.

Having the list of the things that one really needs and the things that one wants in addition is a valuable step in preparing for negotiation. I have seen many people come to the table unwilling to compromise on anything; they ask for too much in the beginning and believe strongly that compromising on anything is a sign of weakness. Negotiations like those always take longer than they should and are very frustrating. In some cases, they spend more money in lawyers' fees for fruitless negotiations than the value of the small items on which they refuse to compromise. I recommend starting with a basic negotiation on the core needs of both sides; not only does that keep you focused on the heart of the deal but it also tends to simplify things just by taking all the peripheral items off the table. Once the heart of the deal is done, and both sides feel comfortable that they can be successful because they are getting what they need, adding additional pieces is much easier with a lower stress level and a structure in place.

Remember to be honest with yourself as you detail all this information, because lying to yourself is the surest path to failure. Assume that they will have an accurate valuation of what is brought to the table (regardless of whether they are willing to tell you what it is), so insisting that something is worth more than its real value is foolish. Understand one's own strengths and weaknesses, be honest about what is needed to be successful, and do not promise things that cannot be delivered.

All this brings us to the last rule: always negotiate a win–win. Always negotiate a deal in which both sides feel that they are receiving what they needed and can be successful. Beyond the obvious ethical reasons for doing this, there is also the very practical consideration that the two parties will need to continue to work together. Many people go to the negotiating table believing that signing a deal is the end of the process, when in fact it is just the beginning. Once the paperwork is signed, a relationship that essentially lasts forever begins between the parties. This relationship often makes itself known in unanticipated ways; for example, if one is licensing a patent to a company, the company has a vested interest in ensuring that the patent maintenance fees continue to be paid to the PTO to keep the patent valid and will want to have regular information to confirm that the payments are being made. Almost every deal one can imagine, no matter how cut-and-dry, has some aspect that will require communication between the parties on an ongoing basis after the deal is done. If one licenses a technology to a company, the company may be sending royalty checks, and the licensor may want some way to audit their sales to ensure that they are accurately paying. They, in turn, may want technical support, including important bug fixes and updates. They may additionally have negotiated the option to license future upgrades, and as a paying customer, they will likely want to provide their input on features and enhancements to the technology that would be of most help to them.

59.15 EMBRACING THE RELATIONSHIP

By admitting from the beginning that there is an ongoing relationship, one can embrace this notion and turn it to an advantage. In fact, I encourage its use to build a future revenue stream—and in light of the increasing attention to Chesbrough's "open innovation" model, this is a likely outcome indeed. A researcher can build design and consulting services into the deal, which is particularly helpful for HCI-related technology transfer since, as we discussed earlier, they often need reworking to fit into a larger context. One can use the ongoing relationship as a "foot in the door" to be able to offer future sales and deals as new technologies are developed. In fact, viewed as a "strategic partner," one might even want to offer them the right of first refusal on future offerings, as a way of demonstrating a commitment to them. Finally, as in contemplating future growth of the researcher's business, one may need additional sources of funding, and a partner who has a vested interest in the researcher's success can be a great source for funding. Even if none of this is true, assume that one day there will be a need for a good reference or recommendation from them; that alone is reason enough to want to have a great ongoing relationship.

59.16 COMMONALITIES FOR INTERNAL AND EXTERNAL TECHNOLOGY TRANSFER

59.16.1 Intellectual Property

One of the issues common to both internal and external technology transfer is intellectual property (IP). I am not a lawyer, and so I obviously cannot give legal advice on how to protect intellectual property or how to treat others' IP. What I can do is point out some places where the IP issues get thorny and make some business recommendations about how to deal with them.

Anything received from a third party may carry restrictions on how it may be used and, more importantly, whether it can be redistributed in its original or modified form or combined with some other components. This includes libraries of software routines, data, copyrighted works and designs, and patents. These restrictions can come from explicit license agreements that accompany the third-party components, or they could come from any of a number of different laws, including patent, copyright, trademark, trade secret, and export. Any time a third-party component is used in one's work, a business risk of constraining the ability to transfer the work to another party arises, because either one does not possess the right to do so or the rights that are possessed are not sufficient to the needs of the party that wants to license it. This question fits into the larger scheme of what it traditionally called the "build or buy" decision: whether it makes more business sense to build something oneself or to buy or license it from a third party.*

I strongly recommend that, whenever possible, the IP issues should be dealt with at the time a third-party component is acquired, rather than waiting until an opportunity to transfer it. This accomplishes two things. First, it allows one to negotiate and make business decisions about acquiring the component before there is a commitment and dependence on the component built into your technology; once the dependency is there, the "switching cost" is much higher for moving to an alternate and one could be forced to pay a much larger licensing fee than before. Second, it simplifies the tech-transfer process. Any company worth its salt will perform a "due diligence" on the technology before it closes a licensing deal. Part of that will be an analysis of who really owns the technology or whether the licensor has acquired the right to further license it. In essence, one will need to prove the right to license one's work to the company. And do not be surprised if the company also asks the researcher to "warrant" the work—to guarantee that he or she has the right to license all of it to the company and that right will be defended in court if necessary. The bottom line: clear it up front, and save a lot of trouble later.

59.17 IT ALL COMES DOWN TO THE RELATIONSHIP

The most significant common aspect of internal and external transfer comes back to the notion that we began with: technology transfer is a social process that succeeds or fails based on the relationships that have been built. Tech-transfer partners need to trust each other and that trust is built with communication and follow-through. Researchers should understand clearly and honestly what value they bring to the table at the various stages of the relationship, and they should make it their business to know how their partners see and value what they bring. After all, business is fundamentally the exchange of value between partners who need each other's competencies, and the truly successful companies are the ones that build relationships that last across a continuous series of business transactions.

When beginning a technology-transfer effort, assume that what is started that day is the beginning of a working relationship that will last forever. Build the relationship from the ground up with the expectation of ever increasing levels of cooperation and trust that will allow the partnership to take on ever more challenging technology transfers, in whatever manner is most appropriate to the needs of the business.

There are far too many stories of companies who have struggled with the transfer of technologies that could change

* It is important to point out, though, that building from scratch does not necessarily mean an automatic escape from third parties; for example, one can still violate someone else's patent even with code written from scratch.

the world—and failed. As Buderi (2000) and Freidman (2005) described, the next chapter of this story is being written now. By rewriting the rules to focus on the social side of the process, we can ensure that our best work will see the light of day and this story will have a happy ending. The good news is that there are more companies open to technology transfer today than at any time in the history of the industry, and the opportunities are there—on both sides—for us to take.

Part VII

Emerging Phenomena in HCI

60 Augmenting Cognition in HCI

Twenty-First Century Adaptive System Science and Technology

Kelly S. Hale, Kay M. Stanney, and Dylan D. Schmorrow

CONTENTS

60.1 INTRODUCTION

In 1960, J. C. R. Licklider had a vision for a "Man–Computer Symbiosis" in which the human and computer, although dissimilar from one another, would live together in an intimate association, producing increased handling and new ways of processing information (Licklider 1960). Over the past few decades, several attempts to realize this vision have been made by interactive system developers, but each time it has eluded them. This was likely due to the insufficiency of technology and computational power, but also to the need to mature several fields of basic science necessary to understand how human–machine symbiosis might be produced. A more thorough understanding of human brain functioning and what guides behavior during human–computer interaction (HCI) has been a continuing missing requirement in the ability to enable true human–machine symbiosis.

Fortunately, in the 1990s period known as the "Decade of the Brain," the National Institutes of Health (NIH) and other federal funding agencies invested heavily into advancing neuroscience in order to understand the basic scientific aspects underlying the brain to include human cognition and behavior. What emerged are advanced neurophysiological assessment tools and a wealth of knowledge regarding specific brain areas that could be attributed to particular cognitive and behavioral functions. As brain activity measurement tools, such as electroencephalography (EEG), magnetoencephalography (MEG), positron emission tomography (PET), functional magnetic resonance imaging (fMRI), and functional near-infrared imaging (fNIR), continued to advance into the year 2000, the idea that one could possibly begin to capture brain functioning in real time as users performed real-world tasks came to fruition.

Seeing the promise of such capabilities, in 2001, the Defense Advanced Research Projects Agency (DARPA) began funding a program based on what is now known as the scientific field of augmented cognition (AugCog) (Kollmorgen 2007; Schmorrow and Kruse 2002, 2004, 2005; Schmorrow and Reeves 2007; Schmorrow et al. 2005). Although the field of AugCog has had many predecessors (e.g., DoD-funded programs in Biocybernetics, Learning Strategies, and the Pilot's Associate Program; NASA-funded adaptive automation efforts [Freeman et al. 1999; Pope et al. 1995; Prinzel et al. 2000; Wilson, Lambert, and Russell 2000]), it was not until DARPA's AugCog program, where multidisciplinary teams of neuroscientists, cognitive scientists, computer scientists, software engineers, and human-centered system designers were brought together, that the potential of real-time, closed-loop symbiosis between human and computer was fully realized. Under this effort, human state was captured and analyzed in real time and used to adapt computer interface and procedures with the goal of optimizing human performance. Since the success of the AugCog program, there have been numerous follow-on programs (e.g., DARPA's Improving Warfighter Information Intake Under Stress [IWIIUS] program; DARPA's Neurotechnology for Intelligence Analysts [NIA] program, and the Intelligence Advanced Research Projects Activity (IARPA)'s Tools for Recognizing Useful Signals of Trustworthiness [TRUST] Program) and cutting edge research completed to advance AugCog systems for training (Craven et al. 2009; Pojman et al. 2009; Schnell et al. 2009), and operations (Carroll et al. 2010; Hale et al. 2007; Hale et al. 2008; Kruse and Schulman 2006). Today, the field of AugCog is aimed at substantially improving human–system interaction by using proactive systems that (1) detect and gauge a user's cognitive state (operator functional state [OFS]) in real time using a combination of diagnostic behavioral, physiological, and neurophysiological sensors, and appropriate data classification methods, (2) diagnose periods of nonoptimal performance (e.g., operator overload and repeated evidence of training error), and (3) mitigate the HCI experience via dynamically adaptive strategies with the goal of optimizing human performance (Schmorrow et al. 2005).

This chapter summarizes the latest science and technology (S&T) advancements from the field of AugCog, identifies applications of AugCog technology, lists lessons learned from the first decade of AugCog advances, and outlines future directions for AugCog research and development.

60.2 NEUROPHYSIOLOGICAL AND BEHAVIORAL TECHNOLOGIES FOR ASSESSING USER STATE

HCI researchers and practitioners must be able to rely on tools and techniques that allow them easy access for noninvasively observing and assessing users while interacting with human–computer systems. A critical component in gaining cognitive-state data is the use of behavioral, physiological, and neural sensors that can be appropriately combined to measure cognitive load in order to sufficiently characterize the cognitive state of users while they interact with a computer-based system in real-world settings. Here, cognitive state is defined as OFS—the moment-to-moment dynamic and functional capabilities (e.g., capacity and bottlenecks) of the human brain and/or a condition that has a causative/moderating/predictive relationship to a performance variable (Reeves, Schmorrow, and Stanney 2007a). This section outlines technologies that have been implemented in AugCog systems over the past 10 years that meet the requirements of (1) sensitivity to different brain states and/or processes, (2) reliability, and (3) practicality in fielded use (Gratton, Kramer, and Fabiani 2008). For a more thorough review of sensor technologies that encompasses technologies that are today cumbersome and nonportable, but which show promise in the future for capturing cognitive state in real time, readers are directed to the NATO report on OFS Assessment (Wilson and Schlegel 2004).

60.2.1 ELECTROENCEPHALOGRAPHY

EEG records electrical activity produced by the brain via sensors placed on the scalp (Figure 60.1) with high-temporal resolution (milliseconds). The activity recorded is a summation of millions of individual neuronal synapses, which limits the spatial accuracy of EEG in determining distinct, localized activity compared to other measurement techniques (Gratton, Kramer, and Fabiani 2008). However, despite its limits in spatial accuracy, EEG in closed-loop systems has been used to capture subtle shifts in cognitive function and cognitive processes such as sensory memory, working memory, attention, and executive function (as reported by Morrison, Kobus, and Brown 2006), alertness/vigilance (Duta et al. 2004; Jung et al. 1997), engagement (Freeman et al. 1999), cognitive load (DuRousseau 2004), and workload (Pleydell-Pearce, Whitecross, and Dickson 2003; Smith et al. 2001). Some specific AugCog gauges that have been developed using EEG include the eXecutive Load Index (XLI) gauge (DuRousseau 2004), which utilizes EEG signals to allow measurement of patterns in tightly coupled cortical networks tied to an individual's allocation of attentional resources as a user's cognitive state changes in response to conditional task load (Kobus et al. 2005), the Engagement Index, which is a ratio of EEG power bands (beta/[alpha 1 theta]) (Kobus et al. 2005; Freeman et al. 1999), and workload, engagement, distraction, and drowsiness gauges, where probability scores on each of these scales are provided on a

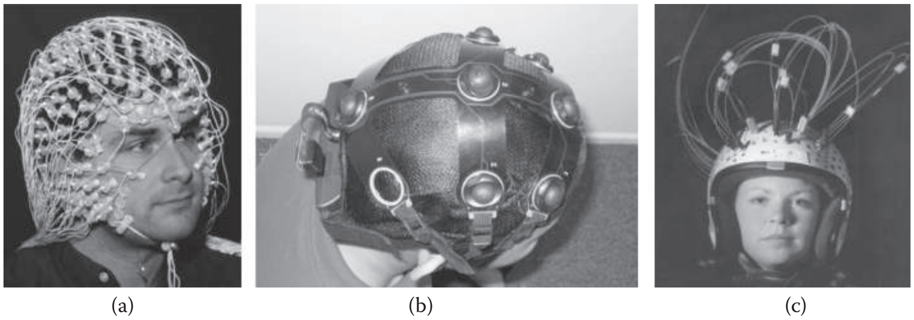

FIGURE 60.1 Electroencephalography (EEG) headsets used in AugCog systems developed by (a) Electrical Geodesics, Inc. (b) Advanced Brain Monitoring, Inc. (c) Beckman Institute.

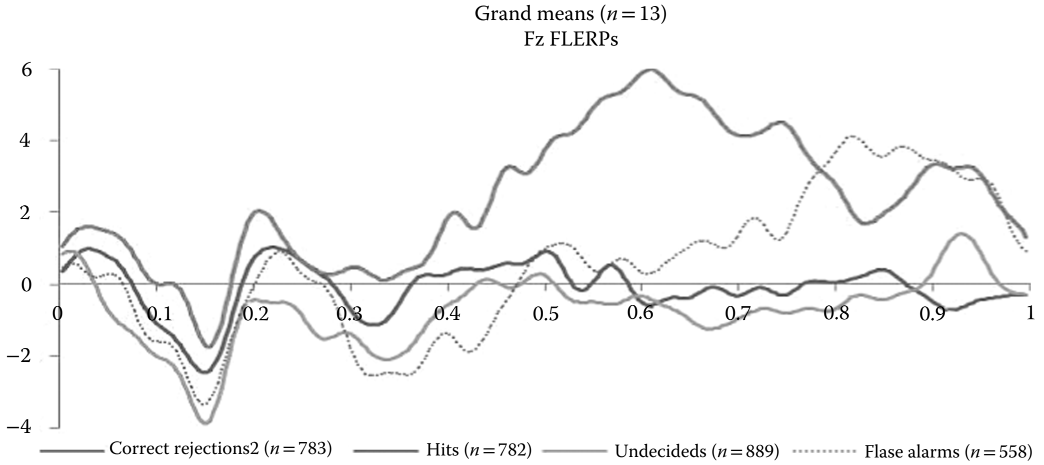

FIGURE 60.2 Example of fixation-locked, event-related potentials (FLERPs) from the Fz scalp site for distinct fixation classifications (correct rejections, hits, undecideds [misses that were later classified as hits] and false alarms).

second-by-second basis (Berka et al. 2007). The current state of EEG suggests it is effective in measuring the general level of arousal of the brain and has a good signal-to-noise ratio, low cost, low invasiveness, and relatively good portability (Gratton, Kramer, and Fabiani 2008).

Although the above gauges relied on changes in EEG band activity, a second approach to analyzing EEG is via event-related potentials (ERPs), which are thought to reflect "the cognitive processes that underlie task processing and responses" (Stanney et al. 2009). Using this technique, EEG signals are time stamped to an event (e.g., system event, behavioral response, and physiological event), and distinct patterns of response are used to distinguish various states, such as categorizing events as interesting versus uninteresting (Hale et al. 2008). Examples of EEG/ERPs include the P300, elicited by attended stimuli, and the error-related negativity (ERN), elicited when one is aware of making an error (Gratton, Kramer, and Fabiani 2008). Luu, Tucker, and Stripling (2007) found distinct EEG ERP components (specifically the medial frontal negativity [MFN]) that changed over time as participants learned a task. Research also indicates the feasibility of using EEG/ERP to differentiate between correct responses (i.e., hits and correct rejections) and highly biased responses (e.g., false alarms and misses) (Vogel and Luck 2000; Yamaguchi, Yamagata, and Kobayashi 2000; Sun et al. 1994), thus supporting the potential for using neurotechnology for enhancing operator performance.

Although most ERP work has utilized system events as triggers, more recent work has used eye fixation data to identify an analysis window to identify fixation-locked ERPs (FLERPs) using complex imagery (Hale et al. 2008) (Figure 60.2). Visual inspection of EEG ERP (time locked to image onset) and FLERP patterns showed distinct template signatures associated with a number of fixation classifications (e.g., hits, misses, correct rejections, and false alarms). Preliminary evidence suggests that the waveshape characteristics of FLERPs resemble those of stimulus-evoked ERPs, and a 1-sec analysis window from fixation onset indicated distinct signatures for correct rejections in addition to hits and false alarms (based on signal detection classification; Hale et al. 2008). This work suggests that FLERPS could be used during image analysis to increase efficiency and effectiveness.

The challenge in EEG/ERP classifiers is developing algorithms that can accurately and reliably determine classifications on a single-trial basis in near real time. While group classifiers would result in generalizable systems across individuals, all existing single-trial classifiers today utilize an individualized model to achieve accurate results (Parra et al. 2005; Mathan et al. 2006; Sajda, Gerson, and Parra 2003).

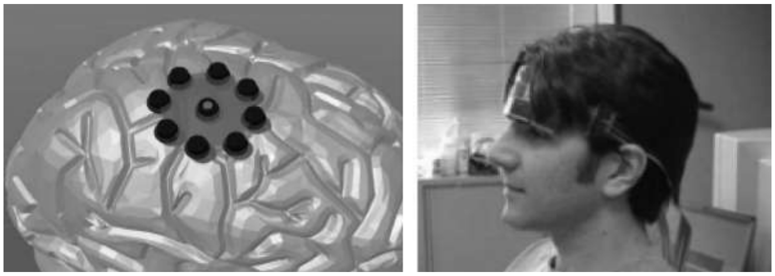

FIGURE 60.3 Functional near-infrared imaging (fNIR) sensor developed by Archinoetics, Inc.

60.2.2 Functional Near-Infrared Imaging

fNIR technology measures blood oxygenation and volume changes in the brain relative to where the optical sensors are placed on the head (Kobus et al. 2005) (Figure 60.3). fNIR has been shown to be an effective tool for diagnosing cognitive activity associated with spatial and verbal working memory, given its often known right- and left-hemispheric separability, respectively (Smith and Jonides 1998). fNIR sensors have been used to measure a variety of cognitive states in closed-loop systems, such as sensory memory and working memory (as reported by Morrison, Kobus, and Brown 2006), general workload (Izzetoglu et al. 2003), and loss of concentration (Izzetoglu et al. 2005). fNIR provides almost continuous estimates of changes in blood flow with a spatial resolution of a few centimeters, providing a relatively low cost and low invasiveness solution (Gratton, Kramer, and Fabiani 2008), however, there is time delay on the order of seconds associated with this sensor, due to the relatively slow nature of oxygenation changes within the brain (several orders of magnitude slower than EEG; Gratton, Kramer, and Fabiani 2008). In addition, fNIR cannot accurately measure deep brain activity, which may limit its diagnostic capacity (Gratton, Kramer, and Fabiani 2008). Even with such limitations, the relatively low cost and compatibility with other systems make fNIR a valuable addition to AugCog sensor suites (Stanney et al. 2009).

60.2.3 Electrodermal Activity/Galvanic Skin Response-Based Arousal and Cognitive Workload Gauge

The sympathetic nervous system modulates fluctuations in the electrical resistance of the skin, known as electrodermal responses (EDRs; commonly referred to as galvanic skin response or GSR) (Stanney et al. 2009). Although GSR is typically measured using the palm of the hand or the fingers, the soles of the feet and toes have an equal abundance of eccrine sweat glands. Thus, the feet and toes offer an optimal site for sensor placement because they will not intrude on a user's ability to interact with input devices that require hand operation (e.g., keyboard and mouse). GSR levels have been linked with variations in attention and working memory (as reported in Morrison, Kobus, and Brown 2006); cognition, attention, and emotion (Critchley 2002); engagement (Mandryk 2005); emotional response (Bradley, Moulder, and Lang 2005); and anxiety and stress (Healey 2000). This metric has been included as one of a suite of metrics to assess cognitive state in AugCog systems (Kobus et al. 2005).

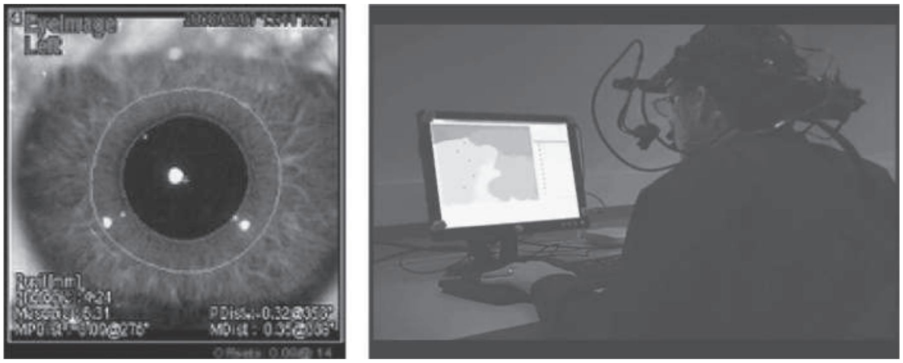
60.2.4 Heart Rate Variability

Heart rate variability (HRV), which captures variation in cardiac interbeat intervals, has been used to estimate arousal and workload (Kobus et al. 2005). Jang et al. (2002) used HRV to determine levels of arousal and engagement, as have Hoover and Muth (2004), who developed the arousal meter that derives autonomic arousal from the cardiac interbeat interval derived from an electrocardiogram (ECG) at 1-ms accuracy. This particular gauge provides three levels (low, medium, and high), which increase or decrease with respective increases or decreases in autonomic arousal. The arousal gauge has been used to track decrements in performance due to low-arousal states and is thus appropriate for assessing human information processing (HIP) bottlenecks related to attention (e.g., divided attention and vigilance effects).

A combination of heart rate and variability can discriminate emotional states (Jang et al. 2002; Lee et al. 2005) and level of presence during training (Vinayagamoorthy et al. 2004). Further, these cardiovascular measures can capture arousal and stress related to specific tasks such as aircraft takeoff and landing, time-pressured performance, and crisis-based activity (Cacioppo et al. 2000; Kramer 1991; Wilson 1992). However, when used in isolation, these measures have not always been found to be as sensitive as a workload index (Kaber et al. 2007, as cited in Stanney et al. 2009). The greatest utility of HRV within closed-loop systems is when it is combined with other physiological measures mainly because physical fitness of the individual, outside influences (e.g., drug use and nutrition), physical activity performed during cognitive evaluation, and daily circadian rhythms can substantially impact HRV measures. It is thus important to take each of these factors into account when incorporating HRV into cognitive sensor suites.

60.2.5 Pupillometry

Cognitive workload and emotional arousal are both known to be associated with pupil dilation. Using comparison of normalized means with temporal windows of 500-ms length, the difference in average pupil size from 0- to 500-ms postfixation onset and 2000- to 2500-ms postfixation onset has



(a) (b)

FIGURE 60.4 Equipment used to collect pupillometry data as part of Lockheed Martin Advanced Technology Laboratory's AugCog system. (a) Pupillometry display. (b) Head-mounted hardware to capture pupil changes.

been associated with an arousal-related effect (Partala and Surakka 2003), where the difference from 0 to 500 ms and 6000 to 6500 ms has been associated with a workload-related effect (Kahneman, Beatty, and Pollak 1967).

An Index of Cognitive Activity (ICA) developed under DARPA's AugCog program is based on binocular eye tracking sensors and measurement of pupil dilation (Kobus et al. 2005) (Figure 60.4). This system estimates cognitive activity from changes in pupil dilation (e.g., abrupt changes in pupil diameter indicate an operator's current levels of mental effort, whereas the point of gaze metric highlights specific elements causing difficulty [see Section 60.2.6]). Researchers found that it may be possible to determine different levels of utilization of left versus right brain hemisphere regions by comparing pupillometry data from each eye (Kobus et al. 2005). Such data could be used as an indicator of whether a user was using more verbal (left hemisphere) or spatial (right hemisphere) processing resources. In a more recent study, de Greef et al. (2009) found that pupil diameter significantly differed with workload; specifically, pupil diameter values collected during an underload scenario were significantly smaller that those collected during an overload scenario. However, the results failed to discriminate among all workload conditions (no significant difference was found between normal and overload scenarios). Conclusions from this study note that pupil diameter responds to many factors, with workload being one such factor. Further research is required to further advance pupillometry measures of cognitive state that are valid, reliable, and generalizable.

