Fiero* (Italian)	Personal triumph over adversity (Ekman 2003). Overcoming difficult obstacles, players raise their arms over their heads. They do not need to experience anger prior to success, but it does require effort and some frustration.
Boredom**	Repetitive, dull, or tedious tasks (Ekman 2003). Lack of interest in the outcome or in playing. Dispelling boredom is also a major reason to play games.

* Fiero is a positive emotion that has a body rather than a facial gesture. It is not yet known what fiero gestures look like across cultural boundaries.

** Ekman does not list boredom as having a universal facial gesture; however, it is frequently seen in games that lack sufficient challenge.

Source: Lazzaro 2004b.

affect from *Bookworm*'s burning letter tiles (which makes their use a priority and picks up the perceived pace of the game). Emotional states also focus effort and attention on available choices in play. Positive affect, for example, helps to generate new ideas such as what gemstones to match in *BeJeweled*, or negative affect, surrounding an impending invasion in *Civilization*, provides additional focus for decision making on how to respond.

31.4.2 Fiero Enhances a Player's Sense of Progress

"I have to concentrate!"

> **—Traveler in St. Louis airport on what he likes most about *JamDat Bowling* on his mobile phone. Playing removes distractions from his consciousness and engrosses him in a rewarding activity while he waits.**

Players enjoy many other aspects of games with emotions outside of flow's balance of difficulty and skill. To enhance a player's sense of progress as play continues, games offer new tools or abilities along with new obstacles, constraints, and tradeoffs to maintain interest. Levels divide challenge into gradually increasing amounts of difficulty. The difficulty also increases inside each level, with most levels ending in a "boss monster" final challenge similar to a major plot point in a story. Defeating boss monsters or boss puzzles produces fiero, and the start of the next level is often dramatically easier to provide emotional relief. The best-selling game, *Halo*, uses Hard Fun to enhance a player's performance by the way it breaks a variety of challenges into levels, rewards progress, provides power ups, such as new weapons or armor, and adds new vehicles to offer fresh strategy options (Figure 31.10).

In fiero, the ultimate game emotion, the sensations are powerful. It is how players feel when they beat the boss monster or make level 20 after difficult struggles, or when they win a tennis match at Wimbledon. As fists punch the air, a victorious player screams, "Yes! I did it!"

In XEODesign's play lab, fiero appears as a positive upward gesture of the arms or body after succeeding a challenge. Some players jump their characters up and down to express this emotion. (*Source:* Lazzaro, N. 2004b. In *Proceedings of the Game Developers Conference.* San Jose, California. www.xeodesign.com/whyweplaygames.html (accessed December 28, 2005)).

FIGURE 31.10 In fiero a player raises an arm to show her excitement. (Courtesy of XEO Design. Copyright © 2004–2007 XEODesign, Inc. All rights reserved.)

31.4.3 Hard Fun Creates Challenge with Strategies and Puzzles

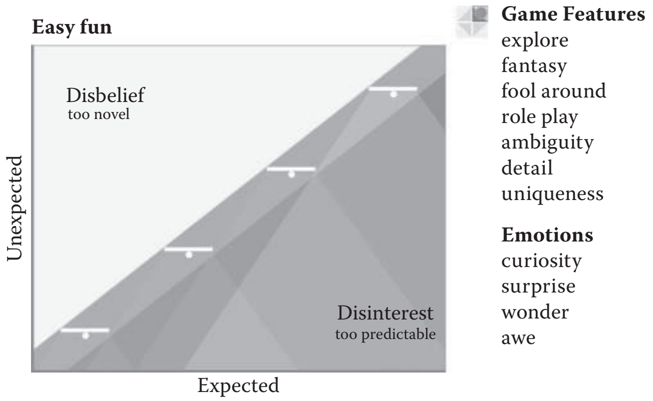
Central to the enjoyment of Hard Fun is the creation and testing of strategies, applying creativity, and the development of skills. While some players focus on the goal, many enjoy the process of learning how to win or take pride in how much better they play with each repetition of the game. Unlike real-world sports such as baseball, computer games increase the challenge by changing the rules and winning strategies between levels to keep the emotions from gameplay fresh. Players must strategize to find new ways to play. Rather than requiring more points in less time, best-selling games such as *Collapse* keep players engaged by making a winning strategy obsolete a few levels later (Lazzaro 2004b). The process of devising new strategies or solving puzzles in new ways is something that players like most about games. The success and failure of these mental tasks and the increase in player skill all create Hard Fun emotion and help players stay engaged and playing.

31.5 CURIOSITY FROM EASY FUN GAMEPLAY

31.5.1 Curiosity Retains Attention

> "Part of the enjoyment comes from the spy technology . . . cool spy tools are part of the Spy experience."
>
> **—Xavier playing *Splinter Cell***

Less apparent but equally important to Hard Fun, top-rated games offer a lot of gameplay outside of or en route to a goal. Easy Fun is a self-motivating activity that maintains player engagement through novelty beyond an obstacle, goal, or score. Easy Fun offers novel interaction to inspire player curiosity to explore, fantasize, and role play. By balancing what is expected and unexpected, careful game design prevents the player from quitting from either disinterest or disbelief. Easy Fun derives from the ability to explore and create exceptional experiences unavailable in the real world. The emotions of curiosity, surprise, wonder, and awe surrounding Easy Fun capture and retain the player's attention, as opposed to Hard Fun where the emotions of frustration in hopes of fiero help players focus on and apply effort toward attaining a goal (Figure 31.11).



Gameplay that fills attention through novelty to inspire curiosity.

FIGURE 31.11 Easy Fun emotions maintain player attention without challenge through novelty and inspiring fantasy. Similar to Csikszentmihalyi's concept of flow, players will leave a game because of disbelief or disinterest. To maintain player interest, the game design must balance the expected with the unexpected. The player experience profile of Easy Fun includes curiosity, surprise, and wonder. (Courtesy of XEO Design. Copyright © 2004–2007 XEODesign, Inc. All rights reserved.)

If Hard Fun revolves around goal achievement, Easy Fun focuses attention by offering opportunities to explore, get lost in a fantasy, role play, or simply horse around. With compelling Easy Fun, the player ignores the goal completely or forgets about keeping score. Easy Fun players find rewarding, open-ended activities on top of the game's main goal. The so-called sandbox play patterns capture player attention and pull players into deep states of immersion through curiosity instead of daring them with challenge. Best-selling games offer opportunities for interaction through unusual yet enjoyable behavior of the controls and novel interaction with the world. Players become fascinated just by interacting with the game, such as being able to flip a car off freeway exit ramps in *GTA* (*Grand Theft Auto*). Like the fiero from Hard Fun, Easy Fun has positive peak emotions that reward play such as surprise, wonder, and that "ah-ha" feeling from figuring something out. However, unlike Hard Fun none of these Easy Fun emotions require frustration. Story can often generate the emotions of wonder and surprise, but role-playing and a player's own discovery through exploration create these emotions on a much more personal level. Positive affect encourages creativity and exploration of alternatives (Norman 2004) that opens the player up to free associations and other possibilities. Easy Fun emotions focus on filling player attention.

Close examination of the conditions, causes, and relationships between emotions provides opportunities for game designers to create even bigger emotional responses in players. It is not that a player cannot feel curious during Hard Fun; but with Easy Fun, curiosity and the sheer joy of interaction drive the player rather than only the score, as it is in Hard Fun. Like improv theater, Easy Fun in games such as *Grand Theft Auto* makes offers to players such as a car and a plate-glass store window. It is up to the player to accept this opportunity and discover how the car and window interact.

31.5.1.1 Chain of Easy Fun Emotions Increases Enjoyment

Open-ended gameplay creates Easy Fun emotions and increases immersion in an activity (Figure 31.12).

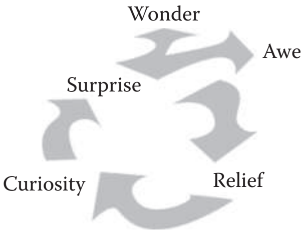
31.5.2 Easy Fun: The Bubble Wrap of Game Design

> "In real life, if a cop pulled me over I'd stop and hand over my driver's license. Here I can run away and see what happens."
>
> **—Xavier playing *GTA Vice City***

Easy Fun is the bubble wrap of game design. It is fun without a purpose. Easy Fun provides novel opportunities for

Chain of Easy Fun Emotions Increases Enjoyment

Unstructured sandbox play creates Easy Fun Emotions that reward players outside of challenge and keeping score



Easy Fun offers emotions surrounding the unique. Games provide a sequence of emotions, often starting with curiosity then creating surprise. Easy Fun can sometimes create wonder or awe if the effect is particularly strong.

Emotion	Common Themes and Triggers
Curiosity*	Unusual, unresolved situation that peaks player's inquisitiveness (Ekman 2003). Something that players find strange, odd, or intriguing, such as *Myst*'s surreal ship-rock island.
Surprise	Sudden change. Briefest of all emotions, does not feel good or bad, after interpreting the event this emotion merges into fear, relief, and so on. (Ekman 2003), such as when matching two blocks clears the whole board.
Wonder	Overwhelming improbability (Ekman 2003). Curious items amaze players at their unusualness, unlikelihood and improbability without breaking out of realm of possibilities, such as in *Myst*'s linking books.
Awe	Combination of wonder with a fear and dread (Ekman 2003), such as a beautiful but impossibly powerful dragon or female warrior in *EverQuest*.