60.2.6 Eye/Gaze Tracking

Eye tracking technology offers a unique methodology for cognitive assessment in that systems can determine where visual attention is focused. By adding observation of the user's visual behavioral responses, insight can be gained into user's situation awareness (SA) of the ongoing situation and/or performance in completing the task at hand. Eye tracking has delivered promising results as a measure of cognitive load (Iqbal, Zheng, Bailey 2004), attention level (Fukuda and Yamada 1986), and task difficulty (Nakayama, Takahashi, and Shimizu 2002). Such oculomotor metrics that may be used to evaluate cognitive state in closed-loop systems include gaze direction and frequency, frequency/length of saccadic movements, pupil diameter, and eye blink. One study found that average fixation time significantly increased with increased mental workload (de Greef et al. 2009), yet found no significant differences in saccade distance or saccade speed. Similarly, King (2009) found increased fixations and longer fixation durations with increased task complexity.

One method for quantifying eye gaze data is to use the Nearest Neighbor Index (NNI), which is a ratio of the average nearest neighbor distances for fixation points (numerator) and the mean random distance (denominator) (Di Nocera et al. 2006). Preliminary results in one study suggested that NNI values may predict workload similar to NASA/TLX ratings (Fidopiastis et al. 2009). Further, eye fixations may be synchronized with other physiological indicators, such as EEG/ERP mentioned above, to create FLERPs, which can be used to evaluate cognitive states associated with specific events in defined visual locations (Hale et al. 2008).

60.2.7 Electromyograph

Skeletal muscle movements can be detected and measured via the electrical signals produced, using electromyograph (EMG) (Reaz, Hussain, and Mohd-Yasin 2006). EMG in psychological research is most often performed using electrodes on the skin surface to detect microtremors in muscle. When used in combination with other physiological measures (such as EEG), EMG can be used as an indicator of cognitive factors such as attention, effort, and stress (Harmon-Jones and Beer 2009). Along with EEG, ECG, pulse oxymetry, respiration, GSR, oculomotor, and facial temperature sensors, EMG has been integrated into aviation cockpit sensor suites (Schnell, Keller, and Macuda 2008).

60.2.8 Body Position/Posture Tracking

Body position and posture tracking can provide further supplemental information regarding cognitive state. Two such instantiations of these measures have been a pressure-sensing chair and a head tracker (Kobus et al. 2005). The sensor chair contains two 64-by-64 grids of pressure sensors in both the back and seat. Data from these sensors are used to compute changes in pressure over time, and the medial–lateral shifts of position in the seat posture shift data, head position, and head velocity, each output every 250 ms, were used to gauge levels of attention (e.g., engagement). Although a few experimental trials indicated ability to correlate with cognitive workload (Balaban et al. 2004), researchers determined more research would be needed to assess whether the body position/tracking system is reliably effective in predicting cognitive workload in command and control-type tasks.

60.2.9 Sensor Suites

In the last few years, AugCog researchers and developers have determined that various combinations of behavioral, physiological, and neurophysiological sensors may be used to improve the robustness for detecting cognitive functioning of users across a variety of conditions. Successful examples of integrated sensor suites are reviewed next. Each of the sensors/gauges discussed below was selected according to how effectively they assess cognitive state in real time, while also considering factors such as portability, usability in the field, potential intrusion on user task performance, and potential electromagnetic interference (EMI) during combined sensor/gauge implementation in operational settings.

A composite stress gauge (Kass et al. 2003; Raj et al. 2003) has been developed, which uses a weighted average of the following three sensor inputs to detect a participant's response to changes in cognitive load: Video pupillometry (VOG), high-frequency electrocardiogram (HFQRS ECG), and EDR. This gauge has been used to track the autonomic response to time pressure in a high-workload environment and to detect cognitive stress related to managing multiple competing tasks on a moment-to-moment basis. Thus, it is appropriate for assessing HIP bottlenecks related to attention (e.g., divided attention effects).

The Warfigher Interface Division of the U.S. Air Force Research Laboratory (AFRL) developed the new workload assessment monitor (NuWAM) sensor suite (Figure 60.5) based on an artificial neural net (ANN) cognitive state classifier of a 20-channel EEG system along with the ECG and electrooculography (EOG) sensors. This suite has been found to discriminate high from low workload levels for specific types of tasks that have been categorized during cognitive task analyses (Wilson and Russell 2006).

The cognitive cockpit (CogPit) sensor suite system's (Dickson 2005) primary function is to provide estimations of a pilot's cognitive-affective status in near real time while interacting in a fast-jet cockpit simulation environment (Figure 60.6). Pilot state inferences are derived from four main sensor sources (e.g., behavioral measures from interactions with cockpit controls, EEG-based physiological measures, subjective measures, and contextual information), which are used to assess the pilot's objective and subjective cognitive state in terms of arousal and workload levels (Pleydell-Pearce, Dickson, and Whitecross 2000). Cognitive state estimations are encapsulated within high-level state descriptors such as levels of stress, alertness, and workload and are then provided to a tasking interface manager (TIM) to aid in directing levels of automation or information presentation within the cockpit. CogPit can be configured to enable both online and post hoc operation.

More recently, there have been a number of systems that have integrated eye tracking and EEG. Merging high density EEG with unobtrusive eye tracking and head tracking measures as reported in Tucker and Luu (2009) allows for single-trial data measures and exact precision of timing of high-bandwidth data streams. A second such sensor suite uses eye tracking and EEG to capture FLERPs to assess the level of interest at specific visual fixation points utilizing neurophysiological indicators (Hale et al. 2007). Synching eye tracking and EEG has also proven effective at capturing

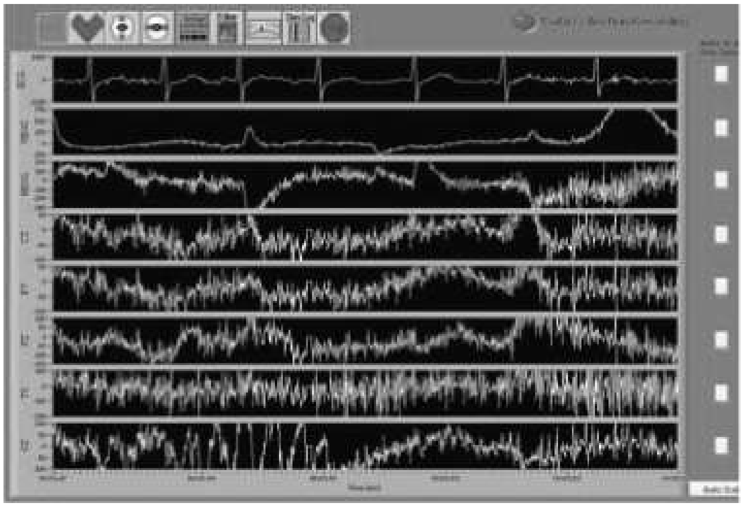


FIGURE 60.5 New workload assessment measure (NuWAM) sensor suite display.

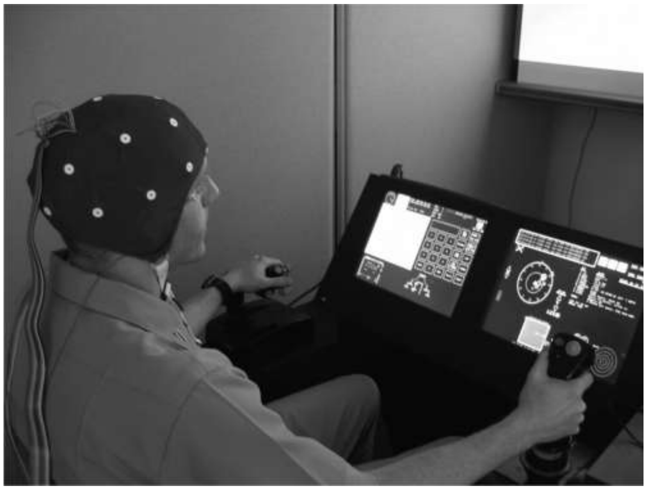

FIGURE 60.6 The cognitive cockpit.

snippets of interest from text data, where eye tracking is used to determine the timeline for EEG activity analysis (e.g., start and end of the sentence) (Hale et al. 2008). This sensor suite has more recently included heart rate measures and been integrated into an Auto-Diagnostic Adaptive Precision Training (ADAPT) framework developed to capture trainee state on a second-by-second basis, and evaluate trainees as they progress from novice to expert using a combination of behavioral events and overall cortical activity (Carroll et al. 2010).

60.3 DATA CLASSIFICATION AND INTEGRATION ARCHITECTURES

Given that AugCog systems will benefit most from a sensor suite of multiple gauges that together are used to assess operator state in real time, there is a need to ensure data classification and integration techniques utilize consistent methodologies to ensure gauges

- Relate to a cognitive state of interest (e.g., arousal and attention)
- Are reliable and accurate
- Are generalizable across applicable domain applications

This section outlines challenges related to real-time data analysis of multiple neurophysiological signals to derive cognitive state metrics that are practical for AugCog system integration.

60.3.1 Data Synchronization

One of the challenges in utilizing multiple sensor systems to evaluate cognitive state is data synchronization. This becomes of critical importance when using EEG/ERP analysis and synching this to eye fixations, as ERPs require synchronization at the millisecond level to pinpoint relevant event markers from the test bed or alternative sensor data (e.g. eye tracking). When using a Windows-based system, variable time delays occur between 1 and 40 ms, which are significant fluctuations for EEG/ERP analysis. Software solutions such as the Cognitive Avionics Tool Set have been developed to synchronize data input from numerous neurophysiological sensors (Schnell, Keller, and Macuda 2008).

60.3.2 State Classifiers

Under DARPA's AugCog program, there were four distinct cognitive state classifiers under development: sensory memory, working memory, executive function, and attention (Kobus et al. 2005). Since that time, researchers have expanded to create cognitive state indicators of interest (Kruse and Schulman 2006; Hale et al. 2007; Hale et al. 2008), decision making (Carroll et al. 2010), and expertise (where distinct EEG ERP components were evident as participants learned; Luu, Tucker, and Stripling 2007). Each of these state classifiers utilized a sensor suite that included neural, physiological, and behavioral measures to evaluate real-time status.

60.3.3 State-Based Architectures

Most early AugCog systems used a state-based architecture, where system mitigation was triggered based primarily on a cognitive state issue (e.g., overload). Although studies showed improvement in operator performance (Kobus et al. 2005), the type of mitigations instantiated were limited in scope, as there was little to no context understood in regards to *the root cause* of the cognitive state issue. For example, if sensory memory is overloaded, one mitigation strategy may be to hold back low-priority information and thus focus on presenting only the most time-critical information during this period. Although this mitigation can result in improved response times due to fewer information bits, the question of the longer term impact on higher level cognitive constructs, for instance SA, were not considered. In early systems, observed performance improvements (Barker et al. 2004; Dorneich et al. 2005; Whitlow and Ververs 2005) have "come at the cost of a loss of SA and survey knowledge of the environment" (Dorneich et al. 2004, p. iv).

60.3.4 Event-Based Architectures

Event-based cognitive assessment provides a more prescriptive way to evaluate cognitive processes in real time, by selecting key events as good/bad performance indicators, measuring the physiological reaction to these specific events, and configuring mitigation strategies "on the fly," depending on the combined system and operator state (Fuchs et al. 2008, 2007). Tracking and analysis of display events through an event-based approach allow for better context sensitivity, as cognitive gauges can now be related to individual events or even display objects, thereby providing the much needed context for how and where mitigations should be applied. In such an approach, each system event would be associated with increases or decreases in the cognitive state of interest (e.g., when a new entity appears on the screen, participants should perceive this change and act accordingly—this should result in increased attentional demands that impact workload). However, given that in complex high-workload systems (such as those in need of AugCog technology) there are usually numerous tasks occurring at any point in time, it is impossible to assume that every missed perceptual event would require mitigation. For example, events of low priority may be missed (i.e., not perceived) within a predefined time because the user's attention may currently be allocated to a higher priority task. In such a case, mitigation should not be triggered at this moment, as the operator is focused on a higher priority task. Disregarding this relationship may result in distraction from a critical task, as the mitigation strategy could, for example, try to shift the user's attention to a less critical event.

In event-based architectures, to ensure the priority of missed events compared to all active events is considered, each system event can be assigned a priority (based on a task analysis and/or SME input), and a dynamic list of active tasks in order of priority can be maintained in real time. In this way, mitigation would be triggered only if a high-priority event was missed. Once the mitigated event has been dealt with successfully (i.e., an appropriate behavioral response event has been detected), the event could be removed from the list and events with lower priority would move up. Missed lower priority events could then be flagged as potential mitigation candidates. Should lower priority events reach the top of the list, (i.e., higher priority tasks were successfully dealt with), mitigations could be triggered for these events, as well. Thus, to regulate mitigation in an event-based architecture, a missed perceptual event could be a first criterion, followed by the priority of the missed event.

60.4 REAL-TIME MITIGATION

Although there have been a number of innovative mitigation strategies identified for applicability within AugCog systems (Fuchs et al. 2007), AugCog systems to date have been limited in the number and variety of real-time mitigation strategies, in part due to limited knowledge regarding context (Fuchs et al. 2008). Thus, many prior implementations of AugCog systems had a problem with inconsiderate augmentation (a term coined by Stanney and Reeves 2005), where SA was sometimes compromised for performance benefits. The below sections (60.4.1, 60.4.2, and 60.4.3) outline various mitigation strategies that may be implemented to enhance performance in an AugCog system. By definition, an AugCog mitigation strategy is "an intervention technique that is triggered by the outcome of cognitive state assessment and context to significantly improve human–system performance" (Reeves et al. 2007b, p. 282). Such a system manipulation has associated benefits and costs, and should be implemented when the benefits to performance outweigh the associated costs. Various strategies have been proposed to adapt what information is presented and how information presentation should change in real time based on OFS to optimize human performance. To address what should be presented, the architectures discussed above (state-based and event-based) should be utilized. As mentioned above, although state-based architectures in isolation may effectively guide when adaptation is needed, they may not provide enough detail about the ongoing situation to effectively guide what information should be mitigated and how it should be presented (e.g., what information should be adapted and for how long).

60.4.1 Adaptation of the Presentation

One group of mitigation strategies involve changing how information is presented. This may include strategies such as modality augmentation and modification of information type (e.g., verbal or spatial) (Fuchs et al. 2007). Modality augmentation includes both switching one sensory modality with another to optimize distribution of processing load and redundancy, which provides complementary information in a second modality. This can also be thought of as "cueing," where salience of information is increased by adding redundant cues (Fuchs et al. 2008). Switching is designed to effectively reduce overload in a given sensory channel, whereas redundancy can improve performance through enhanced clarification of information. Changing the information type is referred to as transposition, where spatial information may be switched to verbal information, for example, to optimize information processing, as suggested by the Multiple Resource Theory (Wickens 2002). Multiple empirical studies (Diethe 2005; Dorneich et al. 2006) have shown that humans can effectively process multiple bits of information from differing resource pools (e.g., spoken directions as a verbal transposition of a visual-spatial map), and that distributing information across available resources improves performance.

Another form of presentation adaptation includes decluttering, where the amount and/or level of detail of information is reduced with the goal of making remaining information more salient. This may include decreasing saliency of lower priority information, reducing the level of detail, or removing information completely to decrease the complexity of presented information (Fuchs et al. 2008).

60.4.2 Adaptation of the Schedule

Real-time mitigation can adjust the timing associated with information presentation, such that information is paced or sequenced in such a way as to optimize performance. Pacing refers to holding back low-priority information until current high-priority tasks are complete (Tremoulet et al. 2005). The goal of such a strategy is to ensure high-priority information that is addressed in a timely manner by reducing the amount of distracting information presented, thereby allowing focus on critical tasks. Sequencing involves the decomposition of tasks into chunks, where multiple tasks may be time shared through rearrangement of task chunks to optimize information processing (Fuchs et al. 2008) while minimizing effects of task switching and task interruption.

60.4.3 Adaptation of System Autonomy

System autonomy is designed to reduce the human's cognitive load by offloading certain tasks or subtasks to the software system. Two methods that have been utilized in AugCog systems include context-sensitive help and mixed initiative strategies (Fuchs et al. 2008). Context-sensitive help inserts task-specific information at the time help is needed (Sukaviriya and Foley 1990), thereby minimizing the need to search for assistance or the risk of missing information that a human might otherwise overlook (Kirsh 2000). Mixed initiative (or adaptive automation) (Scerbo 2001) adjusts the level of control between the human and system dynamically to optimize human performance. This switching can be driven by operator cognitive state alone or by a combination of metrics that provide insights into OFS, system state, and task state to ensure automated systems are effectively assisting in optimizing performance and not causing operator cognitive challenges such as task interruption (by offloading a current task midstream) or loss of SA.

60.5 APPLICATION OF NEUROTECHNOLOGIES

Although other application areas may emerge in the near future, the most appropriate application areas that may presently benefit from effective implementation of current neurotechnologies include: (1) operational systems, (2) training systems, (3) operator selection, and (4) HSI design of systems. This section reviews some of the S&T developments in these areas and implications emerging from the AugCog community.

60.5.1 Operational Systems

Leveraging physiological and neurophysiological technologies, it is now possible to assess the ever-changing cognitive state of the user in real time and mitigate against human performance limitations caused by known HIP bottlenecks or other nonoptimal cognitive states (e.g., disengagement, distraction, and drowsiness). Essential elements of any closed-loop AugCog system must therefore include the following:

- Operator functional assessment capabilities via physio-and neurophysiological tools as discussed in Section 60.2.
- Methods for classifying the data from these tools to identify periods of nonoptimal state (e.g., performance and cognitive state) to drive real-time system mitigation via adaptive automation techniques (e.g., AugCog mitigation strategies).
- An integration architecture that synchronizes and optimizes all necessary components via a robust controller (Reeves et al. 2007b) or mitigation management architecture that maintains system stability (e.g., controlling the "when," "what," and "how" of the adaptive automation techniques).

Under DARPA's AugCog and IWIIUS programs, a number of operational environments and subsequent prototype systems were developed to demonstrate the benefit of a real-time, closed-loop system that utilizes neurophysiological indicators of operator cognitive state to drive optimized human performance. One application domain included the U.S. Army's future force warrior (FFW) program (Kobus et al. 2005) where the prototype AugCog system demonstrated a 380% performance improvement where attention resources were required. In addition, the system was able to correctly classify attention state changes more than 98% of the time and in less than 300 ms. A second domain was light-armored vehicles, where the prototype AugCog system under real-world driving conditions showed that the sensory bottlenecks could be improved by as much as 108% with an accuracy of up to 98%, depending on the modality being examined. The sensory bottleneck status could be detected in as little as 200 ms, and mitigations could be invoked in as little as 0.2 sec, depending on the mitigation being used. A third domain was the Tactical Tomahawk Weapons Control System (TTWCS) simulation environment (Kobus et al. 2005), which is a command and control station that requires management of a number of missiles, targets and shipboard launch platforms, and dynamic reassignment of missiles to targets as critical targets pop-up, missiles fail, and so forth. The prototype AugCog system in this domain demonstrated an improvement in working memory throughput by at least 500% by using an intelligent sequencing mitigation strategy to strategically present related information about specific missile-target pairings when the working memory bottleneck was saturated. Working memory status (high- or low-cognitive workload) was correctly identified in over 90% of the trials, with the sequencing mitigation being invoked in less than 500 ms. A fourth domain was unmanned air vehicle (UAV) systems, where the prototype AugCog system showed a 241% performance improvement in executive function-related tasks, with a classification accuracy of 92% in less than 1 sec.

60.5.1.1 Training Systems

Various noninvasive brain monitoring technologies have been successfully applied to the challenge of documenting the transformation from novice to expert in a variety of domains, including the following: identifying indices of skill level in basic laboratory tasks and marksmanship (Ciesielski and French 1989; Deeny et al. 2003; Kerick, Douglass, and Hatfield 2004); identifying indices of skill acquisition in computer games (Smith, McEvoy, and Gevins 1999), and detection of the progression toward automaticity of syntactic processing (Gunter and Friederici 1999). A recent study examining marksmanship skills found significant differences in EEG parameters between novices and experts (Pojman et al. 2009). In addition, experts were found to have lower HRV scores compared to novices during the least cognitively challenging task. Authors note that "it is unclear whether this apparent ability to regulate expert's physiology is a genetically determined trait or a skill that can be acquired and refined with training" (Pojman et al. 2009, p. 531). Additional studies have also documented brain activity patterns that are indicative of a shift in cognitive processing from focused conscious effort to "automatic" processing (Floyer-Lea and Matthews 2004; Peres et al. 2000). This shift to automatic processing may occur after task performance has leveled off and is significant because it marks the point at which minimal cognitive effort is required to perform the task well. This transition may serve as an indication of the point at which the trainee is ready to learn additional components of the task or be taught higher level strategies within the particular domain.

The identification of neurophysiological measures that correlate with task and skill mastery is of value for three practical reasons:

1. It could serve as the basis for real-time, closed-loop training systems that adapt to the individual's current state of task proficiency and automaticity; this application would have the most profound impact on the training capabilities, but is not ready for widespread distribution.
2. Prior to widespread distribution for closed-loop training, AugCog-based technologies could be used to evaluate alternative training strategies and systems to identify those that provide the most effective learning environment. This application is potentially feasible in the near future, but would require more upfront research to confirm the neurophysiological patterns associated with task mastery are applicable to more complex task environments.
3. During the course of this type of research, novel training strategies may emerge that are validated by laboratory observations of accelerated task mastery and automaticity, but which do not rely on real-time monitoring of brain activity to enact. Such observations would potentially be immediately transferable to instructional environments.

One example of an AugCog training system that has been developed is the Quality of Training Effectiveness Assessment (QTEA) tool (Schnell et al. 2009). This system builds on the measurement capabilities outlined above and quantifies the student's workload level in real time to drive scenario manipulations. In addition, the cognitive and physiological measures also serve as "a quantitative manifestation of a student's learning curve" (Schnell et al. 2009, p. 641). A second AugCog system showed that workload and engagement levels through training were correlated with eventual performance outcomes, and thus, provided evidence that cognitive state gauges can provide predictive assessment of training outcome prior to completion of the training (Craven et al. 2009). Developing such AugCog-based training systems could have substantial impact on the training community, including the following:

- Enhanced instructor understanding of a trainee's capabilities and limitations
    - More suitable operator assignments to match skill levels
    - Ability to predict fast learners early during training
- More timely delivery of information provided to trainee
- Increased learning capabilities (e.g., via an increase of an individual's cognitive processing capabilities during training)
- More expertly trained and mentally prepared operators
- Enhanced training acquisition
- More effective training per unit time (reduce required financial investment)
- Enhanced development of effective individual and team performance (possibly in real time)

60.5.2 Operator Selection

AugCog systems developed for assessment of training progression could also be used to determine an individual's cognitive potential in general or their potential to reach a certain skill level in a particular task domain. For instance, the military has been using screening tools for decades to select for fighter pilots before thousands of dollars and man hours are wasted in training someone who may never be cognitively equipped to attain the necessary skill level required for such a domain. AugCog enabled screening tools could be used for similar purposes to improve the diagnostic capabilities of existing screening strategies.

Assessment of capabilities via an extensive neurophysiological and neuropsychological/psychometric components skills battery would be required in such an effort. An example of such an approach could be to determine the neural correlates of the knowledge, skills, and attitudes (and/or abilities) (KSAs) required for a particular task domain and training level. Individuals with the greatest human performance results related to the required KSAs for the particular task domain could be used as the expert model with which to compare other individual's neurophysiological indicators and patterns. This approach would also need to leverage the novice-to-expert training progression assessment techniques discussed above to establish the KSA neurolevel correlates along the entire training progression continuum for necessary comprehensive comparative evaluations. Individuals could be assessed initially to determine a priori how suited they may or may not be for a particular task domain (e.g., aptitude assessment). They could later be assessed to determine how their training is progressing at both the human performance and neurolevels. The KSA approach is only a recommendation, as other neurolevel correlates of performance and aptitude may also be used. Specific benefits of any neurolevel screening/selection approach could include the following:

- Identifying which individuals may be most apt to reach deploy-ready or expert levels for a given task domain and/or who may never have the "aptitude" to get to required levels
- Identifying operators with the greatest capacities for information processing and decision making, and then assigning them to critical information operations
- Identifying users who could be trained to deployable-or expert-level more quickly than others
- Reassessing trained individuals to see when retraining may be necessary (e.g., to reacquire necessary KSA levels)

60.5.3 Improving HCI System Design and Evaluation Capabilities

The ability to build systems truly tailored to a user's HIP needs and capabilities is now possible. Based on the review of AugCog technologies presented in Sections 60.2, 60.3, and 60.4, it is evident that HCI practitioners now have available to them various physiological- and neurophysiological-based tools and techniques that may be used to better specify both the design and evaluation of human–computer systems. Craven et al. (2009) propose using AugCog cognitive state indicators to drive the type of training provided to ensure the overall training program optimizes workload and engagement while avoiding distraction and drowsiness states. For example, "Including mental state gauges as part of a computer-based training solution would allow the system to make the individual adjustments necessary at distinct points in the training without waiting until the training has concluded and poor posttest performance indicates that they likely lost focus at some point during training" (Craven et al. 2009, p. 594).

Most any of the neurophysiological tools and techniques implemented in the AugCog community could be used and applied to the design and evaluation of most any human–computer system, resulting in more rapid, effective, and eventually less expensive HCI design and evaluation processes.