* Not all researchers including Ekman recognized curiosity or interest as a universal emotion with a distinct facial gesture. However, those who did recognize it saw the emotion indicated by a lifting and drawing together of the inner eyebrows. In our research, we saw it frequently combined with leaning forward. It was also a feeling reported verbally by players (Lazzaro 2004b).

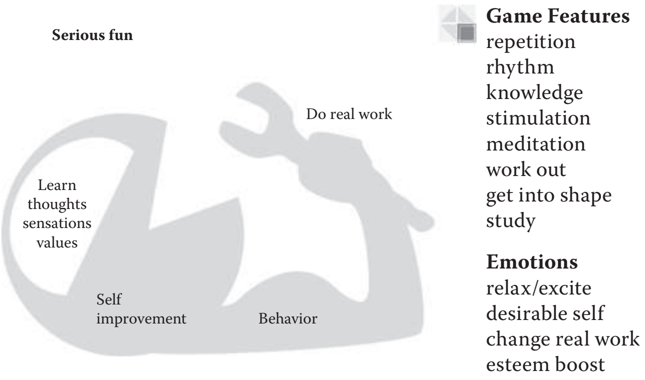
FIGURE 31.12 Easy Fun Emotion Cycle. (Courtesy of XEO Design, Copyright © 2004–2007 XEODesign, Inc. All rights reserved.)

interaction that players "discover" alongside of or outside of the main play. The enjoyment and label for Easy Fun comes from the way players goof around, frolic, explore, and play with an ease they do not have when pursuing a specific winning condition as with Hard Fun. Best-selling games such as *GTA, Halo*, and *Myst* offer numerous opportunities for Easy Fun so that when the challenge gets too tough or loses its appeal, the players have many other things to do that create emotional responses. A big role of Easy Fun in best-selling games is to refresh the player between or in the middle of challenges. In *Halo*, for example, players can cycle between the Hard Fun of combat and the Easy Fun of exploring a ring world. The game's battlefield is on the inside of a ring-shaped planet, which inspires curiosity as players investigate as they approach a horizon that instead of dipping down from view, dips up overhead. Easy Fun also provides interest when players pursue the opposite direction of a game goal such as putting the Sims in the pool and removing the ladders in *The Sims* or placing predator and prey animals in the same pen just to see what happens in *Zoo Tycoon* (a flurry of dust and the prey disappears). Through exploring both what's right and what's wrong, games offer more opportunities for emotion, especially from violating norms. In addition to relief from challenge, Easy Fun prevents progress in gameplay from feeling like a skeleton of correct decisions. Easy Fun reinvigorates emotionally and often reinterests the player in the goal. By offering both kinds of fun, the game extends the average play session and lets the player self-regulate the challenge if the Hard Fun becomes too hard.

> "The journey is the reward."
>
> **—Design philosophy at Cyan, creators of *Myst***

The emotions from Easy Fun both inspire and satisfy a player's curiosity. To create the emotions of curiosity, surprise, wonder, and awe in addition to novelty, Easy Fun gameplay uses juxtaposition, where contrast between items or events requires the player to investigate. Like Magritte's surrealist painting, "This is not a pipe," a player of *The Sims* must interpret the Siamese pictograph language spoken by the characters. The player projects in and provides an explanation for any conversation between Sims. The Easy Fun of games provides opportunities for fantasy and role play. Players can take elements of the game and do their own thing with them whether it is wielding an orc's mace in *World of Warcraft (WOW)* or donning a superhero's cape in *City of Heros*. Games also reward player curiosity with details such as in Cyan's *Myst*. In addition to the Hard Fun of puzzles, *Myst* offers Easy Fun gameplay from exploring worlds. To encourage players to slow down and notice, *Myst* provides numerous small details in the environment that reward closer inspection and encourage a slow, careful gameplay style.

Instead of running through at top speed, players spend more time exploring and looking for clues to solve the mystery. This supports the style of interaction needed to play and win the game. In addition to detail, *Myst* captures player attention through ambiguity in the setting, surrealistic juxtapositions such as the boiler room inside a tree, linking books, and faded sketches of other wondrous technology. The conflict that creates emotional tension in Easy Fun is often between what the player knows and does not know. Easy Fun offers detail that rewards player exploration and paying closer attention. Because challenges can feel like a grind, Easy Fun refreshes and provides new and interesting things to do in the game. Easy Fun provides novelty to keep play open ended and interesting not because players wonder about whether they have "the stuff" it takes to reach a goal, but simply to make the player experience interesting, surprising, and far from routine.