60.6 LESSONS LEARNED AND FUTURE DIRECTIONS

Over the last decade, AugCog technology has seen rapid advances in real-time cognitive state detection and applications of closed-loop systems in operational and training environments. Despite the great advances achieved to date, there are a number of lessons learned for AugCog system design. Below is a list of such lessons learned from the last decade of AugCog system research and development.

- The need to understand the user. A cognitive task analysis should be conducted in order to fully understand the cognitive requirements of the operator. Having a clear understanding of who the user is, as well as thoroughly understanding what they do, is essential for successfully constructing future AugCog technologies.
- Integrate early, integrate often. The earlier and more thorough system integration (e.g., of the various sensors, computer hardware and software) was considered, the fewer the setbacks and more effective the mitigations. Slight modifications in sensors should not be treated superficially and require systematic assessment throughout development.
- One sensor/gauge does not fit all. The selection of specific gauges for use within the AugCog systems is highly context (task) dependent. Gauges that are well suited for one environment may or may not be applicable to another domain.
- Cognitive bottlenecks may be task specific. Although the original DARPA AugCog program focused specifically on distinct cognitive bottlenecks, it appears that when applying these concepts to real-world tasks, they are often overlapping or interacting in nature. More recent research and development efforts have found it useful to define bottlenecks and gauges in terms of the tasks that are to be mitigated, vice attempting to address conceptual bottlenecks that are not adequately defined in terms of the operational task. It should be noted, however, that regardless of the operational definition of a specific bottleneck, the net result of the mitigation strategies employed by AugCog teams improved overall task performance.
- Artifact detection and correction. A continuing challenge to the AugCog community is the ability to differentiate between physiological changes related to cognitive activity vice the physical requirements of the task. Such an issue may be even more of a concern for applications involving mobile users. The critical need is to be able to reduce the effect of the motion artifacts in order to continue to provide adequate estimations of cognitive state.
- Perceived stability/trust. An issue with stability and predictability of AugCog mitigation strategies concerns the use of a combination of physiologically based gauges in conjunction with context-based sensors. If an operator does not understand the logic (e.g., the rationale for triggering the onset/offset of the mitigation), there is a significant potential for disruption and degraded performance. Another issue relates to the impact of degraded sensors. If users are not aware of the degraded functionality of the system, their expectations of augmentation

would not be met, and the system may be perceived as unstable. Before such a system is deployed, training strategies will need to be developed to allow users to learn how to operate in the face of degraded augmentation.

- Timing of mitigation strategies. Many of the changes in perceived cognitive load may be momentary. The physiological measures being used as gauges may detect either a transient or sustained change in cognitive activity. It may be unrealistic, or at least have little practical application, to have a system that is sensitive enough to detect and implement mitigations in terms of seconds. It is clear that in the operational environment, momentary changes in one or more of the cognitive bottlenecks areas may occur rapidly (1 min). More research needs to be conducted to investigate optimal timing for implementing various mitigation strategies, including on/off strategies of when and how to transition in and out of mitigated states.
- Hardware integration. As sensor technologies improve in their sensitivity and robustness, it is anticipated that calibration process will be more feasible for field conditions, as it is critical that AugCog technologies can be easily donned and readily calibrated. Significant consideration must be given to potential interference sources in the field (particularly when wireless devices are used), and potential design solutions that could avoid such issues in the first place. Integrated sensors designed to be used in the field from the outset are more likely to adequately address this issue than technologies adapted from laboratory or medical applications. System integration architectures will need to be refined and streamlined in order to improve new sensor integration and to reduce the processing demands on any emerging sensor integration requirements.
- Individual differences. Past AugCog research has noted challenges with both interindividual and intraindividual differences, particularly for the EEG-derived gauges. Another aspect of the underlying EEG phenomena that is poorly understood is the effect of extensive experience with the tasks on the utility of EEG-derived gauges. It appears that successful utilization of EEG data in an AugCog system may require that the filters used in separating signals from artifacts will need to be tailored to every user and even be dynamically adaptable during the course of use of the AugCog system.
- Proactive vice reactive AugCog. AugCog closed-loop systems developed to date are largely reactive in that the user must first become overloaded (or at least close to overloaded) before the system will invoke a mitigation strategy. Although it is important to detect when such levels of activity occur, it would be of great operational importance to develop systems that are also predictive (proactive) rather than simply reactive.

In addition to lessons learned, there are a number of continuing challenges that AugCog system designers face. Below is a list of future research and development directions organized by key area that will be key to driving the community of AugCog forward in developing revolutionary closed-loop systems that optimize human performance.

- Cognitive-state sensors
  - Designing future sensors for ease of use, calibration, appropriate resolution/sensitivity, noise cancellation, less invasiveness, and accommodation of individual user variability
  - Designing future gauge algorithms that accommodate day-to-day fluctuations and skill acquisition
  - Enhanced understanding of neurological, psychological, and cognitive theories that should be driving sensor placement, data analysis, and subsequent "cognitive load" and/or "cognitive state" gauge derivation
  - Determining appropriate experimental techniques in applied task settings to assess effectiveness of sensors to accommodate both general use settings and individual differences across task domains
- Mitigation strategies
  - Pursue only those mitigation strategies that affirm the goals of AugCog (e.g., those that extend, by an order of magnitude or more, the information management capacity of the human–computer integral).
  - Seek only to implement mitigation strategies based on objective and scientifically valid human performance assessment.
  - Pursue only those mitigation strategies that are operationally feasible (either now or in the foreseeable future).
  - Identify how/when individual differences will affect appropriate mitigation strategy choices and determine how to manage these differences such that human performance is enhanced for all.
  - Enhance the effectiveness of mitigation strategy implementation by identifying which strategies may be user, context, or domain dependent and which are generalizable across these dimensions.
  - Validate entry/exit and transition techniques to ensure optimal system mitigation, where mitigations are applied at opportune moments and transitioned out of at the earliest possible moment.
  - Leverage the arts to develop truly innovative mitigation strategies that are "invisible" to the user, particularly as AugCog S&T is applied to new display devices (e.g., PDAs, augmented reality systems, etc.).
  - Consider how mitigation strategies may impact a team training environment and develop validated approaches to optimize team training and operations.

- Robust controllers
  - Given the complexit.y of HIP, mathematical approaches are needed, but are not the sole answer to developing robust controllers, as there is a need for real-time user and system models based on complex human biology and physiology, as well as a need for task models, which take all contexts into account.
  - More basic and applied research is needed to develop sufficiently comprehensive and accurate models of the components (e.g., user, task, and system contexts) that are to be controlled, as well as determining how to control them with appropriate approaches, be they mathematical or otherwise.
  - Any robust controller should be stable and seamless, where a user is unaware of when a controller is being used yet trusts the system when subsequent effects are noticed (e.g., mitigation turned on/off) and therefore benefits and not suffers from the effects.
  - Both users and funding sponsors need proof of the effectiveness of any controller's ability to integrate the human within the system-of-systems architecture, where input and output of information flow and mitigation control are sufficiently adaptable to improve user performance and maintain overall system stability.
  - Return on investment (ROI) must be justified in terms of development cost (time and money) and benefits (significant user/system performance improvements).
- Roles of National and Supranational Institutions
  - Continued need for more funding to be funneled into the development of AugCog sensors from national and supranational institutions (e.g., DARPA, ONR, NIH, and NSF).
  - Institutions need to foster the ability of HCI practitioners to begin identifying uses for neurotechnologies in various application domains.

60.7 CONCLUSIONS

The field of AugCog has emerged in large part as a result of substantial investment from DoD-funded programs and projects that have been focused on developing neurophysiological-based tools and techniques to enable revolutionary changes in HCI system design. Whether the application context is an operational closed-loop system, system design and evaluation, or education and training, such tools and techniques offer the ability to create human–machine synergy and optimization never before realized. Similar to Licklider's original visions of human–machine symbiosis in 1960, AugCog researchers and practitioners aim to build tightly coupled brain–machine interfaces that surpass the information-handling capacity of traditional HCI systems and empower one operator with the ability to perform a job normally required of two or more operators. Such an improvement in the human–computer integral is a worthy goal. Being able to noninvasively measure and assess users' cognitive state in real time, and then use automated computational systems to modify and enhance HIP capabilities of these users in any application context, is a goal that could substantially improve human performance and the way humans interact with computer-based systems in the twenty-first century. It is up to HCI researchers and practitioners to begin implementing various AugCog tools and techniques by selecting the most appropriate neurophysiological tools for their task applications and users. The technologies reviewed in this chapter will hopefully provide a nice "initial" tool set from which to begin such a selection process.

61 Social Networks and Social Media

Molly A. McClellan, Julie A. Jacko, François Sainfort, and Layne M. Johnson

CONTENTS

61.1 INTRODUCTION

Social media and social networking systems have become ubiquitous phenomena in the daily routines and activities of hundreds of millions of citizens around the world. In many ways these platforms and technologies have supplanted longstanding traditional forms of communication, information sharing, and relationship building. Although a variety of these social tools are heartily embraced by users, they have been extant for only a relatively short period of time and have become much like a thief in the night, stealing traditional modes of commerce, love, war, and survival and upending them to form an exciting and significant influence on the development of humankind. Yet in some ways, the new social milieu that has been catalyzed by the creation of various social media and networks is rudimentary and relatively crude. The basics of functionality and design have been monetized in rare cases and the necessary refinement and further development of these tools stand to complement the progress of societies in many revolutionary ways.

We describe major social media tools based on their popularity and influence as observed from evidence gathered from significant applications that have impacted disciplines, processes, current events, scholarly paradigms, and social contracts. Our presentation is not limited to social networking sites and includes a discussion of progress in professional networks and research networking software that have arisen as innovative collateral and are being leveraged to further the advancements of commerce, research, and scholarship. Opportunities to describe the application of design principles and aspects of human factor engineering are also presented to provide the reader with a foundation on which to build hypotheses for future contributions to allow for improvements in the use, analysis, and application of social media.

61.2 CONTEXT

Computer mediated communication (CMC) systems have been available for several decades. Initially, the primary form of CMC existed as e-mail applications supported by basic text editing software backed by message exchange functionality that provided users linked to a single mainframe computer to communicate asynchronously. As computing evolved from a mainframe-based model to a personal computer-based model, the drive to link users via local area networks and wide area networks gave rise to the realization that CMC systems could be readily connected over networks in a client server fashion. Users began to realize the efficiencies of e-mail; however, ubiquity of CMC systems did not gather significant momentum until the advent of the World Wide Web. To understand the genesis and evolution of social media, one needs to recognize that the proliferation of the personal computer as a commodity and the adoption of its use by the public at large in most of the developed world drove innovative minds to discover means to deploy a variety of tools to the masses.

Social media then emerged and has experienced explosive growth in the past few years. Wikipedia has over 3.5 million pages with descriptions of entities, Flickr has experienced over 5 billion photos, YouTube has 35 hours of videos uploaded to the site each minute, and Twitter users generate 65 million tweets per day (El Abaddi et al. 2011). The ubiquitousness of social media and social online services provides more and more ways for people to connect socially and professionally, while also transforming the ways we think, behave, and share with others. For example, Facebook, MySpace, Twitter, Wikipedia, Blogs, YouTube, tagging in Flickr, and bookmarking in Delicious are all enacting dynamic social change. People with shared interests now have the ability to form groups, defining and reinforcing virtual community structures, which frequently overlap. Early studies (Garton et al. 1997) of computer-supported social networks did not receive as much attention as studies of human–computer interaction, online person-to-person interaction, and computer-supported communication within small groups. This was, in part, due to the state of the technology at the time. More recently, researchers and developers have often focused their studies on the behaviors of single individuals connected within multiple communities. Wang et al. (2010) have taken this a step further and proposed a novel co-clustering framework, which takes advantage of networking information between users and tags in social media to discover overlapping communities to develop a deeper understanding of group evolution.

Some researchers have expressed concern that the ubiquitousness of the global Internet, in general, has weakened local community and stymied local citizenry involvements in particular, by leading people away from meaningful in-person contact. Hampton and Wellman (2003) examined this in the context of a "wired suburb" near Toronto and concluded that the Internet in fact supported neighboring by facilitating discussion and mobilization around neighborhood issues. It was determined that the Internet especially supports increased numbers of contacts with weaker ties. That is, Internet supports the formation of acquaintance-level friendships that are essential to organization and information-sharing at the neighborhood level. In way of follow-up, Wang and Wellman (2010) used two American national surveys to analyze how changes in the number of friends are related to changes in Internet use. The authors found that friendships continue to be abundant among American adults between the ages of 25 and 74 and that they grew from 2002 to 2007. This trend is similar regardless of whether someone is a nonuser of Internet or a light-to-heavy user of Internet. However, heavy Internet users are particularly active, having the most friends both online and offline.

61.3 WEB 1.0, 2.0, AND 3.0

The naming of web 1.0 did not occur until after the concept of web 2.0 was introduced in 2004 to reference the second generation of the World Wide Web. Realistically, you cannot have a 2.0 version without a 1.0 version, so individuals worked backward to define web 1.0. However, creating this definition would prove to be challenging because the changes that led to the term web 2.0 are not technical changes to the Web, but instead it is a reference to applications that facilitate interactive information sharing, interoperability, user-centered design, and collaboration. Additionally, web 1.0 and 2.0 cannot be defined on a timeline since some of the so-called 2.0 techniques were in existence with the launching of the World Wide Web (Strickland 2008a).

Simply stated, web 1.0 sites are considered to be static, not interactive, and proprietary. For example, in web 1.0, a photography studio may create a static profile page about their business that never changes. In web 2.0, this same studio could create a profile on Facebook that can be frequently updated and allow interactions with "friends." In web 1.0, users could locate a dictionary or encyclopedia online and read the information. The interactivity of web 2.0 allows users to update wikis such as Wikipedia with their knowledge. Firefox is an example of non-proprietary web browser for web 2.0. Unlike previous web 1.0 browsers such as Netscape, Firefox source code is available and users can create their own applications or make enhancements. A variety of interactive web 2.0 applications can be found on the Internet. Web-based communities, hosted services, web applications, social networking sites, video sharing sites, wikis, blogs, mashups, and folksonomies are just some examples of the applications.

Web 2.0 has also been utilized for applications such as healthcare. Social media and social networking enable patients, caregivers, families, and healthcare professionals to connect around topics of mutual interest. Examples include communities that form around topics such as (1) common or related health conditions, (2) treatment options, (3) decision making, (4) support groups, and (5) health lifestyle and well-being. Researchers are just now recognizing, and thus further investigating, the value such applications bring to people in the management and experience of their own health or that of a loved one. Social media is transforming traditional patient–clinician relationships, empowering patients to demand more collaborative approaches to care and encouraging patients and clinicians to engage in shared decision making. Social networks have also enabled people to extend their natural circle of social support to include others who may be facing similar circumstances or experiences, but may be at a more comfortable emotional distance (Colineau and Paris 2010).

Cancer survivorship is an area that has realized much attention where social networking is concerned. A diagnosis of cancer is always scary and very often life-changing. YouTube is one tool that has been used by cancer patients to share their personal narrative with others who may be facing a similar diagnosis. Chou et al. (2011) conducted an in-depth characterization of authentic personal cancer stories on YouTube to extract common attributes of those narratives and further illuminate their value to cancer survivors. Their results point to common characteristics of authentic cancer survivorship stories online, such as themes of dramatic tension, emotional engagement, markers of loss of control, a sense of depersonalization, and the unexpectedness of a cancer diagnosis.

There is evidence, too, that online social networking is good for one's well-being. Toma (2010) demonstrated that social networking tools, like Facebook, have self-affirming value. Self-affirmation is the process of bringing awareness to one's own talents, tendencies, goals, treasures, and values. When research subjects spent time on their own Facebook profile pages, as supposed to someone else's, they demonstrate identical behaviors to those who experienced a classic self-affirmation manipulation, namely, displaying fewer ego-protective mechanisms in the face of negative feedback on a task. Other researchers have demonstrated that directed communication between pairs of users on Facebook (e.g., wall posts, comments, and "likes") is associated with greater feelings of bonding, social capital, and lower loneliness (Burke, Marlow, and Lento 2010). Social media has also emerged as an important platform for promoting public health efforts such as public health communication and public health information exchange (Kontos et al. 2010).

There is some concern that social media may be harmful to children and families, primarily due to children's limited capacity for self-regulation and susceptibility to peer pressure and the time social media can take away from traditional face-to-face family interactions. Social media also merits awareness in the contexts of Internet addiction and concurrent sleep deprivation (Christakis and Moreno 2009). The benefits of children and adolescents using social media are also recognized; namely, fostering socialization, communication, and enhanced learning. The minimum age for most social media sites is 13 years. Hence, parents and pediatricians play a critical role in monitoring and informing children about the risks and benefits associated with using social media (O'Keefe and Clarke-Pearson 2011). For more information on web 2.0 in Healthcare, see Sainfort et al. (2011).

Web 3.0, or its synonymous term "the semantic web," is a term coined by Tim Berners-Lee, the man who invented the (first) World Wide Web (Metz 2007). The idea behind the semantic web is that instead of search engines scouring websites for keywords, the browser will understand the information on the web and be able to gather, analyze, and present the data to the user. Instead of a human having to read the webpage, the software will essentially do it for us. To better conceptualize web 3.0, consider the following example. You want to take a date out to a critically acclaimed romantic movie, then an Italian dinner at a restaurant with a terrace, but spend less than $150.00. Using web 2.0 technology, you would have to search for available movies, read reviews, search for Italian restaurants with a terrace, and check pricing information yourself. This could be a timely endeavor because of the separate searches required. With web 3.0, it is anticipated you could enter your search as "critically acclaimed romantic movies near an Italian restaurant with a terrace for less than $150." Your search would be returned with options that meet the above criteria.

Although the technology is not yet mature, many experts agree that web 3.0 will be a more personalized and relevant experience. It is also believed that browsing history will create unique Internet profiles for users and that web 3.0 will use the profile to customize their browsing (Strickland 2008b). This would mean that two different users could search for the same term and wind up with entirely different results.

One of the biggest challenges the semantic web faces is the creation of ontologies. In order for the semantic web to work, programs called software agents will crawl through the web, searching through collections of information called ontologies. These ontologies would have to be detailed and comprehensive, existing in the form of metadata, or information included in web page code unseen by humans, but read by computers (Strickland 2008b). The question remains as to whether developers would want to maintain these complex ontologies.

Despite all the conversation and conferences to define the web, many critics still say that this is a marketing ploy or at the very least inconsequential since there are not actually different versions of the web at this point. Perhaps the numbering of the web is arbitrary, but it has sparked excellent conversations about the future of web-based technology. After all, it is important to know where we have been to determine where we are going.

61.4 DEEP WEB

Most web users use common search engines (Google, Yahoo!, etc.) that index only material found on the Surface Web. At a greater magnitude than the Surface Web is the Deep Web, which has been estimated to be 500 times greater (Wright 2008). These seemingly nonexistent pages are hidden from common search engine view until they are created dynamically as the result of a specific search. The Deep Web is also commonly known as the Invisible Web, Deepnet, DarkNet, Undernet, or the Hidden Web.

Although the Deep Web has existed in parallel to the Surface Web for almost the same length of time, it has not been relevant to most users until the explosion of user-generated content (UGC) and web 2.0 applications. Popular web 2.0 applications such as Wikipedia, Tumblr, Flickr, and YouTube allow both the extensive numbers of contributors and various media content to grow at an exponential rate. This rate of growth is nearly impossible for common search engine index sizes to keep up with.

Social networking sites cause an additional problem for common search engines. Security controls for sites such as Facebook, MySpace, Twitter, and Bloggr allow users to segregate their information between "public" and "friend" or "invite only" views. Because of the various privacy settings, common search engines may not have access to any of this information. This makes web crawling a challenge for users seeking out specific social information, such as medical support groups or blogs.

Based on consumer demand to be able to web crawl UGC, new search engines are being developed that specialize in Deep Web content. Common search engines are attempting to keep up by adding additional document types such as .pdf and .docx to crawl this type of information. One of the most impressive, albeit scary, Deep Web search engines is pipl (http://pipl.com/). This Deep Web search engine scans databases for personal profiles, public records, and other people-related documents that are invisible to regular search engines. Examples of Deep-Web resources pipl is able to search using advanced algorithms are personal profiles, member directories, scientific publications, and court records. An initial attempt at scanning one of this chapter's authors using only first and last name produced private Facebook and MySpace profiles and photos, as well as all previous addresses the author has lived at since birth as well as scientific publications. A subsequent search using the same parameters on another Deep Web crawler, Spokeo (http://www.spokeo.com/), produced the home the author lives in, a photo of it, the current property value, marital status, and number of adults living in the home as well as time living there. If one chooses to subscribe to Spokeo, it is advertised that they could learn additional information including current income, Internet user names, e-mail addresses, and phone numbers.

While the information contained on the Deep Web is now more readily accessed, it is still not the primary source of information for most people. The majority of people searching for information on both old friends and new will often go as deep as entering the persons' name in a social networking site or a Google search. Despite this, both users of the Internet and even nonusers should be aware of the potential for security risks and even identity theft that can arise from information shared on the Internet.

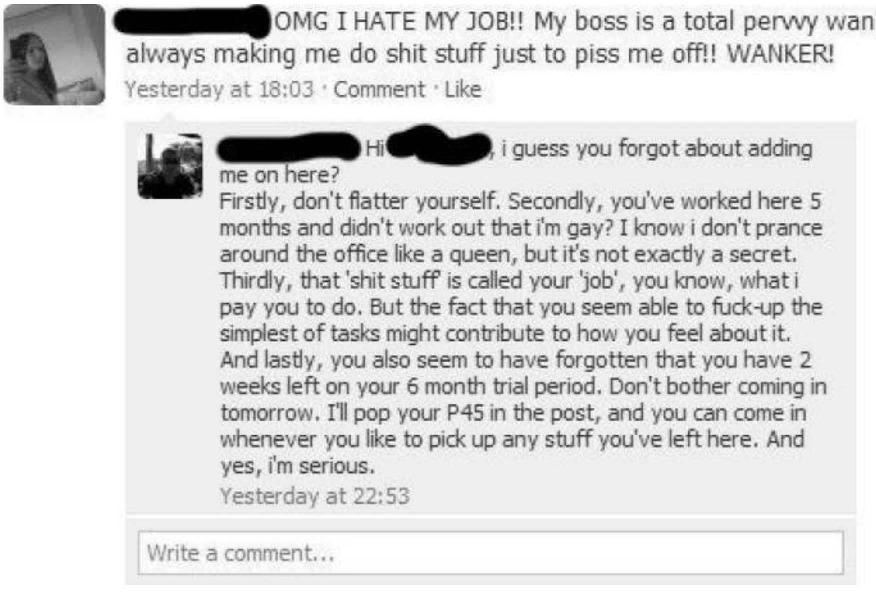
61.5 BE CAREFUL WHAT YOU POST

While social media use is on a rise globally, so is the number of employee layoffs for violating corporate policies. An Internet security firm, Proofpoint, released results of a 2009 survey. They found that of companies with more than 1000 employees, 7% report having issues with employee's use of social media and 8% of those companies report having dismissed someone for posts on Facebook and LinkedIn. In addition, 15% have disciplined an employee for violation of multimedia policies, 13% of U.S. companies investigated an exposure event using mobile or SMS, and 17% disciplined an employee for violating blog or message board policies (Proofpoint 2009). See Figure 61.1 for an example of an employee Facebook post that resulted in job termination. The term "Facebook Fired" has even found its way into the Urban Dictionary (http://www.urbandictionary.com/define.php?term=Facebook+fired) with the definition of "being fired for something you post on Facebook."

Facebook is not the only social media site where employees are finding themselves in trouble for posts. Unfortunately, Twitter's 140 characters or less posting standard makes it even easier than Facebook to blast a statement that results in worldwide shame or loss of a job.

In a now infamous Twitter situation from 2009 known as the "Cisco Fatty" incident, a prospective Cisco employee named Connor Riley innocently tweeted "Cisco just offered me a job! Now I have to weigh the utility of a fatty paycheck against the daily commute to San Jose and hating the work" (quoted in Mangla 2009). Unfortunately for Riley, a Cisco employee named Tim Levad saw her post and tweeted the following in response: "Who is the hiring manager? I'm sure they would love to know that you will hate the work. We here at Cisco are versed in the web" (quoted in Mangla 2009).

While the previous scenario was not an example of an employee losing a job, it caused quite a fuss on Twitter, social media sites, and eventually major media outlets regarding the alleged stupidity and squandering of a job opportunity by not being careful about what one says online. Since then, the number of celebrities, government workers, and everyday people coming under fire or being terminated from employment has risen. Comedian Gilbert Gottfried was terminated in March of 2011 from his contract with Aflac. (Gottfried voiced the Aflac duck for its television commercials.) Gottfried had



[redacted] OMG I HATE MY JOB!! My boss is a total pervy wanker always making me do shit stuff just to piss me off!! WANKER!

Yesterday at 18:03 · Comment · Like

[redacted] Hi [redacted], i guess you forgot about adding me on here?

Firstly, don't flatter yourself. Secondly, you've worked here 5 months and didn't work out that i'm gay? I know i don't prance around the office like a queen, but it's not exactly a secret. Thirdly, that 'shit stuff' is called your 'job', you know, what i pay you to do. But the fact that you seem able to fuck-up the simplest of tasks might contribute to how you feel about it. And lastly, you also seem to have forgotten that you have 2 weeks left on your 6 month trial period. Don't bother coming in tomorrow. I'll pop your P45 in the post, and you can come in whenever you like to pick up any stuff you've left here. And yes, i'm serious.

Yesterday at 22:53

FIGURE 61.1 Employee posting on Facebook, resulting in a termination (From Stewart, T. 2009. Facebook entry that earned 'Lindsay' her P45. *London Evening Standard*. Retrieved November 29, 2011, from http://www.thisislondon.co.uk/standard/article-23732446-facebook-entry-that-earned-lindsay-her-p45.do.)

tweeted over a dozen jokes regarding the Japanese tsunami, and Aflac, Japan's largest insurance company was not amused (Fisher 2011). While many people would have been more sensitive to the tragedy in Japan, many comedians like Gottfried know no boundaries with their jokes. However, even comedians with no ethical code should consider the global reach and impact of their online statements.

Politicians are not immune to potential scandals on social networking sites either. Congressman Anthony Weiner, a democrat from New York, was caught in a Twitter scandal after a photo of a male's genitals was sent from his account via Twitter to a 21-year-old female college student (Kellman 2011). Initially, the congressman denied the allegation that he had sent the photo and claimed his account was hacked. On June 6, 2011, Congressman Weiner held a press conference where he admitted to engaging in inappropriate behavior via social networking sites. He admitted that he had spent the past 3 years sending and receiving dirty online chat messages from six women, which included the exchange of X-rated photos and lewd messages (Fasick and Lisi 2011). This scandal became known almost immediately as Weinergate across all social media sites.

In addition to political scandals, missing job opportunities, or being terminated, social media posters should also be wary of breaking federal laws. Jennifer Carter, a University of Mississippi Medical Center nursing school employee, responded to a tweet from Mississippi Governor Haley Barbour that read "Glad the Legislature recognizes our [state's] dire fiscal situation. Look Forward to hearing their ideas on how to trim expenses" (quoted in Edwards, 2010). Her tweeted response was that Barbour should "Schedule regular medical exams like everyone else instead of paying UMC employees overtime to do it when clinics are usually closed" (quoted in Edwards 2010). Carter was referring to a visit Barbour had made to the medical center several years earlier on a day when it was normally closed. What Carter did not consider was the fact that she potentially violated federal HIPAA regulations through her tweet. While no legal action has been taken against her at this time, she was disciplined and encouraged to resign.

Not only do social media users have to be concerned about what they post publicly, but according to the Maryland Department of Corrections they should be just as worried about their private activities. The American Civil Liberties Union alleged that the state of Maryland required new applicants and those applying for recertification provide their social media account usernames and passwords for use in background checks (Madrigal 2011). To most people it seems reasonable that a current or potential employer would check social media sites to ensure that employees are following a code of conduct or not releasing trade secrets. It seems entirely irrational and unconstitutional that an employer would be able to require access to a private account and seems tantamount to reading your mail (e-mail or paper) or listening in on your phone calls at home.

In reality, despite the public scandals associated with the use of social media, few people wish to share everything, with everyone, all the time. Hence, users often seek to strike a balance between which things to make public and which content to keep private. This also involves how users define "public" within their social sphere, and how to give graduated access to content based on the nature of their relationships. There is a need for design solutions that help users manage the burden of managing privacy and publicness (Lampinen 2010).

61.6 INTERNET DATING AND SOCIAL APPS

The popularity of social networking sites is not limited to maintaining or engaging in new friendships, but has also lead to an increase in online dating sites. Some suggest that because of the economic downturn in the global economy over the past several years, people are fleeing from traditional and more expensive methods of meeting new people (such as meeting at bars, restaurants, or clubs) and instead opting for the less expensive online dating sites. In 2009, it was reported that some of these online dating sites were posting 400% sales growth year on year (Espinoza 2009). Additionally, this billion dollar industry is projected to continue to grow at a rate of 10% annually through 2013 (Tulsiani, Best, and Card 2008). One of the more popular dating sites, Match.com, has seen record growth in 2011. The company's first quarter revenues increased by 18% to $93.3 million, which equates to a 22% increase in subscribers to their website (Silverstein 2011).

In Britain, seven out of ten (69%) dates in 2008 were arranged online through dating sites (Espinoza 2009). In the United States, Internet dating is just as popular. According to a Pew survey, of the ten million Internet users who are single and looking to date, 74% have used the Internet to pursue romantic relationships. The survey also found that approximately 30 million Americans report knowing someone who has been in a long-term relationship or married someone they met online and 60 million people know someone who has engaged in the online dating scene (Madden and Lenhart 2006).

Sautter, Tippett, and Morgan (2010) state that usage patterns of Internet dating services are a result of the following factors: (1) technological change and growing computer literacy making Internet dating available, efficient, and accessible; (2) demographic change causing increased numbers and a variety of persons interested in romantic relationships; and (3) increased acceptability of Internet dating due to social change.

The majority of dating sites such as Match.com or eHarmony operate on similar principles. For a fee, users are allowed to post a profile and photo, search for matches, and communicate through the website. Some of these vendors even offer personality profiling as a feature to suggest personalized matches for the users. Specialized sites have been created for individuals looking for specific types of people, for example, ChristianMingle.com serves to match individuals of Christian faith.

Other sites exist to service people who desire to cheat on their spouses, such as AshleyMadison.com whose slogan is “Life is short. Have an Affair” (http://www.ashleymadison.com/). AshleyMadison even offers an iPhone app called iWipe that will wipe your location data from your iPhone, iPad, or other Apple iOS device so you can prevent others from tracking your whereabouts. Concerns about location tracking were raised when it was discovered that when iPhones were synced to computers, they were building a location database of where users had been. iWipe was released prior to the fix Apple released for consumers to eliminate this location tracking.

AshleyMadison has over 9 million users and assures anonymity to its users. Additionally, if someone leaves their service, AshleyMadison deletes any trace of their account, including messages that they had sent to other members (Kane 2011). Yet another iPhone app that is under fire is from SugarSugar. It is aimed at matching women with rich men, or sugar daddies, and vice versa. Their website sugarsugar.com boasts the motto “Where Romance Meets Finance” and their new app is called “Sugar Lifestyle” (http://www.sugarsugar.com/).

GPS-enabled smartphone apps ignore the complexity of personality profile matching and simplify and speed up dating based on location. Apps like Skout, Grindr, and StreetSpark allow users to search through lists of people based on the users’ GPS location. The apps display the proximity between the user and other people using the app in feet. Users can then exchange messages through the applications to each other and potentially meet face-to-face within minutes. This avoids the need for months of secure online communication and can result in a face-to-face meet within seconds. Although these apps are quite popular, it does raise questions about the safety of meeting a complete stranger based on a few SMSs and due to proximity. Not all users of Skout and Grindr use the GPS feature as both apps allow the ability to turn off the location-aware feature.

61.7 PRIVACY CONCERNS WITH ONLINE DATING

Although online dating sites and apps have seen increases in popularity, there are concerns for safety and privacy. Unlike most social networking sites where friendships are built with colleagues from work, old schoolmates, and friends online, dating brings together two complete strangers with a lack of physical context and verbal cues via the Internet. This can lead to confusion and difficulty in creating and maintaining appropriate relationships. Cyberstalking is another concern for those looking to meet online. As stalkers have increased access to technological tools that allow both intrusion and surveillance into individuals’ lives, society may be making itself more vulnerable to privacy invasion by participating in some of these applications (Spitzberg and Hoobler 2002). There are also concerns over identifying theft and sexual predators lurking online. In April of 2011, a woman filed a civil suit against the popular dating site Match.com alleging that she was sexually assaulted by someone she met online (Associated Press 2011). According to the news article, the suit contends that alleged assailant had faced sex crime charges and the attack could have been prevented if criminal background checks were done by the website. If online dating websites were to begin conducting background screenings, users would then have to pay additional fees and provide the sites with their social security numbers—something many users would not do because of the risk of identity theft.

Another concern with online dating is misrepresentation or skewed self-presentation. In his seminal sociology book, Erving Goffman defines self-presentation as the process of packaging and editing the self to create a certain impression upon the audience (1959). Some instances of misrepresentation are extreme, such as the case of Thomas Montgomery. Montgomery, a 48-year-old married man, posted as an 18-year-old marine to pursue a relationship online with what he believed to be a 17-year-old girl. Montgomery’s wife contacted the girl to tell her the truth. In retaliation, the 17-year-old girl began an online relationship with Montgomery’s 22-year-old coworker. Montgomery then shot and killed his co-worker out of jealousy and pled guilty to the charges in criminal court. The surprising twist was that the 17-year-old girl the coworkers were fighting over was actually a middle-aged housewife engaged in her own online misrepresentation (see Labi 2007).

While extreme cases of misrepresentation exist, research has found that deceptions are usually self-enhancing as opposed to outwardly malicious. For example, male daters have been found to add couple of inches to their height, whereas female daters subtract a few pounds from their weight to appear more attractive to the opposite sex (Toma et al. 2008). According to Hancock and Toma, self-presentational choices are guided by the following: “(a) self-enhancement, or daters’ desire to appear as attractive as possible in order to be noticed by potential mates; and (b) authenticity, or the need to appear honest in their description of themselves” (2010). With improvements in technology, dating profiles are no longer limited to just text. In fact, the profile picture has become a vital component of online dating. Research has found that online daters rated their photos as relatively accurate, but independent judges rated approximately 1/3 of the photographs as not accurate. In addition, female photographs were less accurate than male and were more likely to be older, to be retouched or taken by a professional photographer, and to contain inconsistencies, including changes in hair style and skin quality (Hancock and Toma 2009).

61.8 SOCIAL NETWORKING APPS

The Foursquare app combines social networking with location information by using GPS location, similar to the dating apps in the previous section. Users will “check-in” at a friend’s house, movie theater, or restaurant to display their location. Merchants benefit by adding promotions for people who “check in” to their establishment such as coupons and loyalty programs. Users can bookmark information about venues that they want to visit and find relevant suggestions about nearby venues. Concerned with privacy, Foursquare changed their settings to also allow users to "go off the grid" while still allowing users to receive the benefits of checking-in at a particular merchant (Albanesius 2010). To further engage Foursquare users, in June 2011 a scavenger hunt called "The Clip Trail" powered by AnyClip was launched. Foursquare users play an interactive game to unlock some of the most memorable movie scenes in New York, such as climbing the Empire State Building with King Kong (AnyClip Ltd. 2011). The hunt began during Internet Week New York (IWNY) where users obtain sticker quick response (QR) codes for famous New York film locations. Scanning the QR codes entered them into the scavenger hunt, where they travel to various locations to unlock movie moments for a chance to win 6 months of free movies. This novel scavenger hunt idea takes advantage of Foursquare's open application programming interface (API) and engages social media users in an entirely unique way. We anticipate that more vendors in the future will work to engage consumers through social media apps as the consumer base will demand more engaging and complex experiences.

Meebo is another social media app involved in IWNY 2011. Meebo is an open source platform that integrates all social networks and communications channels into a single, simple-to-use solution (Meebo 2011). It is available on popular social networking sites for instant messaging (although the parent website has likely rebranded their chat but is uses the Meebo API) and mobile devices. Similar to the FourSquare concept, Meebo has a MiniBar that allows users to "check-in" to websites instead of physical locations. As opposed to sharing great new restaurants with your friends, you would share web discoveries with friends and across social networks. It also allows you to follow people with similar interests to see what websites they are visiting. For IWNY 2011, Meebo has launched the "True New Yorker Quest," a guided tour of New York; the twist is that it is for the best New York websites instead of landmarks. By logging in daily during IWNY 2011, users can learn about new websites that give a real feel for the city while having a chance to win prizes (https://www.meebo.com/quest/q/newyork-2011).

61.9 SOCIAL CLOUD

Definitions for cloud computing are changing as rapidly as the technology. Likely the best definition for cloud computing has been defined by the U.S. National Institute of Standards and Technology (NIST). NIST describes cloud computing as a model for enabling convenient, on-demand network access to a shared pool of configurable computing resources (e.g., networks, servers, storage, applications, and services) that can be rapidly provisioned and released with minimal management effort or service provider interaction. This cloud model promotes availability and is composed of five essential characteristics (On-demand self-service, Broad network access, Resource pooling, Rapid elasticity, Measured service); three service models (Cloud Software as a Service [SaaS], Cloud Platform as a Service [PaaS], Cloud Infrastructure as a Service [IaaS]); and, four deployment models (Private cloud, Community cloud, Public cloud, Hybrid cloud). Key enabling technologies include (1) fast wide-area networks, (2) powerful, inexpensive server computers, and (3) high-performance virtualization for commodity hardware (2011).

Despite whether web 2.0 users are aware, a large amount of their user data is stored in the cloud. Examples of cloud computing services include Facebook, MySpace, Picasa, Flickr, Bloggr, and YouTube. The advantage of these sites is that users can share their data at any time from any location. This ranges from sharing their blog to utilizing applications on a free social networking platform such as Facebook or Google Docs. The drawbacks are that with the ability to use all these sites, users may lose data and become inconvenienced by their reduced capacity to monitor and manage the data (Seong et al. 2009).

Google appears to be at the forefront of the cloud revolution—with its Android OS and abundant online services it could easily be the hub where everything syncs. Facebook, Amazon, and Microsoft (with its acquisition of Skype) are just a few companies that are also developing new strategies for the cloud. New on the horizon is the Apple announced release of iCloud for Fall 2011. In an attempt to prevent user inconvenience, the iCloud promises to store music, photos, apps, calendars, documents, and more while being able to automatically and wirelessly push them to all your devices (Apple 2011). Apple touts that this will make content management easier, because it will all occur automatically. For example, a picture can be taken with an iPhone and instantly pushed to a Mac or Windows 7 PC. Songs or applications that were previously purchased on the iPhone are now available for the iPad without repurchasing. In addition, users will not have to upload their music to the cloud. Instead, the iCloud will check its vast database, and if it recognizes a song that you own in iTunes, it will automatically add the version to the cloud.

Apple also reports that storage space will not be an issue. Upon signing up for iCloud, users are said to receive 5 GB of free storage. Apple reports that only mail, documents, Camera Roll, account information, settings, and other app data will be applied against that 5 GB of storage. The users-purchased music, apps, books, and Photo Stream will not count against the storage. By taking this route, it encourages the users to use the iCloud for new uses (documents, mail)—not just the typical music and apps most users are familiar with.

Despite Apple's promises about the iCloud, many tech writers and market watchers are skeptical. Apple has released several failed web apps over the past few years, and one author notes that this may just be Apple's Achilles' heel (Fortt 2011). Apple's webmail .me free version lacks essential functionality such as Exchange sync, and the paid version is still not as good as big competitors such as Google who offer superior quality for free. Prior to the iCloud, Apple's experimentation with the cloud was MobileMe, a paid service for $99/year that only provided cloud storage and photo sharing. Similar to the e-mail issue, many free alternatives were available to users and a buggy release of the application only caused it further harm in the public eye. MobileMe is said to be decommissioned with the introduction of iCloud. The final failure for Apple was the launch of Ping, an iTune's social utility that did not integrate well with Facebook, the leading social networking application in the world.

While the iCloud could bode well for Apple if it becomes successful, it may also be yet another signal of the end of the PC as a digital hub. The notion that everything has to be synced back to a PC is antiquated since wireless networks handle this better. While the PC used to be the central device for a tech savvy user, it is clearly now shifting to other devices including smartphones and tablets.

61.10 WIKIS AND TECHNOLOGY-MEDIATED SOCIAL PARTICIPATION

A wiki is defined as "collaborative website comprises the perpetual collective work of many authors. Similar to a blog in structure and logic, a wiki allows anyone to edit, delete, or modify content that has been placed on the website using a browser interface, including the work of previous authors" (Webopedia 2011). It not only refers to the site, but also to the server software that allows users to create and edit content using any web browser.

The most popular and commonly known wiki is Wikipedia, a multilingual web-based free encyclopedia written collaboratively by many users. As of June 9, 2011, the English Wikipedia (http://en.wikipedia.org/) had 3,654,148 articles, 24,147,440 pages in total with 466,735,596 edits. There were 14,708,291 registered users, including 1,790 administrators. Wikipedia is self-governed; any user can add content. However, there are guidelines that should be followed and are available on the site. Because the site is self-organizing, anyone can build a reputation to become an editor. Amongst the editors, there are varying hierarchies including administrators. Despite having over 14 million users, there are less than 2000 admins. These users are allowed to delete articles, block accounts or IP addresses, and edit fully protected articles (http://en.wikipedia.org/wiki/Wikipedia:About).

Although over 14 million registered users are on Wikipedia, even more access their pages to view content but do not edit or add any to the site. A fraction of those users register to become involved in editing and even fewer become editors. Some of those editors will move on to become admins in more of a leadership role. Of those admins, very few excel to roles in governance as Bureaucrats, part of the Arbitration Committee, or Stewards (http://en.wikipedia.org/wiki/Wikipedia:About). Researchers have been trying to build a framework to explain the motivation for this technology-mediated social participation. Preece and Shneiderman proposed the Reader to Leader Framework in 2009 aimed at helping researchers, designers, and managers understand what motivates participation to improve interface design and social support (Preece and Shneiderman 2009).

The Reader to Leader Framework includes some usability and sociability factors that may influence each stage from reader to leader (Figure 61.2). One example of a usability factor that may influence reading is clear navigation paths so that users have a sense of mastery and control, while repeated visibility in online, print, television, and other media is a proposed sociability factor. A usability factor that may lead to contributing would be low threshold interfaces for easily making small contributions, such as no login required. Policies and norms for appropriate contributions are likely sociability factors that would lead to contributing on a given site. Collaboration tools such as the ability to communicate within groups, schedule projects, assign tasks, share work products, and request assistance are usability factors that likely lead to collaboration. Some sociability factors that lead to collaboration may be altruism, respect for one's status within the community, and having an atmosphere of empathy and trust. Usability factors for leaders may include providing enhanced access to promote agendas, expend resources, or limit malicious users. The cultivation and encouragement of leaders is another sociability factor that may influence the creation of that stage (Preece and Shneiderman 2009).

Wikis are often used within and among organizations. Employees within organizations report the use of Wikipedia and other public wikis, private wikis designed for interaction with vendors and customers (Wagner and Majchrzak 2007), and wikis internal to the organization that are used as an information repository for project management and for communication (Grudin and Poole 2010). Researchers collected data from three large companies, online marketing firm, and three start-up software companies. Semi-structured interviews were conducted with employees concerning wiki deployment and use. Three major challenges were identified as barriers to wiki adoption and long-term sustainability: (1) aligning manager and

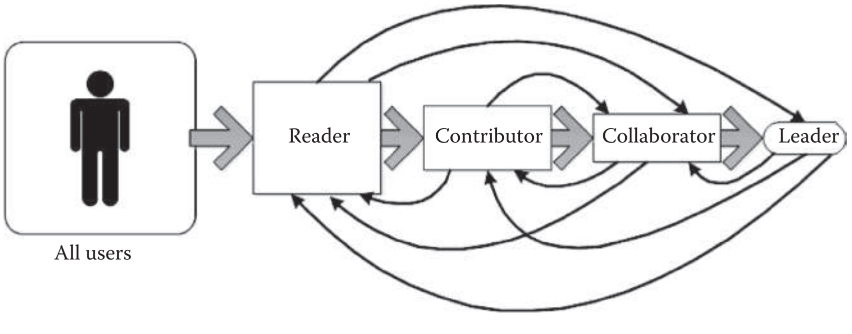


FIGURE 61.2 Reader to Leader Framework. (Adapted from Preece, J., and B. Shneiderman. 2009. The reader-to-leader framework: motivating technology-mediated social participation. *AIS Trans Hum Comput Interact* 1(1):13–32. http://aisel.aisnet.org/thci/vol1/iss1/5.)

individual contributor expectations; (2) content organization and flexibility; and (3) positioning a wiki in an existing information ecology and corporate culture (Grudin and Poole 2010).

61.11 TRENDS IN SOCIAL MEDIA USE

A 2009 Pew Internet Project report reveals that 93% of both teens aged 12–17 and young adults aged 18–29 go online, while 74% of all adults (18+) go online. It is true that while we see increases in Internet use across the generational board (especially increases among ages 65+), the fastest growing Internet users are the millenials and young adults. Social media and web 2.0 applications are extremely popular among younger people, but are also increasingly popular for those over 30. When web 2.0 applications such as Twitter are first launched, we see people of all age categories rushing to be first adopters. As the "newness" of these applications wears off, the demographics for usage are starting to stabilize. These data are now available, and social media usage can explain some of the differences.

A recent report based on the 2009 Parent–Teen Cell Phone Survey, sponsored by the Pew Internet and American Life Project, found a decline in blogging among those under 30, while an increase in blogging activity for those over 30 (Lenhart et al. 2010). One explanation for this decrease in blogging among younger adults is that they may have exchanged blogging for micro-blogging or using applications such as Twitter or Facebook status updates instead of longer, more personal blogs. Another reason may be fear of cyberbullying, as teens realize the more personal information they expose to the world, the greater the possibility of someone using it against them. The increase in blogging for those over 30 may be a result of a slower technology acceptance curve for those who are not digital natives. As content management systems (CMS) such as WordPress continue to provide interfaces that allow templates and widgets to be easily rearranged without knowledge of PHP or HTML, it makes blogging more accessible to everyone. Currently, WordPress has a CMS market share of greater than 50% (W3Techs).

Use of social networking sites has risen dramatically across all age groups. Almost three quarters of both online teens (under 18) and young adults (18–29) use social networking sites. The number of teens has significantly risen from only 55% in November of 2006. Although there is not much difference between teens and young adults, there is a large gap between those groups and adults aged over 30. Only 39% of online adults over 30 use social networking sites (Lenhart et al. 2010).

Although overall usage is up, there is a decline for teens in some of the functionality. Teens are using the social networking sites less for daily messaging, bulletins, and both group and private messages. One can assume that the decline in messaging is due to greater cell phone accessibility for teens—75% of teens now report having a cell phone and 58% of 12 year olds now have phones (Lenhart et al. 2010).

Based on some social networking behaviors, one could assume that concern for privacy is an issue. Many adult social networking site users now maintain two different profiles—over half report having at least two different profiles (Lenhart et al. 2010). Many users maintain two different profiles to keep "work" and "home" life separate. Adults may be worried that having business colleagues view wall postings by friends or pictures they are "tagged" in may lead to embarrassment and possible termination from employment. For this reason, adults may maintain a professional profile as well as a family profile. This may not always be successful as we learn in the section of this chapter on the Deep Web—if the information exists on a social networking site, it may never be truly private.

The most popular social networking site for adults both under 30 and over 30 is Facebook (Lenhart et al. 2010). This statistic is not surprising as Facebook was initially created for college students and later opened up to high school and then everyone over age 13. It is estimated that over 40% of the U.S. population has a Facebook account, one-third of which are aged 24 and younger (Wells 2010). Americans do not just create their social networking accounts, they are actively using them. Nielson Company reports that U.S. Facebook users log in approximately 19 sessions per month and spend an average of around 6 hours per session (The Nielson Company 2010).

Twitter is likely the least popular social media application amongst teenagers. It is interesting to note that although teens aged 12–17 flock to most social media applications, only 8% of them use Twitter for posting status updates or following other users (Lenhart et al. 2010). Teens may not have avidly adopted this situation because they have a wide variety of ways to communicate with each other—text message via cell phone, status updates on their social networking sites, and instant messaging services. They are also likely not politically active and, therefore, do not follow news and politics via Twitter. Likewise, the survey also found that Twitter is similarly less popular for those over 30—only 19% use the application (Lenhart et al. 2010). This age demographic may have social media overload, and although adopting Facebook to keep in touch with old friends may seem reasonable, following what the latest celeb had for breakfast that morning is not that appealing. The lack of popularity may also have to do with the slower rate of technology adoption for older adults. Twitter is the most popular for young adults aged 18–29, of which one-third use Twitter (Lenhart et al. 2010). This popularity may be due to increased interest in being tuned in to the latest news, politics, and celebrity gossip among this age group. It may also be due to increased self interest. This group of people is just coming of age as adults and may be narcissistic enough to believe that other Twitter users would be interested in their thoughts, experiences, and favorite morning breakfast cereals. More research is warranted to determine the true causes behind the age disparities in Twitter usage.

61.12 TEENAGERS AND SOCIAL MEDIA

Teenagers are using social networking sites at an ever increasing rate. Because of the digital divide between teens and adults, many parents are unaware of what their kids are posting or how much time they are spending on these sites. In a national survey of more than 1000 teens, CommonSense

Media discovered that over half of the teens surveyed check their accounts at least once a day, while almost a quarter of them check more than 10 times daily (2009). While avidly checking social networking sites is not a problem for most teens, the behaviors they engage in can be harmful or dangerous. The following results from the teenagers who participated in the survey outline some disturbing trends:

- 37% have made fun of other students.
- 28% have shared personal information about themselves they would not normally share in public.
- 25% have created a profile with a false identity.
- 24% have hacked into someone else's social networking account.
- 13% have posted naked or semi-naked photos or videos of themselves or others online.
- 12% of teens with Facebook or MySpace pages admit their parents do not even know about the account.

The last statistic lends credibility to the assumption that preteens are lying about their ages to sign up for social networking sites. Currently, social networking sites require that users be at least 13 years of age to create an account. This is a minor obstacle for digitally savvy children since there is no method of "carding" or checking IDs for subscription to these sites. Parents may also give permission to their children or assist in creating these false accounts so that their child is not "left out." Allowing underage children to access social networking sites exposes them to situations they may not be prepared for, such as threats of inappropriate content and contact from strangers and bullying by computer (Richtel and Helft 2011).

61.13 CYBERBULLYING

Cyberbullying is an ever increasing form of bullying occurring on school campuses nationwide. Bullying no longer requires face-to-face encounters in the school yard. With the increased access to unsupervised technology, cyberbullys can use e-mail, text, chat rooms, cell phones, cell phone cameras, personally created websites, and social networking sites to taunt and torture their victims.

The importance of this issue was first recognized in 1999 in a report from the United States' Attorney General to the U.S. Vice President Al Gore that suggested incidents of cyber harassment were an increasing problem for law enforcement officials (Beckerman and Nocero 2003). In 2004, a U.S. survey found that 15% of teens identified themselves as Internet bullies, while 7% said they had been targets of cyberbullying (Ybarra and Mitchell 2004). In a Pew Internet Project research survey, approximately one-third (32%) of all teenagers who use the Internet report having experienced receipt of threatening messages, private e-mails or text messages forwarded without consent, an embarrassing picture posted without permission, or having online rumors spread about them online (Lenhart 2007). This survey also found a gender gap for bullying. Girls are more likely than boys to be bullied, and more often it is the older girls (ages 15–17) who experience it the most. Social networking also appears to play a role in frequency of bullying. The survey also found that 39% of teen social network users have been cyberbullied, compared with 22% of teens who use the Internet but not social networks.

More recently, Li (2010) found that 40% of students would do nothing if they were cyberbullied and only about 1 in 10 would inform adults. Reasons for not informing adults include fear of retaliation from the bullies and a feeling of helplessness that anything would be accomplished by reporting the bullying. The increase in incidences of cyberbullying coupled with the lack of reporting makes this a difficult problem for parents, schools, and law enforcement to address.

61.14 SPECIAL POPULATIONS AND SOCIAL MEDIA

Unfortunately, the ability of social networking sites to enhance community ties and structure is not universal across the population. People with learning disabilities or cognitive impairments often encounter substantial barriers when attempting to use them. Older adults also experience challenges when attempting to use such services or avoid adoption altogether.

Some of these difficulties for people with learning disabilities or cognitive impairments are inherent to accessibility and usability problems common to all Internet services. However, this issue also stems from the fact that many simplified versions of popular social networking sites were developed primarily with visually impaired persons in mind or for people using the service over slow network connections or on mobile devices. The problems encountered by people who have learning disabilities or more dramatic cognitive impairments are often related to a lack of comprehension or understanding of the operating environment and the unique terminology/lingo that are used within those environments. In 2009, the Papunet network service unit of The Finnish Association on Intellectual and Developmental Disabilities (FAIDD) launched a project to create an easy-to-use social network service. Principles learned from this effort were applied to the development of a new user interface, based on the Elgg application framework (Elgg 2011) that enabled design and testing of features that render an easily accessible network service. The testing revealed that simplicity and clarity are the keys to design with these populations (Sillanpaa, Alli, and Overmark 2010). A qualitative study involving an existing social networking site and interviews of individuals and groups of older adults revealed that in this population, social networking sites are often perceived to involve socially unacceptable behavior (Lehtinen, Nasanen, and Sarvas 2009).

61.15 RESEARCH NETWORKING SOFTWARE

Another form of networking that is enhanced by social media is research networking. Research Networking Software (RNS) is based on the ability to discover resources and people and use data-mining, social networking principles, and semantic web solutions to facilitate the identification of expertise and collaborators (Friedman et al. 2000, Schleyer et al. 2008, Gewin 2010). The identification of collaborators outside of one's primary discipline has become more important as science becomes more interdisciplinary, albeit in small steps (Porter and Rafols 2009). Most recently, convergence has been recognized as the merging of distinct technologies and disciplines into a unified whole, particularly in the engineering, physical sciences, and life sciences (Massachusetts Institute of Technology 2011), and is highly dependent on collaboration among research groups that have traditionally been viewed as distinct and potentially contradictory.

While friends and families share information on Facebook, researchers have various RNS platforms available to connect and transcend disciplines. This approach allows more rapid discovery, leads to the development of collaborative research teams, and provides access to a multitude of resources that are being surfaced through research networking systems. VIVO (vivoweb.org 2011) and Profiles (Harvard Catalyst Profiles 2011) are two open source RNS platforms that allow users to identify experts and collaborators and are being used by a number of research institutions conducting clinical and translational research (Weber et al. 2011). VIVO is an RNS based on a structured information architecture that leverages a number of existing and developing ontologies and relies on semantic web principles including Resource Description Framework (RDF), Web Ontology Language (OWL), SPARQL Protocol and RDF Query Language (SPARQL) to help ensure interoperability with other RNS platforms. Profiles also uses the same structured information architecture to produce open data that can be easily linked to other systems. SciVal is a commercially available RNS (that also provides access to research expertise, collaborators, and other research assets including patents and grant information).

The efficiencies that can be experienced through the use of an RNS include the self-population of a database of publication history, research interests, and professional relationships for investigators in an organization. A representative "snapshot" of a researcher's profile from UMN Profiles (profiles.ahc.umn.edu) is shown in Figure 61.3. Research networking tools most often include visualization capabilities to allow users to view and manipulate dynamic coauthor networks, review publication history over time, analyze geographical interrelatedness of investigators, and probe the degree a researcher collaborates with other investigators. As other forms of visualization develop, it is anticipated that tools such as ResearchWave (Hinrichs, Fisher, and Riche 2010) will be increasingly used to permit a "walk up and use" approach to engage people with information about research at an institution in an aesthetically pleasing manner.

Most recently, a national network of institutions using RNS platforms has been created. The pilot work has been

platforms. The semantic web as the annotation web (Goble et al. 2006) will include RNS platforms as key drivers to promote the development and use of open data and linked open data. The VIVO advances to use linked open data to describe investigators, and their research is being adopted by other RNS platforms to create an RNS-linked open data cloud during 2011–2012.

61.16 SUMMARY

Although we have covered the major social networking tools and discussed progress in professional networks and research networking software, there are many applications and areas of research left untouched. Because of the rapid pace of technology development and the increase in accessibility for broader areas of the population, we anticipate a more dramatic climb in the use of social media applications. Future applications and areas of research would likely include the utilization of social media for national priorities such as healthcare, emergency response, economic development, and education.

Privacy and security issues will continue to be at the forefront as we learn new ways to communicate and share information via the web. New hardware and improvements to smartphones, tablets, and other mobile devices will foster opportunities to engage humans with their social and physical environments in unique ways. The PC will likely become just another device instead of a hub as we continue to look to the cloud for data storage and accessibility. Increased awareness of design principles and aspects of human factor engineering will serve to improve usability of current systems and help define even better applications in the future. Social media and social networking are phenomena that will continue to transform the ways we interact, connect, communicate, share, work, and build communities.

62 Human–Computer Interaction for Development

Changing Human–Computer Interaction to Change the World

Susan M. Dray, Ann Light, Andrew M. Dearden, Vanessa Evers, Melissa Densmore, Divya Ramachandran, Matthew Kam, Gary Marsden, Nithya Sambasivan, Thomas Smyth, Darelle van Greunen, and Niall Winters

CONTENTS

62.1 INTRODUCTION

This handbook is about the design of human–computer interaction (HCI) and of solutions for specific applications and domains. This chapter* is about how you can go beyond creating interfaces or improving user experience and make a difference in the world. That difference might be global, such as by doing work that supports the UN's Millennium Goals, or it might be local in ways that are meaningful only to a particular community. The funding for the work may come from a government, a non-governmental organization (NGO), a research council, a charity, or a company; the budget may vary from the price of a ticket to millions of dollars. The people or group for which you hope to make a difference might be on the other side of town or on the other side of the world. Regardless, this chapter is about applying what we know about user-centered design (UCD) to worldwide economic and community Development.

62.1.1 Introducing HCI4D

HCI for Development, or HCI4D, is a new multidisciplinary field. It is still defining itself, as is witnessed by the number of names under which it goes: HCI4D, UCD for Development, Human-centered design for Development, Interaction Design and International Development, and others. While there are nuances that distinguish these, we are using the term "HCI4D" in this chapter to encompass them all. This field is being developed by academics and practitioners, by people all over the world in "developed" and "developing" countries, and by young researchers and senior researchers and practitioners, often working hand-in-hand together in the creation of this exciting new area. Furthermore, consider the following:

- HCI4D is interdisciplinary. Therefore, there is no "one way" or one interpretation that is the only "correct" one. There is discussion and sometimes controversy, but no specific orthodoxy.
- We come from both applied and academic settings. We recognize that both have something important to offer and each has its own set of limitations. We are committed to dialogue across what is sometimes a barrier.
- HCI4D is young and is still changing and defining itself.
- HCI4D is deeply rooted in fieldwork. This brings with it a certain set of responsibilities that all fieldwork does, but they are heightened by the emphasis on Development.
- HCI4D is international. We have colleagues on all continents and have worked on as many as six continents.
- HCI4D focuses on the larger goal of making the world a better place.

The authors of this paper reflect some of this diversity: We include academics and practitioners from four continents, who count themselves as researchers, teachers, consultants, and practitioners. We have all worked in countries other than our own and have dealt with challenges big and small to do so. We represent different worlds on many dimensions. However, there are other voices that are not explicitly part of this chapter, although they are no less important: people in NGOs, people in government Development offices, people in foundations, and perhaps most important, people in local communities with whom we work. We have tried to represent these perspectives as faithfully as we can, but realize that this would have been a different chapter had we been able to include their voices directly.

62.1.2 Terminology

Because HCI4D is interdisciplinary, it is important to define some terms that have multiple different meanings. Additionally, several of these terms are also politically charged, which makes it particularly important that we are clear about what meanings we are ascribing in this chapter.

62.1.2.1 Development

The term "development" has a number of different meanings. In the technology world, "development" refers to the actual creation of a program or design. There are several related

* This chapter has been a group project. Some of the case studies have been provided from additional HCI practitioners in the field. The material was edited by Susan Dray, Ann Light, and Vanessa Evers.

uses of the term in information technology (IT) organizations. Software development, application development, and platform development are among the terms that IT people use to describe different aspects of this process of creation. A second meaning of the term relates to the larger technological process, usually described as Research & Development, which includes earlier phases of planning and investigation ("Research") to guide the actual development. However, neither of these is the meaning that we are stressing in HCI4D. In this chapter, Development refers to broad interdisciplinary efforts and transformative projects to address specific human problems and to influence the "complex economic, social, and political processes of change in countries in the poorer parts of the world" (Oxford University 2010). We will distinguish this meaning of the word from the previous two by capitalizing the initial letter. We will discuss the meaning of this term in more detail below both because it is a new concept for the HCI community and because it is far more contentious and politically charged than the more technically focused meanings of the word.

62.1.2.2 Developing World

In addition to clarifying the term "Development," there is also the question of how to refer to different regions of the world. There are simply no good terms for describing the so-called developed and developing regions. Many older readers will remember the first world/third world distinction that has almost disappeared. Nowadays, we have a range of ways of talking about parts of the world, which reflect economic differences in different regions. "Developing countries" is a prevalent term, but the more accurate description might be "emerging economies" or "developing regions." For the remainder of this chapter, we use the terms "developing/developed" regions to distinguish parts of the world that are distinct from each other in terms of access to resources and so on, but in settling on these two terms (obviously related to Development) to discuss HCI4D, we are merely choosing the best tools that we have for the job of making this distinction. Like so many people working in this area, we have yet to find a way of talking about it that captures the nature of the exchange that we would like to foster.

Last, but certainly not least, it is important to be clear when we describe the main actors in HCI4D.

62.1.2.3 Practitioners

For the purposes of this chapter, "practitioners" are people working within industry. They may do applied research, innovation, design, and/or development. We will refer to their work as HCI4D projects, even though they may do research.

62.1.2.4 Researchers

For the purposes of this chapter, "researchers" are people who work and/or teach in academic settings (or quasi-academic settings such as Corporate Research Labs within companies). We will refer to their work as HCI4D research, even though they may also do design and/or development as part of their research.

As mentioned earlier, we are not explicitly differentiating people in NGOs, government, or other settings. They may work to develop policy or may oversee projects, whether done by researchers or by practitioners.

62.1.3 Related Disciplines

Like HCI, HCI4D has interdisciplinary roots. As Ho et al. (2009) pointed out, these make it challenging to get a complete picture of its history and literature, as well as to define the field from the different mindsets of some of the contributing subdisciplines. This is both a strength and a weakness. Because there are different perspectives, there is a potential for rich dialogue and for collaborative discussion of how to solve problems in holistic ways. This is potentially very powerful. But it is also complex, messy, and very challenging. It makes it very difficult to reach consensus on what is "in" and what is "out" of an area like HCI4D. The risk is always that the holistic and collaborative efforts to solve problems will not be realized in endless discussions of the definition of the area, disagreements about which methods are "best," and which world view is "right."

Most current HCI4D professionals come from a HCI background and are, therefore, aware of these interdisciplinary challenges since they are also present in HCI. However, the addition of Development adds a complexity beyond the challenges within HCI. Within the academic discipline of Development studies, there is a great deal of debate as to what exactly "Development" is and what is the "proper" frame of reference (Economic growth? Post-colonial? Marxist? To name a very few). These debates are deeply political and can be quite contentious. It is beyond the scope of this chapter to describe these in detail, but we would refer the interested reader to Ho et al (2009) for references to the relevant literature.

HCI4D is closely intertwined with Information and Communication Technology (ICT) for developing regions. While the debate on the utility of ICTs in developing countries has largely been won, the challenge of how best to use ICTs for poverty reduction remains (Avgerou and Walsham 2000). Although the link between economic growth and ICT has been established (Kraemer and Dedrick 2001; Jalava and Pohjola 2002), the exact process of how ICTs can be used for poverty reduction in developing countries needs exploration and is open to challenge. In particular, there are few if any theoretical explanations as to how ICTs can assist in building human capacity for poverty reduction in a developing country setting. A strong correlation exists between the access to education and knowledge and poverty indicators such as infant mortality, family size, and women's health (Marker, McNamara, and Wallace 2002). Other studies have also established a close link between poverty and an information gap of the poor (see, e.g., Humphrey 2006). ICT Development projects suffer from high project failure rates (United Nations Asian and Pacific Training Centre for Information and Communication Technology for Development 2010). Therefore, it is clear to us that there is a need for greater emphasis on participative processes of design, greater engagement with potential beneficiaries, and more in-depth and culturally relevant ways of making ICTs available, useful, and usable to a diverse population of people.

62.1.4 From Improving the Interface to Improving the World

Most of the HCI methods and processes described in this handbook are designed to be of service in the development of technology. The term HCI defines the interaction between people and machines and what they can do together, but not why they are interacting. We may have a goal beyond making better interfaces and better means of interaction or improving the interface may be that there is an end in itself, but the term HCI implies nothing about the technology that is being improved or for what reason.

A key difference in the work discussed here is that researchers and practitioners doing HCI4D are not just applying techniques to improve digital tools. They are looking beyond the effectiveness of the tool to the impact that it has on a society, most often in terms of the specific individuals, groups, and communities being studied. What distinguishes HCI4D work and makes it so interesting are these additional goals implying a purpose. If it is "for/4" Development, then it has social and moral intentions to change life in particular ways. Development is inherently and inevitably a political and moral activity—in other words, it involves ethics, values, and beliefs—as well as an economic one. The challenge for HCI4D as a field then is how to go beyond the International Standards Organization (ISO) notions of what constitutes a "successful" technology and incorporate some of the "success" criteria from work in the Development community. This involves more than simply adding a few new criteria from the Development literature to the checklists for evaluating our studies. Criteria for success will be different for different communities, and there may be cultural differences between communities that make it impossible to develop global standards. Finding new ways to describe what is a "successful project" increases the complexity of the questions we are asking and the time needed to understand what we need to achieve. It alters how we relate to the people who will use the technology and the methods we use to engage them in the design process. HCI4D projects can take differing forms, from studies of the appropriation of technology, which can inform future application development, to projects that are more interventionist in nature. But if we come in from outside a community to do HCI "for/4" Development, we are coming in to do more than explore what would constitute well-designed technology for our hosts. We are also assessing aspects of their lives and how this might be improved.

As Kleine and Unwin (2009) discussed in looking at the related field of ICT and Development (ICTD): "Rather than the 'and' of ICTD, the 'for' of ICT4D forces users of the term to confront the moral and political agendas associated with 'Development'." While HCI4D researchers are very knowledgeable about their research agenda, they may not have as good an understanding of Development studies and the associated subtleties of Development practice. If we take the "4" seriously, confronting "moral and political agendas" requires understanding of these issues. Ho et al. (2009) point to the serious responsibilities on HCI4D researchers:

> Thus the acronym "HCI4D," as our community has adopted it, carries a level of intent and purpose. As a community, we do not seek merely to understand how humans and computers interact in developing regions, but are concerned with applying this understanding to improve lives, livelihoods, and freedoms for people in these regions. (ibid)

In the majority of HCI4D projects, we work with local communities as equals, generating local capacity so that participation works, defining Development as a joint endeavor, or supporting existing local initiatives. In doing so, we indicate our interest and our responsibility in understanding the social and political agendas at work and the wider context in which our research is taking place. Therefore, our remit for research is broader and deeper than relating Development to economic growth alone. Development is associated with empowerment through the transforming power of technology and its related activities.

62.1.4.1 "D" in HCI4D

So, the "D" in HCI4D stands for Development, but even this is not straightforward. The tradition that Development grows out of is rooted in the idea that some parts of the world are more developed than others and that these areas have a responsibility to address the gap. It is not altogether distinct from the system of beliefs that allowed parts of Europe to run all over Africa, Asia, and the Americas, ostensibly bringing "civilization" to the world, and the United States ostensibly bringing "peace" by doing so more recently in Vietnam, Afghanistan, and Iraq. Meanwhile, the blatant self-interest of much of that history has left its legacy in the economic conditions in many "developing" countries, where production and trade arrangements benefitted those imposing the terms. This colonial past hangs on in the terminology "developing" and also in some of the attitudes to be found in the field, often much to the indignation of people receiving aid. Many practitioners from "developing" countries have argued that Development too often involves remote and powerful decision makers imposing their idea of what is best on other people and places, often on the basis of very limited information. The World Health Organization talks about *Development cooperation* to throw attention on the collaborative nature of all aid activities and the need for a partnership between donor and recipient. Proponents of participatory Development strategies such as Participatory Action Research (Fals-Borda 1987) and Participatory Rural (or urban) Appraisal (Chambers 1994) aim to enable marginalized people to give voice to their concerns, to participate in decisions that affect them, and to exercise their rights.

An underreported but important side-effect of Development cooperation is that researchers and practitioners in the field learn from the people they are working with. Most often, it is not a case of pouring knowledge into communities, even when many resources come from outside. People have been solving problems successfully using the resources available to them for thousands of years. Local knowledge, skills, and history are imperative to understand patterns that will influence a Development project as well as provide sustainable solutions to problems. In developing these solutions, the external researchers and practitioners gain knowledge and experience that they would not have otherwise, and this knowledge can be used to solve problems in other settings also.

62.1.4.2 Little More on the History of Development to Put HCI4D in Context

The idea of Development as a policy goal can be traced to the inaugural speech of American President Truman in 1949. The vision he declared was of, "…making the benefits of our scientific advances and industrial progress available for the improvement and growth of underdeveloped areas." This has been interpreted as the United States' response to the segregation that accompanied the Cold War and a move to limit the threat of Communism (Truman 1949).

At that time, Development was widely interpreted in terms of increasing nations' economic output. However, this view is now widely recognized as inadequate for a range of reasons. First, it assumes that increasing average incomes will benefit all the population, whereas huge inequalities may not be addressed. Second, it assumes that increasing economic production and consumption is a fundamental good in itself, whereas it often has damaging environmental impacts and might be achieved in the context of extremely repressive regimes. Third, it frames Development of a process of making "underdeveloped" areas more like the "developed world," implying that the way of life in these "developed" countries represents the "best of all possible worlds."

In contrast, the concept of "sustainable Development," upon which much HCI4D work is more or less implicitly based, draws attention to the need to consider the whole technical, financial, social, and environmental "ecosystem" in which a Development initiative is sited. Sustainable Development is in part a response to the failure of projects where technical equipment was given by government donors (or often purchased on the basis of a long-term loan). When the equipment requires maintenance, or parts need replacing, the recipients do not have the skills, the infrastructure, or the currency to solve the problem. The Sustainable Livelihoods framework (Department for International Development 1999) is a widely used framework that reflects this perspective. One dimension of sustainable Development is a concern with "capacity building," which concentrates on developing the skills and capabilities to sustain external initiatives after initial funding is withdrawn. Another approach is "capacity centric," which focuses on sustaining initiatives with funding that builds on those capacities that are present in the community or on finding solutions that capitalizes on the communities' existing capabilities.

A recent interpretation of Development that is gaining much support in the new millennium was articulated by economist Amartya Sen. His book *Development as Freedom* (1999) provides an introduction to this so-called capabilities approach. Sen argues that Development should result in people having greater freedom to make and act on choices about the kind of life they want to live. Of course, lack of finance is one limitation on people's freedom, but there are many others. Sen discusses the importance of other liberating factors such as political freedoms (such as freedom of speech and democratic governance), social opportunities (such as education and social mobility), guarantees of transparency (from agents of government and other wielders of power), protective security (health care and other social safety nets), and the economic freedom in the form of opportunities and abilities to earn or create a livelihood. The creation of the Human Development Index (HDI) by Haq in the 1990s (Haq 1995) shifted metrics from national income to people-centered policies [23]. The HDI is a measure of life expectancy at birth, adult literacy, combined gross enrollment in education, and gross domestic product per capita. The underlying conceptual framework was inspired by Sen's capabilities model.

Another key influence on HCI4D was the creation of the agenda-setting Millennium Development Goals for the turn of the millennium. In the late 1990s, in part as a result of Development" loans and the fact that only a handful of "developed" countries had met their promise at the UN to raise aid to 0.7% of their GDP, critics pointed out that many countries in the "developing" world were paying more back to the developed world in interest on past loans than they were receiving in aid from donors. International campaigns such as Jubilee 2000 exerted significant pressure on political leaders to act (Carrasco, McClellan, and Ro 2007). The Millennium Development Goals agreed at the UN set out eight specific targets that the world aimed to achieve by 2015 (UNDP 2010). The targets focus on poverty and hunger, education, gender equality, child mortality, maternal mortality, HIV/AIDS, environmental sustainability, and building a global partnership for Development. This framing of Development provides a broader vision of Development that focuses on many features that are important for quality of life.

The recent growth of ICT4D can be traced to the 1998 World Development report, which highlighted the role of information, knowledge, and ICTs in Development (Heeks 2009). The G8 Digital Opportunities Task Force in 2000 set up an agenda for action on ICT4D. Following which, the World Summits on the Information Society was held in Geneva in 2003 and Tunis in 2005. Heeks describes a shift in ICTD from late 1990s-early 2000s to the late 2000s model of ICTD 2.0, marked by a shift in goals from realizing Millennium Development Goals to social Development and growth (Heeks 2009). He also notes a significant departure from the telecenter/Personal Computer approach to mobile phone-based solutions. Moreover, Heeks identifies a shift in key Development actors, from philanthropic organizations and donors funding NGOs to "South-based" funding from governments and private players.

62.2 CHALLENGES

HCI4D takes a user-centered approach to both design and Development. The role people from the local communities play is key and may include co-designing, using software in context, co-evaluating the project, and/or reflecting on their own role in the process. Good HCI (in research and in practice) requires an understanding of context and users, iterative design, opportunities for testing and evaluation, and ultimately uptake and application of technologies. UCD always requires that we are keenly aware of not only our participants and their context but also of differences between our own expectations and assumptions and those of our participants. The cultural diversity of “developing” societies has important implications as far as UCD is concerned. For example, under normal circumstances in “developed” regions, user and task analysis techniques offered by HCI provide adequate information about users and their work. However, these techniques are inadequate when a large number of cultural variables must be factored in. To cope with cultural diversity and still ensure optimum performance, a designer needs to know about a much wider and variable range of factors that will affect a person’s work and social behavior. This implies that the emerging HCI practitioner cannot function effectively without including ethnographic techniques.

62.2.1 Local Conditions

Local realities in the “developing” world pose particular challenges that HCI researchers in “developed” regions do not typically face. These can include massive poverty, weak social capital, significant inequality of access, power, and wealth, and weak governance and resulting corruption. Legal structures after often very different from those encountered in “developed” contexts, as are local economic and regulatory environments. The political, economic, and international climate can introduce instability and even danger. While many sustainability issues are relevant in both developed and emerging economies, the way they play out with respect to the users frequently differs.

These same local characteristics manifest in problems with infrastructure that can affect working conditions for local people and the practitioner/researcher. For instance, electricity is often limited or absent, even in urban areas, at certain times of the day or year. Communications can be extremely difficult, and ubiquitous cell phone service is often not available, although it is improving in most geographies. Transportation infrastructures are often variable and can range from quite good to quite bad in the same country at different times of the year and/or in different regions.

In light of these systemic differences, it is not surprising that users and their context typically differ from the people who HCI professionals encounter in “developed” regions. They may lack skills often taken for granted, such as reading, writing, and/or counting in their primary language, although they may be able to speak fluently in multiple languages. They typically lack physical access to technology and, therefore, may have very different experience with and skills to use technology. When technology does exist, it is often shared or may be used in a “mediated” way, where one more technically “savvy” person handles technical use by others with less experience. Technology that may be available may not be the most appropriate—for instance, some parts of “developing” regions are “dumping grounds” for older technology from more “developed” regions and/or locally relevant applications may not be available.

Users’ expectations can be very high—because of a belief in the transformative power of technology—or very low as a result of experience with or exposure to previous technology failures. Similarly, trust in technology can fluctuate widely depending on previous experience and on-the-ground realities.

Therefore, when working with communities in “developing” regions, researchers and practitioners must pay particular attention to the ways in which these local conditions can influence their own work. While some of these factors are similar in any setting, others can be intensified or magnified by the challenges of infrastructure and user characteristics, making it particularly important for the HCI4D researcher/practitioner to deal with them proactively whenever working in contexts that are significantly different from their own. The risk of misunderstandings, assuming too much, and starting from an irreconcilable position exists in virtually any cross-cultural work, but especially when work takes place across a developmental “divide.”

62.2.2 Impetus for Development Work

It is important that we, as researchers and practitioners, examine our comportment, processes, and intentions carefully before undertaking this kind of work. The sensitivities mentioned earlier throw a spotlight on our practices and increase the potential for misunderstanding. There are two key elements to starting out: we need a clear idea of what we are hoping to offer and to gain and we need to understand ourselves well enough that whatever happens in the field, we can respond with flexibility and integrity. In this context, understanding oneself goes beyond the individual and extends to a person’s capacity to understand the place and a way of life they represent. If we are working for a famous corporation, we are often seen as its emissary even if we do not feel like we are important in that corporation. If we hail from somewhere known to be a rich country, although we may not feel affluent, we have to understand that we may be perceived that way. We may come from a country that used to run the administration in the place we are visiting. It may make us seem authoritative even though we wish to be seen as open to ideas.

Nonetheless, it is critical to any design intervention to elicit the local idea of Development—what does the target community consider as empowerment or progress? Juxtaposing these perspectives, that is, the local idea of Development with that of the researcher’s, leads to interesting and useful tensions.

One key difference in outlook is likely to be over how participants in the work see the benefit of being involved.

Local people who become involved in researching or trialing an idea may expect the concept to be developed fully and brought back for use. But, in academia, there is often no intention to see the object of the research into a product through to the point where is it useful to the people with whom it is being researched. And in industry, any products that are inspired from the research are not likely to appear for several years.

Part of understanding what we have to offer and to gain involves understanding and being clear about the benefits that will come from conducting our work successfully in the field. Quite often, there is no immediate benefit to the group who is helping us with our work, despite the long-term potential of our learning. For us, on the other hand, there may be a series of professional accolades: As researchers, we may be able to generate publishable research findings and disseminate our work. As practitioners, we may be able to capitalize on our discoveries by launching new products or opening new markets. The learning may pass from the department that is seeking to understand and design for the communities involved to the people who are wondering whether there is a way of commercializing the learning. Therefore, we have to recognize the potential for repeating a pattern of exploitation. A careful consideration of how a local community will benefit from our research needs to be made. Since HCI4D has the social and moral intention to improve lives of people, each project should be designed in such a way that it yields immediate benefits regardless of its long-term potential benefits. For example, research carried out by Sukumaran et al. (2010) concerned the evaluation of the role of intermediaries between information from a computer and the subsistence farmer who required information. The research was carried in rural India in a remote region of substance farming. Since there was no immediate benefit for members from the local community to participate, the researchers designed the experiment around a service to have the farmers' soil analyzed and subsequently inform the farmers about what types of fertilizer would be best for the crops they intended to grow. Even though this is a very particular example, it illustrates that it is possible to ensure that local communities always benefit from participating in research.

Like any project, at least part of the true benefit of HCI4D work is expected to be realized in the future, when the innovative ideas developed during the project are implemented and scaled. To expect or strive for immediate outcomes would be a misallocation of effort—understanding, experimentation, analysis, and innovation are important despite the seemingly much more pressing needs on the ground. But certain ethical questions are particularly important to pose, especially as we grow our understanding of HCI4D and what this entails. Norms are still being established. Seeing that they develop with continual and deliberate consideration of the intended beneficiaries is an important responsibility of this emerging field. Are we taking more than we leave? Have we respected the priorities found in the field? Are we representing the interests that we found fairly to the rest of the world? The answers to these questions determine the extent to which the incentives of HCI4D align with the ultimate goal of improving the lot of the world's poorest people.

For those who are not in the academic community, the question of motivation may seem to be moot. After all, practitioners are often working in the context of an organization/company, which is interested in expanding a market, and understanding people in that new market is a critical step in that process. However, these HCI4D practitioners often find themselves in situations where what they learn "on the ground" is radically different from what they or their company had expected and where they have to find ways to bridge between their organizations' goals and what they discover. And no one is exempt from considering how the expectations of the local participants on the ground marry up with those of the incoming team and managing those expectations appropriately.

62.2.3 Collaborative Work with Partners and Informants

HCI4D is concerned with the interests of people in some particular location even if there are many different locations in a project. Here we talk about ways of thinking and acting that deal with those local details. If the project involves multiple sites, it will be sensitivity to these details that makes each location study valuable and useful. For instance, Light and Anderson (2009) focus on differences in context and process between rural Chile and rural India in discussing how to develop a global tool for supporting micro-enterprises. But, whether single or multi-sited, the people involved may come from diverse sources and that in and of itself creates interesting dynamics. Even a single study located in one spot may involve partner agencies at that location; it may include people based at another location in the same country; it may include people from other countries who live locally for a few months or years; and/or people whose home is outside the country who perhaps visit occasionally or not at all.

A team of international researchers and practitioners may represent a relatively expensive resource within a project, especially if their work includes a lot of international travel. Models of research and practice that maximize local contributions may be preferable. However, it is not always the case that international collaboration is a negative for an HCI4D effort. International colleagues sometimes add credibility to a project and local contributors can gain status from working with them. In addition, the very real cross-cultural perspectives that all team members bring in to such situations are extremely powerful, especially when consciously used in integrative ways.

One mistake that is easily avoided is to assume that HCI specialists working in research institutions or major corporations based in the country in which you are working will know all about the conditions in other areas of their own country. They may, if they have been working there, but they may never have explored these aspects closely. (Many of us have done little Development-style research in areas of urban or rural deprivation in our own land. We would have to learn about the distinct qualities that make these places what they are.) Social divides may be even greater in "developing" countries, where access to education is more patchy and economic distribution more extreme. So, while a project team with local staff is valuable for the shared learning, capacity building, and more, it cannot be assumed that the people in a university working on HCI know the same as people in the NGO down the road just because they are all from one area and project partners need to be assembled with this in mind.

Teams engaged in HCI4D may face competition between the goals of capacity building, reliability of research, or the quality of design and engineering. As always, there are tradeoffs to be weighed. Having researchers from local universities participate in the work and/or involving local software developers to contribute can aid capacity building but may involve working with larger numbers of less experienced people, requiring a different skill set than is needed in HCI practice or research in other settings. This could also affect the reliability of the research or the quality of design and engineering. On the other hand, such capacity building may contribute to sustainability and have long-term impacts on future Development in the region.

Choices about decision-making authority, responsibility for different aspects of the work, budgets, and how accountability will be distributed between the different stakeholders, including the accountability of the project team to the community, will have a major impact on all the different quality dimensions of the work. A strong, experienced community-based organization (CBO) or NGO may be able to ensure that potential risks of harm to community interests are minimized and benefits maximized.

Being in both an international and interdisciplinary field, HCI4D researchers may find themselves looking for design opportunities in a completely foreign context and domain. Therefore, considerable effort must be put into familiarizing themselves in the new space before beginning the iterative design process. This can include multiple rounds of field work using methodologies like contextual inquiry, qualitative interviews, surveys, field observations, etc. A common strategy is for a researcher to work closely with a grassroots NGO or CBO. The staff at such organizations usually have years of field experience and are very familiar with the daily lives and practices of intended users of any innovation. They can serve as local informants, as well as facilitate meetings, interviews, and observations, enabling an insider role for the researcher. A caveat to this, however, is that if researchers are perceived as associates of the partner organization, they might inherit any negative traits as well. In addition, it is important for the researchers to learn to differentiate opinions of the organization from those of their target users as well, which can be done through triangulation with multiple sources.

Some researchers take the approach of designing a solution that directly aids the partner organization. For example, a researcher might design a tool to simplify an NGO's process of health data collection and analysis and study how this improves the NGO's ability to pinpoint and address health problems in the field. Focusing on strengthening the capacity of an NGO can help ensure that human resources will be available to sustain the use of the technology. However, the flip side is that technologies might end up catering too specifically to the needs of one particular organization, making the result difficult to replicate in other places. Therefore, some researchers engage with a partner NGO mostly as a means of entry into a village, but then work directly with people in the community or village to identify more scalable solutions to widely prevalent problems. For example, the researcher might design a way for villagers across a nation to share video messages about political issues with one another, as well as with higher government authorities.

Researchers from outside the village coming into a village often find themselves in a position in which the villagers attempt to give the answer which they hope will please the researcher the most. This is especially the case with researchers possessing technology (Cheng, Ernesto, and Truong 2008). However, this also holds true in general, and in some cultures it will be considered impolite to say no to the guest (Anokwa et al. 2009). So, it is not unusual for an interviewee to hide their opinion to provide more *socially acceptable* responses. Simply showing up in a village in a car can give off the impression that the researcher has strong political or financial power, influencing the dynamic between the researcher and village residents. The presence of technology gadgets often draws a lot of excitement and interest initially, but one must keep in mind that it might eventually wear off. Many of these challenges can be overcome if the researcher spends extensive time in the field with the mindset of making friends, rather than recruiting subjects. The more the researchers can adapt to conditions in the field, by sitting and sleeping on the floor, eating the same food, or traveling by foot rather than by car, the less "foreign" he or she becomes. While all this takes time, it can make interactions more meaningful and informative.

62.2.4 Internal Conflicts

It is frequently necessary to collaborate with one or more partnering organizations or departments to conduct HCI4D research. These different groups often have very different goals and methods. It is rarely the case, for instance, that an aid-based organization has the same goals, time scale, or budget as the researcher. It is incumbent upon the researcher to listen to and accommodate the needs of the partnering organization(s); however, it is also important to select the appropriate organization(s) based on the researcher's own requirements.

Anokwa et al. (2009) relate a number of stories in which partners are disappointed by broken promises, suggesting from experience that it is important to manage expectations effectively. How does one decide who to design with and what impact to have? Light and Anderson (2009) talk about the shifting sands that beset the research team that has money and motivation but whose outcomes will be largely determined by which set of stakeholders will be involved in the study. How do you choose whose agenda to prioritize or which subset of potential beneficiaries to involve as informants to the design process? Clearly, these questions can be resolved where there is enough time budgeted for a thorough investigation of the wider socio-technical context, but the diversity of issues to consider often makes this a lengthy consultation and deliberation process.

HCI4D industrial projects have a different set of internal conflicts. Practitioners are often well versed in negotiating priorities for research and projects with different groups within their organization, reflecting the different needs and requirements of different functions. However, this becomes particularly important when an HCI4D project is being conducted to understand a new market or region. Unlike other projects, international projects often face the tendency to overload the research with many diverse agendas in the interest of "getting the most" out of the research investment. This risk is greatly heightened with HCI4D projects, especially when they are a company's first experience with a new region. It is critical to negotiate the priorities carefully and to be very clear on what "success" would look like.

In summary, there are a diverse set of people to manage in HCI4D contexts and a greater number of perspectives, but good leadership and management practices still apply. Where there are conflicts, some means of resolution is necessary and, though the mechanism may vary according to the situation (and there will be cultural differences in the acceptability of a more decisive vs. participative approach, for instance), patience, attention to detail, and respect for the reasons that viewpoints differ have and will make these circumstances into opportunities for learning and deeper working relationships.

62.2.5 Scoping

The scope of HCI4D projects needs to be carefully defined, since their viability is often limited by funding and/or by time. HCI4D often involves situations where the scale of the challenge is immense and the budget of time, money, and person power insubstantial in comparison. Can poverty alleviation in an urban slum be actualized by tracing the problem to a single root cause, such as unemployment (hence, job generation as a solution)? Or, is it related to broader issues, such as overpopulation, lack of education, and social inequalities? Establishing causal relationships may help in defining scope for design, possibly creating positive impact. Defining the time frame of the project also helps in designing relevant solutions. Projects need to be designed with sustainability—cultural, environmental, and economic—in mind. Development often involves working with several parties, such as NGOs and donor agencies. Contemplating the future of the project when the designer leaves the field is crucial in the solution design and should be considered from the start.

For example, a project by Sambasivan et al. in an urban slum, the high rate of alcohol abuse was disturbing—women were harassed by their husbands on an everyday basis and family budgets were significantly reduced by alcohol expenses (Sambasivan, Cutrell, and Toyama 2010). The researchers were tempted to create a design intervention to counter domestic violence. However, they felt they were ill-equipped to address a deep socio-cultural issue in their short-term intervention, possibly at the risk of exacerbating existing arrangements without understanding cultural mechanisms. They, therefore, focused their attention on healthcare and education—two important and relevant Developmental areas that generated positive responses and avoided a serious, controversial issue. The ambitions of the project matched the resources.*

62.2.6 Environmental Constraints

More than usual, HCI4D projects take place in a context that offers real restraints to design solutions. Several practical factors affect what is possible in designing and in terms of what we design, such as designing amidst disruptions, cost constraints, recourse constraints, heterogeneous illiteracies (textual, numeric, and symbolic), and communal norms (Spicker no date).

In most developing countries, a divide exists between the technological "haves" and "have nots." Most users in developing countries have access to only very specific technologies such as radio, television, and mobile phones. There may be a sharp urban/rural divide, with slums and shanty towns flanking the more affluent parts of a town or city. Each area will have very different social protocols, access to resources, and expectations. For instance, rural areas in the "developing" world, especially those defined as "deep rural," often experience the following realities:

- Literacy is low, especially among women, and female participation in the public sphere is limited.
- Settlements are scattered spatially and for many residents quality healthcare, agriculture information, and formal education are out of reach or expensive to access.
- Distances to services and facilities are long and often roads are poor and severely affected during rainy seasons.
- Transport services are infrequent in places, which further constrains the accessibility of local residents.

These conditions severely limit the ability of residents to access basic services, social infrastructure and support, attain higher education, or have regular social interaction (social networks) to name a few.

* It is worth bearing in mind too that domestic violence has been seen to increase as a result of certain kinds of take-up associated with ICT use, such as women successfully running their own phone companies (Bantebya Kyomuhendo 2009). While not every eventuality can be anticipated or planned for, thinking about the potential implications of different kinds of intervention allows us to conduct work that has a meaningful outcome for all concerned and avoids leaving a legacy of distrust or destabilization when we depart.

However, such challenges can provide fertile stimuli for innovation in design. In their work on rural microfinance services, Parikh and Lazowska (2006) designed architecture ["CAM"] for mobile phones that would improve efficiency by decreasing the time taken between transporting paper documents between self-help groups and regional offices and decrease error rates in documentation. The CAM framework operates locally on mobile phones, capturing bar codes using the phone camera. It supports existing paper-based interactions familiar to the microfinance operators and minimal navigation, being suited to infrastructural and user constraints. Medhi et al. (2006, 2008) created text-free user interfaces for non-literate users, which included semi-abstracted hand-drawn images for easy comprehension and audio prompts for constant help.

62.3 PRACTICAL GUIDANCE IN GETTING STARTED ON AN HCI4D RESEARCH PROJECT

62.3.1 Before Commencing Fieldwork

As mentioned earlier, the cross-cultural collaboration literature is replete with vital information that should inform HCI4D research and projects. See Anokwa et al. (2009) for more comprehensive coverage.

The effort expended in the early parts of a project on establishing mutual respect and trust between researchers and the local community can be critical (International Development Research Centre 2005). To build trust, early communication has to be a two-way process. Researchers need to listen carefully to understand community concerns and priorities and not simply focus on their external project goals. This demands attention to cultural and nonverbal cues, which may be unfamiliar. It may be valuable at this stage to attend events and meetings organized by the community or by project partners. Acting as a helpful outsider with a willingness to assist others in reaching their goals can also help establish the researchers' credentials as co-operative partners. Only when such trusting relationships are established will it be possible for an external researcher to obtain genuinely valid feedback and data from research participants or to effectively facilitate the identification of problems and priorities. As with any project, the relationships between researchers and other stakeholders will require continuous attention throughout the project.

Following the initial relationship-building phase, projects should define a clear agreement between the organizational partners that clarifies what their different roles will be. The form of such agreements may depend on the capabilities and customs of the collaborating organizations. It may be a Memorandum of Understanding (MoU), a more formal Project Initiation Document, or in a few cases, it could even be a legally binding contract. The point of developing such a document is not that the research group will seek to impose the contract terms. However, the activity of discussing such a document ensures that key issues are made explicit and agreed at an early stage and that project partners integrate the project into their own set of priorities. Key issues include how the activities will be funded, what responsibilities each party has to ensure for the sustainability of any intervention, and how the ethical conduct of research will be monitored and ensured. An additional benefit of such a document is that it can be used as a reference during later project planning and can be particularly useful if there are changes to key staff in the project partner organization. The MoU can then be used to brief new staff to ensure continuity of support. Being sensitive to local cultures and customs of showing commitment will improve relationships with local communities involved. For instance, in some cultural settings, it may be valuable for a senior member of the team to visit the project during this initiation phase to demonstrate the commitment of the "hidden" external partner.

After this, as with other field research, there is usually an introductory session to formally kick off the project's research stage. Often this is a good moment to set expectations of each other and mitigate misinterpretations. Honesty and humility can go a long way in establishing transparency and trust. Inherently, there may be power differences between the researchers and study participants (social class, income, language, skin color, and so on). As standard field practice, it helps to level difference by wearing traditional clothes, sharing meals or sweetmeats, sitting on the floor, or adopting other culturally relevant norms, and above all, revealing genuine concern (Sambasivan et al. 2009). For instance, it may also be appropriate to provide informants with gifts—usually utilitarian ones such as talk time top-ups, utensils, or bed spreads, or symbolic ones, such as certificates of training, photo prints, or sweets. Placement of gift-giving is important so as not to affect responses dramatically. Gifts should be proportional to local incomes (Sambasivan et al. 2009).

62.3.2 Agreeing on Ownership and Responsibility

Another issue to consider early and begin to discuss with other partners is the answer to the question "what is going to happen when the money runs out?" Most academic research is funded for a limited time, and the end of the funded period needs to be a consideration in all major decisions. External academic HCI4D researchers should plan carefully for their withdrawal. This planning should influence research design decisions, as the sustainability of any system after funding is withdrawn will be dependent on the capabilities that are already available or have been developed locally during the project.

Key questions to consider are the following:

- Who within the community or organization will own or control any equipment when the project comes to an end?
- Who will manage any services?
- How will equipment and software be maintained or replaced when required?

- What relationship will the HCI4D researcher/practitioner maintain with the community or organization?
- How will the transition and handover be managed?
- How might the level of support be "tapered" so that the community or organization has time to learn to manage without external support?
- What other resources (local or external) might help to support the work?

62.3.3 Planning to Evaluate Research Results

The other thing that is best considered at outset is evaluation. Evaluating the outcomes of any Development activity is always complex for various reasons. Key challenges lie in the possibility that successful Development involves dynamic social change, so that situations may be changing during the evaluation period; that data capture may be complicated by the social, cultural, and language distinctions between external evaluators and project participants; that ethical considerations may rule out certain forms of data capture and analysis; and that Development involves multiple stakeholders each with legitimate, but different, evaluation criteria.

In this situation it is important that evaluation (and more generally project monitoring) are discussed and continuously reviewed from the earliest planning phases of the project. Many major donors provide useful guides to different approaches to monitoring and evaluation (see, e.g., World Bank 2004; Kasturiaracchi et al. 2009).

Evaluation of HCI4D-related issues needs to be contextualized within the broader context of the community's goals and the agreed concept of Development operating in the project. The link between observable interaction activities and Development project outcomes is rarely (if ever) straightforward. HCI4D evaluators may face choices between evaluating attributes that are easy to measure, but may have little direct relation to Development outcomes (e.g., ease of use or ease of learning of a technology), and attempting to evaluate complex impacts on Development goals, which may be less easily attributable to the specific HCI decisions. These choices are then added to the usual concerns for internal, external, and ecological validity. Typically, a mix of different evaluation questions posed at different levels will be necessary. Thus, it is vital that questions of what to evaluate, how to evaluate, and planning towards such evaluation are addressed at the very beginning of projects and subject to constant review.

62.3.4 Doing Research and Projects

HCI4D Researchers and practitioners working in developing regions sometimes find it difficult to use traditional HCI methodologies. Indeed, many early HCI4D studies focus on appropriate methodologies for developing regions, rather than novel designs or implications for design. However, as mentioned earlier, methodological challenges are not unique to work in developing regions—it is clear that many challenges arise from the fact that researchers are working in cross-cultural contexts and in an interdisciplinary field. Challenges more specific to HCI4D research include language and localization barriers, societal barriers (e.g., political institutions, governments), potentially low prior exposure to technology/training, control over participant selection, and geographical limitations.

It is important to be able to communicate with key informants, whether the researcher or practitioner is performing experiments, observing behaviors, or conducting interviews. Some researchers spend time in formal language training prior to working in a particular country, as a means of overcoming language and localization barriers but, while this might be desirable, it is almost never practical for researchers working in multiple countries, or in countries with many spoken and written languages, or for most researchers in industry. Workarounds include working with populations that speak English (generally more wealthy, educated) or working with and through translators. However, even with translators or English speakers, it is necessary to be careful with interview instrument construction and with preparing the translators. Interview questions must also be constructed carefully from the cross-cultural and cross-technical context: often concepts used in HCI projects like "information" or "data" are not well understood, and particular phrases or gestures may carry different meanings in different contexts. For more unstructured fieldwork, it is important to spend time with translators to make sure they deeply understand the purpose of the research as well as the specific terms or concepts that are important to probe on or observe. Well-trained translators are vital members of the team and can become very adept at noticing subtleties that might otherwise remain hidden.

Often, we are also unable to carry out our research or projects in the manner we expect due to expectations or limitations of the society in which we are working. Anokwa et al. (2009) note experiences in which it is necessary to ask the government for permission before conducting research or projects in a particular country. Braa, Ola Hodne, Johan (2004) also describe how participatory methods are less effective in Cuba than in South Africa. In some countries for instance, it is not appropriate for a man to interview women or vice versa. International team members are often judged by a different set of rules than local team members. Therefore, in some locales, an international woman could interview a local man without violating cultural norms, but a local woman could not. In other places, the social class, ethnic group, or caste of the local team members can open (or close) doors for the team. International team members may make it easier (or harder) for the team to get access to the "right" participants. It is very important to be aware of these kinds of factors that can impact our projects and research, to plan accordingly, and to monitor the situation for possible impacts: being ready to make changes as appropriate to gather the best information we can in order to have the best impact.

In remote and technologically disadvantaged areas, technology poses a constantly changing general methodological challenge. From the researcher perspective, working in villages with no or unreliable electricity makes it hard to depend on audio recorders and digital cameras. It is necessary to carry lots of backup batteries, data cards, and even solar chargers. Introducing users to new designs or new devices also poses issues. Because of low prior exposure to technology, more time must be allocated to training and familiarization, and the impact of the novelty of the technology is important to factor in.

Geography plays a strong role in the typical HCI4D study, since it is hard to return to the investigation site, 2- to 4-week trips are the norm, limiting the depth of human observation to relatively short-term studies. In some cases, researchers are able to return to the same sites multiple times or to stay for longer periods. In these cases, results from earlier co-design or iterative Development cycles are redeployed over multiple trips, with development occurring between experiments. Although time consuming, these types of studies seem to have mixed but generally informative success (Ramachandran et al. 2010a; Luk 2009).

HCI4D practitioners are often even more seriously constrained time-wise than academic researchers. Trips are rarely more than 2 weeks per country and often focus on more urban populations because rural visits are harder to arrange and travel to. Therefore, practitioners more often focus on spending a relatively short time (up to 1 day) with a number of people individually or in naturally occurring groups such as families, communities, or groups of friends. This typically precludes developing the kinds of personal relationships with participants that academic researchers may be able to form. However, this is not altogether a hindrance. It is possible to collect rich information when working closely with local researchers and a team that includes community members and helps identify critical issues in the context of that specific locale. Such a cross-cultural team is particularly critical in this type of focused industrial research and can provide far more nuanced, robust, and useful insights than any monocultural team can hope for. “Insider” and “outsider” participants both bring significant perspectives.

62.4 CASE STUDIES

The challenges in preparing for HCI4D projects, in identifying and assuring commitment from partners, involving local knowledge and communities, distributing and sharing responsibilities, setting goals and expectations, carrying out the research, measuring success, and capitalizing on local culture are each highlighted in the following six case studies. The case studies cover different types of HCI4D projects, in a variety of international cultural settings, and report different problems and solutions. Together, they offer a set of possible approaches toward successful HCI4D.

62.4.1 First Days Project Case Study

(Divya Ramachandran)

62.4.1.1 Overview

Across developing regions, women are still dying due to preventable complications in pregnancy and childbirth, a problem almost entirely eradicated in the industrialized world. The First Days project aims to address an aspect of this issue by providing a method for delivering clear, persuasive messages about pregnancy and delivery care for mothers-to-be. Specifically, the project targets rural health workers and helps them to establish credibility in their communities as health resources, empowering them to effectively convince pregnant women and their families to use maternal health services despite conflicts with traditional customs. The First Days project is being carried out in the state of Orissa in eastern India. Orissa is typical of a number of economically disadvantaged states in India, which struggle with health outcomes in spite of a number of government and non-government health efforts.

To improve maternal health in India, the central government has established a National Rural Health Mission, which employs one woman from each village to serve as an Accredited Social Health Activist or ASHA. ASHAs are charged with promoting free government health services (like subsidies for institutional deliveries, immunizations, and prenatal care) and providing counseling on pregnancy care, family planning, breastfeeding, and so on. In over 2 years of qualitative research with ASHAs, pregnant women, their families, and other key community players, we learned that ASHAs are employed in most rural villages in India but their training, effectiveness, and acceptance within the village is still minimal. Traditional beliefs and rigid social structures limit the change that they promote.

62.4.1.2 Understanding Needs

We identified a number of barriers to information uptake and dissemination in the communities. First, the structure for continuing education of ASHAs does not support the acquisition of new knowledge and information. ASHAs attend a monthly sector meeting where they are trained on one new topic each time. In a particular meeting we attended, roughly half of the ASHAs employed in the sector were present. Moreover, the teaching method (formal lectures on a general topic) was not conducive to the ASHAs’ education level and schooling experience. Experienced trainers of health workers from successful NGOs suggest that rather than formal lectures, ASHAs would benefit more from information that is relevant to specific situations that their clients are in as well as instructions on how to effectively share this information with their clients. Second, we found that ASHAs had not received training in maintaining an effective work routine. For instance, client monitoring and counseling were aspects unfamiliar to the ASHAs. As a result, the local community did not find the ASHAs’ valuable resources and the limited information they could offer was rarely accepted.

Given these challenges faced by ASHAs, we concluded that they could be empowered by more effective tools to share health information with their clients. Considering the educational, language, and cultural barriers they needed to overcome, videos on mobile phones would be a valuable tool to communicate to clients what they needed to do in specific health-related situations. The mobile phone platform was portable, prevalent, and appropriate for ad hoc counseling visits to clients and their families. We felt videos could convey information comprehensively and consistently in an engaging way for low-literate audiences. Furthermore, as ASHAs shared videos with their clients, they themselves would have the opportunity to learn both factual information and effective counseling techniques over time.

We created two types of videos: testimonial and persuasive (Ramachandran et al. 2010a). Testimonial videos provided social proof of the ASHA's role and importance. We trained ASHAs to record videos using their cell phones and asked them to record messages from influential individuals in their own villages. Their videos featured village leaders, pregnant clients, and even street plays addressing topics including endorsements of the ASHA's role and importance, their own personal health experiences, and instructional messages. These videos provided persuasive social proof to clients that other villagers believed and followed the messages promoted by ASHAs. Persuasive videos were designed as short informative segments about pregnancy-related health issues, which we selected based on prevalence in the target communities. We identified relevant content from health handbooks (such as Hesperian Press publications) and adapted these to health advice in line with local resources and cultural practices with the help of local nurses. A local artist sketched some basic illustrations for the content, and we asked staff at our partner NGO to record voiceovers. We strung each video together with panning and zooming to give it an animated feel. Each video lasted between 30 seconds and 1 minute.

We deployed these videos with seven ASHAs for 2 months and we observed ASHAs using these videos on house visits. Our initial observation was that the mobile videos provided ASHAs with a concrete example of the information that needed to be brought across to the client and thus helped them understand what to accomplish during house visits. We also observed an increase in knowledge and self-efficacy by ASHAs. However, ASHAs had to be trained extensively to use the videos. For instance, we encouraged them to pause the videos, discuss the topics depicted, and engage their clients in conversations about the videos. However, during our observations, we did not find that all ASHAs adopted the technique of engaging their clients by pausing the video at relevant moments and asking related questions to their clients spontaneously. We had to provide explicit training about how to use the videos in this way to ensure the videos were regularly used by the ASHAs, and the effectiveness of the videos depended largely on each individual ASHA's ability to grasp this task of pausing and discussion. Therefore, the videos did not seem to ensure any consistency in the quality of counseling. This experience spurred us to create a second version of the videos with two important differences. The new version had a built-in dialogue to facilitate client engagement regardless of whether the ASHA was comfortable with this counseling style. The background voiceover asked questions that required yes/no input; the videos automatically paused at these points to facilitate responses and discussion. The second innovation was the use of persuasive message architecture. We identified prevalent myths and barriers that stopped women from performing particular behaviors and addressed these directly by providing corrections and solutions, respectively. For example, anemia is a serious problem among rural women and is the direct cause of one-fifth of all maternal deaths. ASHAs distribute free iron tablets to all pregnant women, but many women believe that taking these tablets causes the baby to get too big to deliver normally. A typical lecture-style video modeled off of textual information might present an explanation of iron-deficiency and the risks of anemia and then suggest some actions such as improving diet and taking iron tablets. However, our dialogic video opened directly with a question, "Do you believe that taking iron tablets will cause your baby to get too big, leading to complications during delivery?" This was then followed with a correction, "That is not true; in fact, iron tablets will give you more strength to get through a normal delivery," and so on. The value of such a dialogic approach was that women immediately related to the topic of the video and began to discuss this widely believed myth with either the ASHA or others present, and each expressed her opinions on whether it was true. This increased relevance of the message to the client empowered the ASHA to communicate more effectively.

We found that the quality of the counseling session was significantly improved when ASHAs used the new versions of the videos. ASHAs spent more time discussing various aspects of the message and also elaborated on the message more frequently. From our observations, we found that clients showed more interest and were more attentive when the health worker used the phone messages compared with providing the information orally without the use of videos on the mobile phone (Ramachandran et al. 2010b).

62.4.1.3 Lessons Learned

62.4.1.3.1 Lesson 1: Enabling Access to Information Is Not Always Enough

Our first design attempted to capture important health messages by using mobile videos, which we believed would be both informative for health workers and engaging for their clients. Yet we observed that health workers still had little idea of how to use the videos to engage their clients, and clients had difficulty finding the videos personally relevant. Therefore, it was critical for us to create dialogic videos that guided the health workers through a conversation with their clients and incorporated persuasive techniques to engage clients and help them see the relevance of the messages. While access to health information appears to be the premise of this project, the focus on motivation of health workers and persuasion of clients is critical. This becomes obvious only through a very careful and in-depth understanding of the local context of maternal health care.

62.4.1.3.2 Lesson 2: Consider Contextual Factors in Research Design

Although our results show that dialogic messages significantly improved the ASHAs' ability to provide in-depth, effective counseling, we were unable to measure the impact of this improved ability reliably. Throughout the process of designing a formal study to evaluate the impact of the messages, we made changes, iterations, and compromises to our research goals in response to real, challenging factors in our study environment. This is often a disadvantage in field studies, which attempt to maximize realism and, consequently, have limited control over extraneous factors. We learned the importance of considering these factors not just when we studied the context, but through the research and evaluation process. It is important to consider the tradeoffs of prioritizing methodological rigor over accurately preserving the interactions of contextual realities.

In our case, the rurality of our selected field site limited our ability to recruit more participants and introduced some confounding variables. For example, we found that the ASHAs varied individually in their persuasive power, and a possible cause could have been their caste. We found that ASHAs of the same caste, as most of the client base, were more persuasive than those from higher castes. While we cannot make strong conclusions from our limited sample size, this serves as a reminder that various social, cultural, or political factors can be tightly coupled with the success or failure of ICTD projects.

62.4.2 Big Board Case Study

(Gary Marsden, Andrew Maunder, and Richard Harper)

62.4.2.1 Overview

The Big Board project's goal is to build a system that could download information to any handset for free. The idea for the system came from ethnographic studies and interviews with rural mobile phone users in Zambia and Malawi. Many people in these areas have a handset but cannot afford airtime to make calls or send messages. Most people interviewed were hoping that someone would call them or send them a message. At the same time, we were working with various NGOs that needed a way to distribute information (e.g., on HIV/AIDS, voting materials, etc.) to this same user group. The NGO professionals were frustrated as the people they were trying to reach could not afford to download the information.

A detailed description of the system can be found in Marsden, Maunder, and Parker (2008), but essentially it uses a large screen driven by a PC media server. Users take a picture of anything they see on the screen that they are interested in and Bluetooth that to the PC server. The server then recognizes what they took a picture of and sends back, via Bluetooth, all the media it has relating to that particular topic.

62.4.2.2 Understanding Needs

Our previous attempts at using *participatory techniques* to design similar systems had proven less than successful—users felt awkward sketching interfaces; they were unsure of what technology could do and seemed to second guess what answer the researchers were looking for rather than expressing their own opinion about what the system should do. Therefore, we took a *technology probe* approach and built a high-level prototype to deploy within the community. By presenting the community with a functioning system, users could interact with it and start to suggest usages for the system. To manage and record these interactions, we identified a Human Access Point (HAP) within the community, who was paid to record reactions to the system and interview people about its potential uses. We have found the identification of a HAP to be advantageous in a number of projects; by choosing a person from a target community who has spent some time working with technology (in this case, the HAP had taken a course in Windows and Microsoft Office), they are able to translate between their community and that of the researchers. For the purposes of this project, we coached the HAP in how to keep a diary of usage of the system, which she updated daily. We also encouraged her to interview people who were using the system about what they were doing and why. Clearly, this approach is open to biasing, which is why we triangulated the diary results with usage logs and the polyphonic evaluation reported below.

Building on the feedback the HAP provided, we were able to refine the prototype and better fit it to the needs of the community, much as any iterative design process would. To evaluate the system, however, we could not rely on the HAP as she was personally involved with the success of the project. Instead, we turned to *the polyphonic assessment* techniques of Gaver (2007). Much like the work in the developing world, Gaver seeks to create systems outside the users' previous understanding of what technology might be capable of. To provide an unbiased opinion of the system, Gaver employs journalists to interview users and elicit opinion; on the basis of that journalists are highly trained in gaining opinion and to be unbiased. In our project, we recruited two journalists who were from the same language group as our deployment community. The journalists were merely told that some technology had been deployed in the community and we wanted to understand peoples' reactions and thoughts on how it had impacted them. The journalists recorded opinions and peoples' reported usage patterns, which we were then able to triangulate with usage logs recorded by the system. The back stories provided by the journalists were key in understanding usage patterns and tailoring of content. For example, one participant reported that she downloaded media to consume with her husband in the evening—she found it had greatly improved their relationship. A mother used the system-downloaded media simply to show her children that she could get media on her handset, just as they could.

62.4.2.3 Lessons Learned

We identified several issues in the methods we have described earlier. These issues highlight how these methods differ from creating systems in the developed world context: First, in the developing world, it is often unclear what the problem is and much ethnography has to be conducted to explore the nature of the problem space. In this instance, the need to build a system grew purely from studies with rural users and NGOs—at no point did anyone explicitly ask for an information sharing system. The need for such a system grew from the observation that many people had media-capable handsets but lacked the funds to download media from the internet—one person we interviewed had been listening to the same three preloaded songs on his handset for over 12 months! Second, the iterative design process was not conducted with end users, but a proxy for these users (the HAP). Although this is not an ideal process (an ideal process would be where the community were able to build their own technologies), we have found it provides better results than working directly with end users; we refer to this process as "mediated design." We are actively researching the types of compromise we introduce by using a proxy for users, rather than the users themselves, but are convinced that the interpretations the HAP provides are more culturally appropriate than we had been inferring from direct user studies. Finally, for many developing world projects, standard evaluation measures such as effectiveness and efficiency only represent a part of the evaluation; we believe it is critical to go beyond that and measure how the introduction of the technology impacts quality of life. In this example, we chose to evaluate the system according to its usage patterns and through understanding how users consumed the information it provided, which led us to Gaver's polyphonic assessment. In other projects, we have used measures of domestification (Silverstone and Haddon 1996) or appropriation (Heeks 2005) to gauge success. In projects where there are NGO partners, we have even used their success measures to assess the impact of our work.

So, while HCI contains many methods for the creation and evaluation of system designs, our experience has been that these methods cannot be applied "blindly." In other words, we are often driven back to the original assumptions that drove their creation to reinterpret them for users living in the developing world. Not only does this stretch HCI to cover issues in the developing world, but we expose holes in the methods that the rest of the world is using, which can strength practice in the developed world as well.

62.4.3 Rural e-Services Case Study

(Andy Dearden)

62.4.3.1 Overview

The Rural e-Services project combined three methodological questions: The first was how participatory methods used in development could be combined with the methods and traditions of participatory design; The second was how to develop a platform to offer multiple e-Services in rural areas by making use of mobile devices; Third was how to create sustainable business models in challenging environments. The project was concerned with rural areas in India, and we had initially been funded on that basis that we would begin by exploring microfinance. However, as we engaged more deeply with the community and the community-based organizations (in our case, working through an NGO that had both microfinance and agricultural initiatives), we discovered that community members and leaders viewed improving "agricultural information flow" as a higher priority than microfinance development.

62.4.3.2 Understanding Needs

We followed a "deeply embedded" strategy for participation (Dearden and Rizvi 2009). This began with a 3-month period of "entry to the field" (International Development Research Centre 2005), which involved general discussions, getting to know the community, and building relationships. During this period, as well as listening carefully to understand the interests of the community, the researcher was also able to show commitment to the community, for example, one's helping some community members to get home from the state capital when they had run out of funds due to travel delays. This period culminated in a project establishment meeting between the project, the Sironj Crop Producers Company Ltd. (a co-operative of marginal farmers), PRADAN (an NGO), and the state governments District Poverty Intervention Program, where the overall direction of the project was revised to develop an improved "agricultural information flow system." The software design was driven using a combination of techniques from participatory IT design, participatory development practice, and agile software development. These included timelines to explore history and important sequences of activities, chapatti diagrams (which are used to discuss priorities with size reflecting importance; see Figure 62.1), storytelling workshops, scenario generation, and short software development cycles (about 1 month for each cycle).

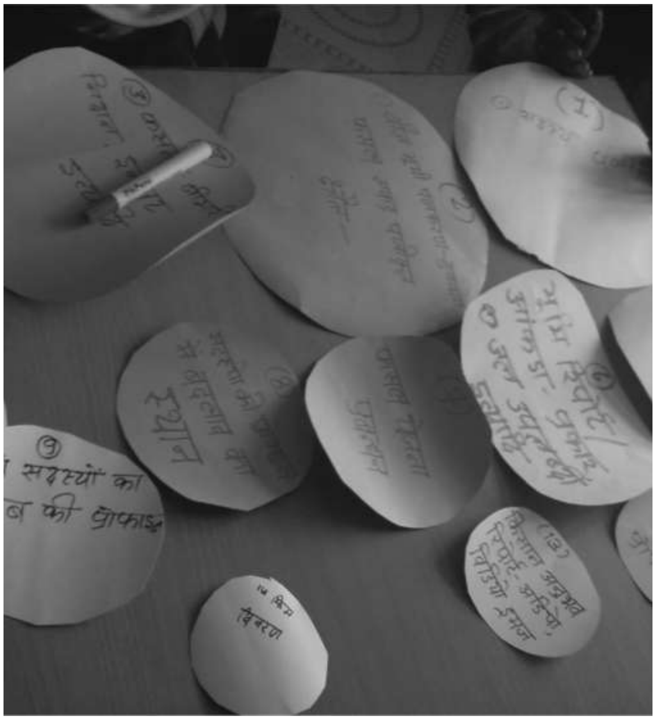

FIGURE 62.1 **(See color insert.)** Example of a chapatti diagram.

The software was developed by Safal Solutions, a software company from Secunderabad, Andhra Pradesh, specializing in systems for the NGO and development sector. Although we could not arrange for the farmers and the software developers to be co-located, during each cycle a delegation of farmers travelled to Secunderabad for 2 days to test and suggest revisions to the designs.

The software produced was called Kheti (which stands for Knowledge Help Extension Technology Initiative and means agriculture in Hindi). The main component of Kheti is a mobile phone-based application (built in Python on a Symbian 60 phone), which allows farmers to create simple multimedia messages that consist of up to six photos plus an audio track. This is then sent to a web server. The CEO and agricultural advisor of the farmers' co-operative can then view these messages (usually they did this in the evening) and call back to the service provider and farmer the following day for a discussion. Other components were a web-based membership database for the co-op so that the advisor knew what the farmers were growing and what their land holdings were and an Interactive Voice Responder System that could store recordings of advisory conversations. The system was field-trialed for 3 months with over 200 multimedia messages being exchanged, and some major pests and diseases were avoided. However, we did not succeed in finding a sustainable business model that could pay all the costs involved in running the system.

62.4.3.3 Lessons Learned

The primary lesson was that participation in design is not primarily about the methods that are used such as paper-prototyping (see Dearden and Rizvi 2008a,b for a discussion), but is about how designers, researchers, and beneficiaries interact and work together. Participation implies negotiating control of not just the design of the technology, but also of goals of the project, the processes of designing the definition of success. For example, we had to engage all the stakeholders from the funders to the farmers to negotiate the switch from microfinance to agricultural information, the software design and development schedule had to be adapted to fit with the seasonal nature of the farmers' work, and the conceptions of success had to recognize organizational development of the co-operative as an important outcome in its own right. During the project, many of the co-operative members gained from considerable personal development, particularly gaining the confidence to interact with and assert their understandings and their interests when dealing with the software developers, government officials, the researchers, and the NGO. The researchers and software developers also learned and were changed by our experiences.

Another important lesson was that effecting change through HCI4D is highly dependent on the input of partner organizations. Kheti can be understood as an information system for the co-operative, and as with other information systems, its introduction has to be led by internal champions. One of the challenges for HCI4D is to organize projects so that the community hosting and operating the technologies take on ownership and drive the project for themselves.

An interesting finding for us as HCI researchers was that when people see real value in a system, they will invest a lot of time and energy learning how to use the technology. In our case, we would have liked to improve the user interface, but project timescales and limits on funding meant that we had to move to field trials before we were completely happy. However, we discovered that the end users were willing to learn to use the system because they could see the potential benefits for themselves.

We began with an assumption that using agile software methods and rapid prototyping would be beneficial to create an interface that was well matched to our users. In practice, we found that we had to allow extra time in each iteration for users to learn and understand the elements of functionality that were already available. However, software prototyping was important so that our users could understand the degree to which software is malleable and can be revised.

Finally, we found that all the farmers we worked with were able to make meaningful inputs to design decision making, but the NGO staff and more educated farmers were better equipped to respond to partial design concepts and ideas about how technology could be. For example, when we tried to develop some future-oriented scenarios and storyboards, many of the farmers were unable to understand what we were asking them to do. Farmers were more comfortable telling stories about their current lives and past experiences, but were unfamiliar with this new kind of storytelling.

62.4.4 Post Conflict Computing Case Study: Video Sharing and Reconciliation in Liberia

(Thomas N. Smyth and Michael L. Best)

62.4.4.1 Overview

In 2003, a comprehensive peace agreement finally brought an end to almost two decades of brutal civil war in Liberia, a small West-African nation of about 3.5 million residents. In the wake of that disastrous conflict, Liberia, like many nations before it, established a Truth and Reconciliation Commission (TRC) charged with investigating the causes and effects of the war and helped to establish a lasting peace. The Commission was the first of its kind to truly embrace new digital media in the service of its goals. As part of the Commission's media strategy, our research group was tasked with building a mobile computer video story-sharing kiosk through which citizens could share their thoughts and opinions on the war and the nation's future path. In undertaking this project, we encountered a heretofore unexplored field for computer interaction design and Development: that of post-conflict reconciliation. This case study recounts some of the novel challenges we faced and the HCI innovations we developed to meet them.

62.4.4.2 Understanding Needs

Based in Atlanta, Georgia, our team faced many practical obstacles in working directly with the Liberian end-users using traditional collaborative design processes. In response, we developed a methodological innovation called HDF, Heuristic → Diaspora → Field (Best et al. 2008). Under this methodology, candidate designs were first reviewed in our laboratory by local usability experts based on widely accepted heuristics. Next, designs were tested with members of the considerable Liberian diaspora (some 10,000 members strong) in Atlanta. We performed user studies and focus groups at various locations including a Liberian restaurant, which also served to expose our Atlanta-based designers to a local, ready-made Liberian "culture capsule" (Foucault, Russell, and Bell 2004). Finally, we shipped designs refined through this process to Liberia for the critical stage of end-user field testing. The interim step of working with the diaspora proved particularly fruitful, leading to early changes in design direction including an emphasis on extreme simplicity, along with helpful feedback on the appropriateness of our choice of symbols, icons, and voice prompts.

Out of this three-part design process emerged the Mobile Story Exchange System (MOSES) (Best et al. 2009; Smyth, Etherton, and Best 2010). The video-sharing concept behind MOSES is simple: citizens approach the kiosk, browse and watch video messages created by others, and record messages of their own. Rather than relying on extremely scarce Internet connectivity for dissemination of content, all videos remain physically within the kiosk, which is itself transported throughout the country.

MOSES is pictured in Figure 62.2. It consists of a screen, a set of ruggedized buttons, a camera, directional microphone, and speakers. Chassis fans and air filters keep the inside of the system cool and dust-free. A glare shade allows viewing outdoors, where MOSES is usually deployed. The system is powered using marine deep-cycle batteries and can run for up to 8 hours completely untethered. All components are housed in a Liberian-made lockable and sturdy wooden housing, allowing the system to be left unattended for short periods. Finally, the system can be separated into two halves for easy transport.

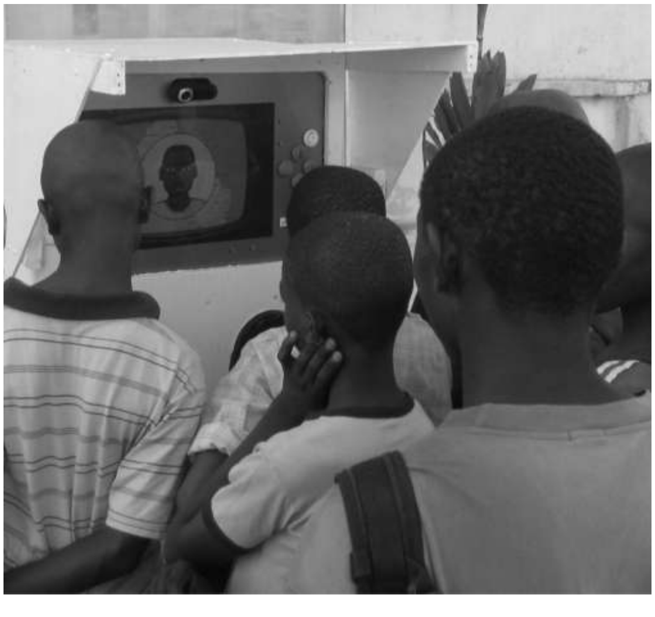

FIGURE 62.2 (See color insert.) People using the Mobile Story Exchange System (MOSES) kiosk.

The user interface features Moses, an embodied conversational cartoon agent, also shown in Figure 62.2.

Moses guides users through browsing, watching, and recording processes using simple verbal prompts such as "Please look into the camera and remember to speak loudly. Press the white button when you are ready." This design allows walk-up use of the system by Liberians with no computer or print literacy. While embodied conversational agents have been widely panned within the HCI community, we find some possible rehabilitation to this design approach when targeting illiterate user populations. The purpose of MOSES is to support public discourse about Liberia's past, present, and future. The public nature of the system is made clear to users by Moses' voice prompts as well as by the physical locations of the system, usually in highly public places surrounded by a crowd of people.

62.4.4.3 Lessons Learned

Over a period of approximately 2 years, MOSES was carried to most major areas of Liberia and was experienced by thousands of Liberians. Over 900 videos were recorded and saved. During this period, we also carried out two evaluations of the system, one qualitative and one quantitative. The results from both suggest that interactive video story sharing systems can indeed help in post-conflict national healing and reconciliation. One demonstrative quote came from a participant who recorded a video about unjust employment practices:

> [My video] will go places and people will witness it, and they will know what happening in some area. For them to know what is happening they will get to know it is not happening in one place, it is happening all over.

Given the complete novelty of the video content creation and sharing technology to most participants, we found this strong and immediate embrace of the medium remarkable. In addition we found that Moses, the animated conversational guide, was warmly received by participants who spoke of him as a "friend" and "teacher" and reported relying heavily on his instructions. Given floundering interest in animated conversational agents in most user interface design circles, the strong enthusiasm expressed by our study participants was intriguing. Finally, we observed that MOSES was almost always used by a group of people rather than by a single individual. Many participants reported that they drew inspiration, confidence, and technical assistance from the group.

General self-efficacy is believed to be important when establishing conditions for sustaining post-conflict peace. If we can demonstrate that interacting with our system can increase a participants' generalized self-efficacy, then we will have to take a critical step towards establishing our broader hypothesis that rich digital media is an important tool in post-conflict reconciliation (Long and Brecke 2003; Ropers 2004). With intrastate conflict emerging as the predominant form of armed conflict in the modern world, it appears that the need for effective new approaches in post-conflict reconciliation is needed. We believe that appropriately designed ICTs can form part of such strategies, and MOSES has been an encouraging first step in that direction. We are proud and grateful to have had the opportunity to work with the TRC of Liberia, and we are currently investigating other potential projects in Uganda and Afghanistan.

62.4.5 Low-Cost Media and Mobile Phones in Data Elicitation: Designing a Method for HCI4D

(Nithya Sambasivan)

62.4.5.1 Overview

A central challenge to conducting research in low-income contexts of developing countries is designing or tailoring methods for data gathering and evaluation. Particularly, in situ studies, which are crucial in understanding development in the real world, are especially difficult to orchestrate. Several interesting challenges may affect the application of traditional HCI methods in such contexts—low literacy rates, technology skill and usage differentials, and social and economic stratifications, in addition to ambient noise, electrical power, and cost constraints. Western-world techniques do not map easily to such contexts, because of profound differences in users, needs, contexts, practices, and goals of projects.

In the spring of 2009, we conducted an ethnographically inspired study in two urban slums of India (Nakalbandi and Ragigudda) to understand low-income communities and their engagements with technology (Sambasivan 2009a,b). We primarily employed ethnographic techniques, such as participant observation, household surveys, and semi-structured interviews, to understand the socioeconomic, developmental, and cultural aspects of our informants. By triangulating our data with inputs from the communities and the NGOs, we determined two key developmental areas that were of interest and relevance to the community—education and health care. To help understand the reality of technology and social structures of the communities, as well as to pilot some technology created for the above-mentioned development areas, we designed *ViralVCD*, a low-cost, rapid data elicitation method (Sambasivan, Cutrell, Toyamo 2010). The technique leverages local practices and existing infrastructure to elicit contextual data. It employs physical media and mobile phone questionnaires to gain access to data on multiple levels: *social* networks underpinning information diffusion; *technological* ownership, access, and usage; and *developmental* impact assessment of HCI4D projects. ViralVCD is an example of a larger class of possibilities that can be seen as a methodological contribution to researchers working in resource-challenged contexts.

62.4.5.2 Understanding Needs

Our initial ethnography pointed to the relatively high penetration of televisions, video compact disc (VCD) players, and mobile phones. Associated with these technologies were the practice of "missed calls" (terminating a phone call before the receiver picks up, to cut costs) and the prominent role of entertainment in everyday life.

To produce useful and interesting content for the pilot, a participatory video framework was created. Based on our ethnography, we highlighted local best practices, along with expert advice, in the format of VCD videos. While the videos provided us content for social development, they also served as a lens to study their own diffusion in the communities (i.e., understand how videos get viewed, by whom, where, why, etc.).

Based on our initial findings, we created videos around the areas of education and healthcare.

62.4.5.2.1 Education

Parental lack of literacy was attributed to poor academic performance of children and high incidence of dropouts, in our study. Based on our ethnography, we elicited best practices in teaching among certain parents whose children enjoyed academic success. Inspired by the heavy viewership of soap operas in these communities, we scripted a role-play between two non-literate women, demonstrating the best practices. Techniques to ensure good academic performance that overcame the non-literacy barrier were demonstrated, for example, making children read aloud and looking for ticks and crosses. An education expert provided actionable steps.

62.4.5.2.2 Healthcare

Our informants attributed their poor nutrition to their low income, and they would often fall sick from eating unhealthy food. We hosted a "cooking contest" in the slums to extract local knowledge in an openly competitive fashion. Taste and nutritional value were used as judging criteria to motivate healthy cooking. Snippets of the contest were embedded into the final video. This was followed by a segment on balanced diet.

62.4.5.2.3 Dissemination

As a next step, we burned the videos (roughly 12 minutes each) onto VCD, owing to their low costs and ubiquity. Then, we screened the videos in six slums using the local VCD player and television. Inspired by the participatory format in Digital Green by Gandhi et al. (Gandhi et al. 2007), where videos featured local members of the community, our hypothesis was that people may want to view the videos more because their peers from similar communities feature in them. Following the screenings, we handed out VCDs with unique identifier numbers and celebrity photos attached to the sleeves (Figure 62.3). At the end of each video, a visual and auditory prompt provided instructions to dial a "missed call" to the phone number on screen (also written on the VCD), which was ours. We immediately called the number back to conduct a short interview, mainly to enlist

FIGURE 62.3 **(See color insert.)** (a) Sample video compact disc and sleeve. (b) A screening session in Jakkur.

the caller's socioeconomic profile and to gauge their understanding and feedback on the content. If the caller answered a content-related question correctly, they were provided with a utilitarian prize (utensil or blanket) as a gift. They were then encouraged to pass on the VCDs to others in their social circle. The contest was limited to a week, after which, calls were no longer accepted.

We distributed 132 VCDs to 65 attendees. For these attendees, the call response rate was 31.25%, with 20 callers. In total, 50 unique callers were registered and 31 VCDs were transferred.

ViralVCD helped us generate social, developmental, and technological insights. Key social insights include tracing paths of transmission (by mapping out who passed VCDs to whom) and the social processes driving the diffusion. At a microlevel, two forms of diffusion emerged—the prominent, peer-to-peer propagation (A→B→C) and actor-driven diffusion (A→ (B and C)). Peer-to-peer propagation was seen in communities where multiple key (active) actors existed, and actor-driven diffusion was visible where there was a strong actor with a strong social network. At a macrolevel, the diffusion reflected the social solidarity of the community—neighborhoods splintered by heavy internal politics showed fewer proclivities towards diffusion activity. Tightly knit communities exhibited quick and widespread responses.

62.4.5.3 Lessons Learned

Key technological insights include understanding the communal usage of technologies: the place, time, and nature and composition of the group in which the shared activity transpired; the working order of VCD players, televisions, and mobile phones; and the correlation between technology ownership and communal participation. Finally, ViralVCD helped in creating developmental extensions for education and health. Because we placed contest details at the end of the video and asked unique questions, viewers needed to watch the entire video to answer correctly. We queried on the understanding and usefulness of the content in health practices and child rearing.

ViralVCD was helpful in identifying critical agents in communities, in understanding their socio-technical makeup, and in identifying and recruiting peers of the same socioeconomic stratum through snowballing. ViralVCD avoided additional infrastructure in understanding community capital, technological ownership and access, and developmental baselines. It complemented our ethnography by providing understandings of organic use, users, and contexts of use, which could be applied to the design of HCI projects.

62.4.6 MILLEE Case Study: Mobile and Immersive Learning for Literacy in Emerging Economies

(Matthew Kam)

62.4.6.1 Overview

The MILLEE (Mobile and Immersive Learning for Literacy in Emerging Economies) research project aims to improve "power language" literacy among low-income children in developing countries. MILLEE revolves around the idea that immersive, engaging, and yet educational games on cell phones that target language literacy can make high-quality learning more accessible to low-income children in underdeveloped regions who lack access to high quality schooling.

Low literacy is without doubt one of the grand challenges in the developing world. But even more challenging is the tension between regional languages and global "power languages," such that economic opportunities are often open to those literate in a power language. For instance, even though more than 20 regional languages are spoken widely in India, English language is widely perceived to be a socioeconomic enabler. The economists Munshi and Rosenzweig (2006) estimate that English speakers in Mumbai experience returns on investment in schooling that are between 24% and 27%. On the other hand, non-English speakers with similar characteristics experience returns that are about 10%. English is thus the language of power in India, such that mastery of the language can almost be associated with membership in the middle and upper classes in India (Faust and Nagar 2001; Kishwar 2005).

Unfortunately, the public school systems in developing regions such as India have poor outcomes. According to a literature review commissioned by the Azim Premji Foundation (2004b), public schooling is out of reach for more than 43% of school-going age children in rural areas who cannot attend school regularly due to their need to work for the family in the agricultural fields or households.

On the other hand, cell phones are increasingly adopted in developing regions to the extent that the cell phone has become the fastest growing technology platform in the developing world (Vodafone 2005). We believe we can dramatically expand the reach of language and literacy learning in the developing world by using portable mobile devices such as the cell phone as the target platform, so as to enable children with work commitment to access educational resources anytime and anywhere, at places and times that are more convenient than school alone.

62.4.6.2 Understanding Needs

At the time of writing, the MILLEE team has made more than 10 trips to India to conduct field research, including iterative design and pilots studies, since the project started in 2004. These trips were also crucial for building relationships with local partners and communities, whose support were instrumental for the success of our pilot studies. In such a multidisciplinary endeavor, the MILLEE team comprises computer scientists, HCI specialists, second language and reading acquisition specialists, as well as videogame designers. The team includes members who, through their experiences growing up in India and/or volunteering with humanitarian organizations working to improve education there, possess a deep knowledge of the local cultural context.

The games we have designed and developed to date in this new suite of MILLEE games collectively targets one semester of English as a Second Language (ESL) curriculum as mandated by the state government of Andhra Pradesh in India.

In the case of the MILLEE project, the designs of our e-learning games draw on best practices in the state-of-the-art language learning software (Kam et al. 2007a), as well as a cross-cultural analysis of the qualitative differences between traditional Indian village games and contemporary Western videogames (Kam et al. 2009). Our goals are threefold: (1) to design pedagogical applications that are informed by the research base on reading literacy and second language acquisition; (2) to take the best practices in commercial language learning applications as a starting point as opposed to reinventing the wheel; and (3) to design educational games that are culturally consistent with the traditional village games that constitute the play experiences of rural Indian children.

62.4.6.3 Lessons Learned

Design knowledge for instructional design: In terms of language pedagogy, we situate our technology and instructional design processes within the Task-Based Language Teaching (TBLT) curriculum development framework (Ellis 2003, Nunan 2004, Prabhu 1987, Skehan 1998). In TBLT, the learner engages with a series of pedagogic tasks that take the form of goal-directed activities.

Our rationale for using TBLT as a guiding framework is twofold. First, the task has an inherent degree of structure that designers can follow and fits well with the existing work practices of designers and educators: just as the language instructor can plan her teaching tasks prior to her classroom lessons, the instructional designer can devise tasks for computer-assisted learning systems that are eventually deployed with learners. Second, TBLT has demonstrated learning outcomes in the Indian context. Prabhu (1987) describes the well-known Bangalore/Madras Communicational Teaching Project, in which task-based approaches for teaching ESL in India were experimented with children aged between 8 and 13 years over a 5-year period. In an independent evaluation, Beretta and Davies (1985) found that children taught using TBLT performed significantly better than their counterparts in the control group on tests of transfer that evaluated them on contextualized grammar, dictation, and comprehension (both listening and reading).

The challenge, however, is that theoretical frameworks such as TBLT remain too abstract for technology designers to grasp easily, much less translate into software designs. At first glance, it appears that the design process calls for multidisciplinary collaboration between designers and educators, in addition to specialists from other domains such as game design. Such a partnership is no doubt necessary but insufficient. In our experience, the typical language teacher may not know how to draw on her teaching experiences and background, so as to imagine concrete designs.

On the other hand, there are existing commercial language learning products that include games and other software. We take the state of the art in existing commercial language learning products as the initial basis for our instructional design and avoid reinventing the wheel. Along this line, how can we capture the existing design knowledge reflected in the instructional design of current language learning software and commercial products?

The formalism that we use for capturing this design knowledge is the design pattern (Alexander 1977), which grew out of building architecture and is increasingly popular in domains such as software engineering. The MILLEE project is arguably the first attempt to apply design patterns to the domain of language pedagogy. A design pattern provides insights into a frequently encountered design problem by describing the problem, the essence of the solution to the problem, the rationale for the solution, how to apply the solution, some of the tradeoffs in applying the solution, and related design patterns. A primary benefit of a design pattern is to encourage the reuse of existing solutions to problems that are frequently encountered, so as not to reinvent the wheel. Design patterns, especially those that capture the design knowledge employed in the instructional design and videogame design of successful language learning games, thus constitute a design tool that designers can use to create more of these games while maintaining reasonable educational quality.

In the MILLEE project, our design processes leveraged a set of more than 50 pedagogical design patterns that we distilled from a review of over 35 commercial language learning applications. We conducted this review in a principled manner by using task-based language teaching as our analytical lens. We selected this sample of more than 35 commercial applications based on the following factors, which we adopted as our proxy indicators for educational quality: a large professional customer base, highly educated users (in the case of adult learners) or parents (in the case of children's software), as well as strong reviews and/or ratings on home schooling, e-commerce, and so on, websites. Our sample included ESL learning software packages that are developed specifically for non-English-native low-income students from the rural areas and urban slums in developing regions (e.g., the series of software developed by the Azim Premji Foundation in India for use in over 15,000 affiliated rural Indian primary schools), best-sellers in the foreign language learning market (e.g., *Rosetta Stone*, Simon and Schuster's *Pimsleur*, Topic Entertainment's *Instant Immersion*, and Auralog's *Tell Me More* series), as well as early literacy games (e.g., the Learning Company's *Reader Rabbit* and Scholastic's *Clifford: The Big Red Dog* series).

62.4.6.3.1 Design Knowledge for Gameplay Design

Next, in designing effective e-learning games, gameplay design is an equally important design dimension in the MILLEE project. As such, we have also experimented with design patterns that capture some of the design knowledge in gameplay design, including heuristics for enjoyable gameplay. However, while we have been able to use the above pedagogical design patterns to culminate in positive learning outcomes (Kam et al. 2007a), our results with game design patterns were less successful (Kam et al. 2007b). Rural children did not necessarily find the games whose designs were informed by game design patterns to be necessarily intuitive, exciting or free from playability problems. It appeared that rural children have relatively little exposure to these videogames, whose designs were influenced by Western cultural traditions that unconsciously incorporated into the game design processes. It seemed that patterns require adequate knowledge of the cultural context to be employed effectively.

We conducted contextual interviews with 87 children in villages in North and South India, during which we asked participants to recall the everyday games that they love and to play these games for us to videotape. We observed a total of 23 outdoor and 5 indoor games. Seventeen outdoor games belonged to the family of "tag" games, in which there is generally at least one player designated "it" who has to "tag" players in the opposing team by touching them, either with a hand or an object. In particular, 2 and 3 "tag" games belong to the "cops and robbers" and "hide and seek" sub-families, respectively. The six outdoor games that do not belong to the "tag" family include tug-of-war, kite flying, marbles, hopscotch, and the spinning top. The indoor games can be generally classified as "tabletop" games. To understand what traditional games are made up of, we examined each of the above 28 games and identified the elements (Fullerton 2008; Björk and Holopainen 2005) that comprised their game mechanics. The game elements that we considered included the players, game resources, goals, actions, and rules.

Based on the insights that we have gleaned from the above analysis, we have devised a tool for designing videogames that target children in rural India and potentially other rural regions. Specifically, by providing a detailed description of the elements in traditional village games (Kam et al. 2009), we have provided the community with a "palette" of game elements that game designers can draw from to put together new game designs for children in rural developing regions. As such, this tool is *generative* in that it facilitates new designs. Our preliminary results with this tool suggest that designing videogames with the same game mechanics as those found in traditional games, while leaving out those mechanics that are absent, ensures the most successful videogame designs that rural children can relate to more readily. We encourage other researchers and practitioners who are working on videogames or literacy interventions that aim to improve lives for poor children in the developing world to experiment further with the design tools and knowledge that we have put together in our work.

62.4.6.4 Next Steps

We are extending the latest suite of games to target an entire academic year of English curriculum as mandated by a local state government in India. Each game will focus on an early literacy competency such as phonological awareness, word recognition fluency, or lexical inferencing. Despite the massive undertaking involved in developing digital content that aims to teach an official curriculum, it is necessary for adoption purposes to align our games with an official syllabus so that we can evaluate the efficacy of the MILLEE approach on a syllabus that stakeholders, including parents and government officials, view as an important educational credential. The undertaking is complicated by the need to develop remedial digital content (i.e., "bridge content"), which covers prerequisite knowledge that rural children who previously had low-quality schooling require so that they would be equipped to learn the official curriculum.

The task is further complicated by the limitation that much research on reading acquisition and literacy is based on learners in industrialized countries with reasonably good access to schooling, whereas our target learners reflect vastly different conditions on measures such as "concept of print" and school-based social practices, all of which are important theoretical constructs in existing literacy theories. We have drawn from the existing research base on literacy studies as best as we could to inform our bridge content. We aim to leverage these games as a research infrastructure that can be used to operationalize and test the extent to which existing literacy frameworks apply in—and have to be extended to be more insightful for—culturally divergent environments. In this way, we believe that undertaking HCI in the developing world can help us as a community of researchers and practitioners attain a more complete understanding of what design, cognition, literacy, and learning truly means.

62.5 WAY FORWARD

As this chapter has shown, HCI4D is bringing UCD thinking and approaches to the creation of technology, which aim to support economic and community Development. Of course, we are not alone in trying to bring user-centered approaches to laterally related domains. Others are also trying to do this, including groups promoting sustainable interaction, easy-to-use "Green" technology, human-centered built environments, and usability of voting systems. Like these colleagues, we face challenges of finding new shared ground, learning how to bridge into a new domain, and figuring out how to make our unique contributions valuable in terms of another domain and/or discipline value. However, unlike other efforts toward sustainable and improved quality of life, HCI4D focuses chiefly on users who are not likely to have the disposable income to pay for the technology. The end users' lack of purchasing power is the main distinguishing feature of HCI4D and brings about many of the challenges addressed in this chapter.

We believe that HCI4D can have a positive impact in projects like those presented here. At the same time, we also hope that HCI4D is moving the whole discipline of HCI forward because we are extending, amending, changing methods and tools—and creating new ones—in ways which are not just useful for the "developing" world. While we and others (e.g., Prahalad 2009) believe that the "developing" world is where we see the growth of the technology industry as more and more diverse people become invested in creating and using technology, we also believe that extending our ability to learn about and design for increasingly diverse populations benefits and informs HCI as a whole. Certainly, when we look at what is happening worldwide, it is clear that technology is being appropriated at ever-increasing rates. Local people are building new technologies and applications to meet locally relevant needs more than ever before. That adoption, design, and implementation is happening without necessarily employing the formal principles and techniques of UCD as espoused by the HCI community.

To this point, most of us in the HCI4D community have focused on the notion of "doing good" with the end-goal of improving the quality of life for a local community. We believe that user-centered approaches are inherently "better" for communities as well as for design in that they avoid attempts to impose technologies—that participation "works better" both because it includes previously excluded people and because it results in a better, more sustainable design. This is an admirable motivation. However, we must also find the overlap between what is well-intentioned and what is economically, socially, and environmentally viable and sustainable. Otherwise, our efforts will not scale and will not benefit the wider world. In the worst case, if a technology is not sustainable, it may bring false hopes and disappointment, increasing the digital divide and decreasing the likelihood that future HCI4D projects will succeed. If the outcomes of HCI4D projects are economically viable, it is inevitable that companies and institutions will become involved. It is only with the wider involvement from industry, policy makers, and development actors that HCI4D can truly have impact. In fact, an enterprising mindset is necessary when carrying out HCI4D projects. While economic viability is not a primary concern in most HCI projects, especially HCI research projects, the focus in HCI4D on alleviating poverty inevitably makes economic, social, and political considerations an important cornerstone of HCI4D, and as such, distinguishes HCI4D from much of HCI.

The case studies described in this chapter illustrate this entrepreneurial, innovative spirit. Faced by sometimes debilitating conditions imposed by the local context of where the technology would be used, all the authors discovered new insights to use in innovating and building a more fitting and "smarter" solution. Each of the case studies tells the story of an attempt to deploy a mainstream iterative interaction design cycle and the inventive workarounds and solutions that were found when conventional processes and methods did not carry across. The case studies show that user-centered approaches can be extremely useful; they are necessary but not sufficient. Building relationships with NGOs and local people is a critical first step. All the authors would agree that these relationships are important in the success of their projects. Therefore, we need to reach beyond the academic community, the Development community, and the handful of large multinational companies which have been involved through funding of single efforts, often through their "corporate responsibility" arms. We must include different partners with different constraints, incentives, and vantage points. Otherwise, there is little chance of bringing about the kinds of systemic changes that are required to make UCD, technologies, and programs that scale. We need to have a principled way of thinking about these economic considerations and integrating them into existing HCI frameworks.

Some of those voices may be those of people from NGOs and those of people in local communities, some of whom we already work with and some of whom are as yet unknown to us. They may include local entrepreneurs, local business people, local developers, and people in regional or local companies who are trying to find solutions to "local" problems—solutions that have the potential to be applied more widely with additional resources, including expertise. International business plays a role too. But, like the other players, it cannot end poverty alone. Designing for the market in user-centered ways is, in the opinion of some (Polak 2009, 2010), the only way for affordable solutions to the problem of poverty to measure up to the challenges they meet. "The ruthless pursuit of affordability is an essential component of this design revolution, which in many ways stands on the shoulders of the appropriate technology movement. Most importantly, to be successful, the revolution in design for the other 90% has to develop disciplined ways to design for the market" (Polak 2010). With a project focus on extreme affordability, industry can partner up with NGOs, CBOs, local entrepreneurs, and governments to develop economically viable and sustainable solutions.

Clearly, if we are to help in this revolution, we may find that we need to adopt new ways of working together. Some have argued (Dray 2009, Buie, et al. 2010a,b) that finding ways for academics and practitioners to communicate and work together better is critical for HCI. That is even more critical in HCI4D at the same time that the challenge is greater. Working collaboratively together—just as we seek to work collaboratively with those in local communities—is key to helping HCI4D change the world. There is much to help us with this, for this is a time of great experimentation. Funding agencies like the National Science Foundation (NSF) in the United States are moving away from their traditional levels of grant support, and now NSF "especially welcomes proposals for cooperative projects involving both universities and the private commercial sector" (NSF 2011). Academics are looking increasingly to non-federal sources of funding to support their research and diversify their funding base. Public–private partnerships, originally developed by governments, have been expanded for use in international development (World Economic Forum 2005). As challenging as this is, it is also exciting.

By sharing lessons we are learning as we collaborate with new and different players, as we find ways to incorporate an understanding of sustainability and affordability, as we experiment with adapting time-honored methods and creating new ones that fit an increasingly diverse world, and we are finding new ways of working that can also benefit HCI as a whole. And that will help all of us to change the world in a positive way—to empower, to learn, to create, and to build a better future for all.

Cell #4 does not possess the E antigen. Therefore, even if anti-E was present, it could not possibly react with this cell. Consequently, this is not a good cell for ruling out anti-E.

FIGURE 26.6 Full test panel with intermediate results marked using color coded markers provided by AIDA. In this case, AIDA has interrupted the user to suggest that an error may have been made in ruling out anti-E.

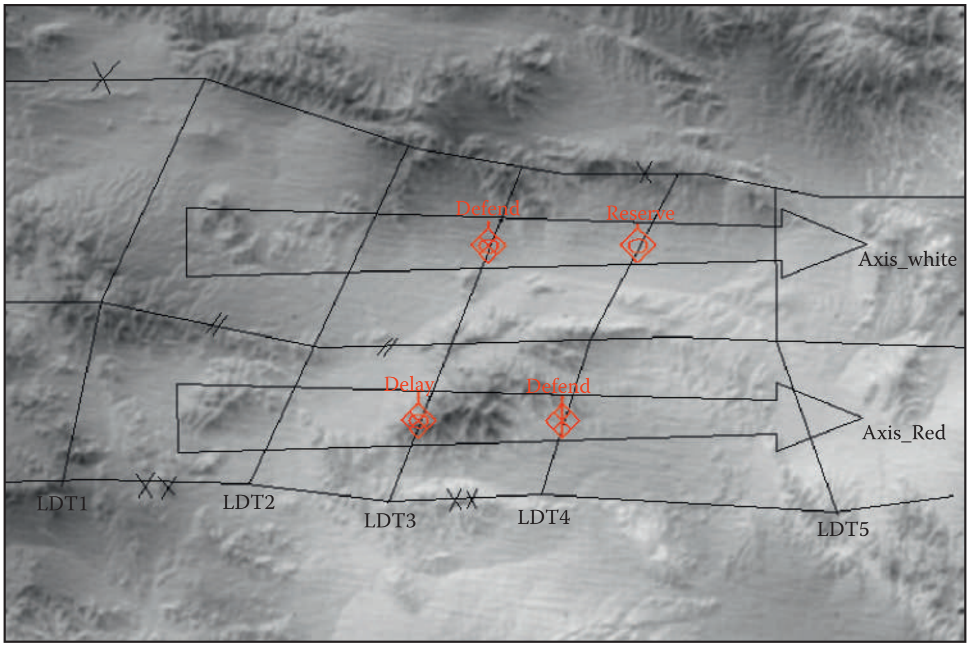

FIGURE 26.7 An example of an enemy course of action (ECOA). The diamond-shaped figures represent the enemy units. Each unit is further labeled by role played by the unit in this scenario: Defend, Reserve, or Delay. The enemy units move along two corridors in the terrain indicated by large arrows and labeled Axis White and Axis Red. Friendly units move in the direction of the arrows, enemy units move in the reverse direction. LDT means Line of Defensible Terrain. LDT 1 through 5 are used as reference lines to mark how far the units have advanced. In this snapshot, all enemy units are currently positioned on LDT 3 and LDT 4.

Ergonomics and Human Factors

The Human–Computer Interaction Handbook

Fundamentals, Evolving Technologies, and Emerging Applications

Third Edition

"… details the progress of this extraordinary discipline … The carefully written chapters and extensive references will be useful … This handbook's prominent authors thoughtfully survey the key topics, enabling students, researchers, and professionals to appreciate HCI's impact."

—from the foreword by **Ben Shneiderman**, University of Maryland

"If you care about Interaction Design, you should own this book. Exhaustive coverage by world authorities. … one book that covers the gamut. Highly recommended, highly practical."

—**Don Norman**, Northwestern University

"Comprehensive and thorough coverage of all the important issues related to user interfaces and usability. A useful reference work for anybody in the field…"

—**Jakob Nielsen**

The third edition of a groundbreaking reference, **The Human–Computer Interaction Handbook: Fundamentals, Evolving Technologies, and Emerging Applications** raises the bar for handbooks in this field. The book captures the current and emerging sub-disciplines within HCI related to research, development, and practice that continue to advance at an astonishing rate. It features cutting-edge advances to the scientific knowledge base as well as visionary perspectives and developments that fundamentally transform the way in which researchers and practitioners view the discipline.

New and Expanded Topics in the Third Edition

- HCI and global sustainability
- HCI in health care
- Social networks and social media
- Enterprise social computing
- Role of HCI in e-Government
- Role of creativity and cognition in HCI
- Naturalistic approach to evaluation, persuasion, and globalization

The chapter authors include experts from academia, industry, and government agencies from across the globe — all among the very best and most respected in their fields. The more than 80 tables, 400 figures, nearly 7,000 references, and four-page color insert combine to provide the single most comprehensive depiction of this field. Broad in scope, the book pays equal attention to the human side, the computer side, and the interaction of the two. This balanced, application-focused design coverage makes the book not only an excellent research guide but also an authoritative handbook for the practice of HCI and for education and training in HCI.