Gameplay that changes the self and the real world.

FIGURE 31.13 Serious Fun creates emotions to engage in activities that players hope will change how they think, feel, and behave or that will accomplish real work. The player experience profile of Serious Fun includes relaxation, excitement, boosts in self-esteem, and the satisfaction from a job well done. (Courtesy of XEO Design, Copyright © 2004–2007 XEODesign, Inc. All rights reserved.)

31.6 RELAXATION FROM SERIOUS FUN GAMEPLAY

31.6.1 Relaxation Changes How Players Think, Feel, and Behave

"Playing helps me blow off frustration at my boss."

—A hard-core *Halo player*

In Serious Fun, people play games with a purpose (Figure 31.13). They play to improve their lives by changing how they think, feel, or behave. The enjoyment motivates continued engagement with an activity that brings the desired results. The Serious Fun in games reliably relaxes or excites gamers as they play for a purpose to change the player's internal state, develop good habits, improve self-esteem, learn, or do work outside of the game itself. In Serious Fun, the entertainment value captures attention from the emotions surrounding the human values expressed through the act of play. Almost like therapy, players report unparalleled states of concentration and focus during play, making this shift in emotional state one of gaming's biggest takeaways. Whether the activity is fast-action with lots of explosions or slow-paced colored-block matching, players play to experience feelings of excitement, blow away frustration, "get perspective" on their troubles, or create a meditative experience. The stimulation and concentration required drives out bothersome thoughts. Some players simply want to feel more relaxed, excited, or less bored. Players look for a physical and mental workout such as exercise in *Dance Dance Revolution*, heightened reflexes in *Project Gotham Racing*, or an increase in mental acuity from word games such as *Bookworm*. Positive and negative affect from play guides the player toward correct moves, and negative affect increases the perceived pace of the game. Real-world benefits include releasing stress therapeutically, learning new vocabulary or math, improving physical fitness through exercise, and increasing a player's mental agility, which some players believe wards off the effects of aging. Physical movement also creates an emotional release felt after exercise and positive feelings from learning and accomplishing tasks in an engaging way. Games played for any of these reasons offer Serious Fun.

Players play to change themselves. Serious Fun is similar to Easy Fun in that players enjoy immersion rather than challenge. However, one aspect of enjoyment many players prefer is achieving a purpose outside the game experience itself such as the ability of the game to calm or excite them. As in Easy Fun, players want the game to fill their attention, but Serious Fun focuses on players' affects long after the game is over. The term Serious Fun captures the real effort and intent that players expend to alter their internal states, express their values and beliefs, and improve their real-world skills. Without Serious Fun, a game leaves few long-lasting effects and the play experience feels more like a waste of time. Playing may be hard or easy, but what is important to many players is that the effects of a game last long after the game is over.

31.6.2 Chain of Serious Fun Emotions Increases Emotions

In Serious Fun, many players play to change how they feel, and they take different emotional paths to get there (Figure 31.14).

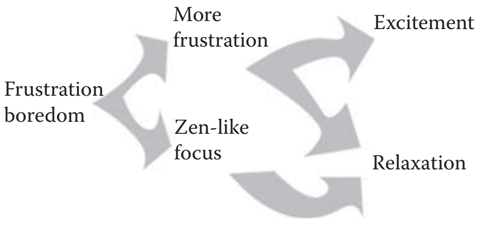
31.6.3 Serious Fun: Enjoyment Helps Accomplish Real Work

"I felt better about playing [crosswords] because it's good for me. If someone would tell me *Tetris* was good for me I'd feel better about playing that."

—Ellen on doing crosswords. She believes the memory demands of the game will keep her mentally sharp and delay the onset of Alzheimer's disease.

Chain of Serious Fun Emotions Increases Enjoyment

Gameplay that changes how a player feels, thinks, or behaves creates Serious Fun emotions from creating something players value.



Emotion	Common Themes and Triggers
Excitement	From sudden changes, novelty, and challenge (Ekman 2003). The unexpected catches attention. Many players enjoy the adrenaline rush. Some want to raise their state of arousal, others like how the emotional intensity makes them more relaxed afterwards.
Relaxation	Relief from negative emotion (Ekman 2003). Gamers often start a game to attain relief from negative emotions and thoughts prior to playing.

* Self-esteem and knowledge acquisition and the result of exercise are not emotions, but changes in a player's internal states that are reported as desirable results from play (Lazzaro 2004b).

FIGURE 31.14 Serious Fun Emotion Cycle. A large part of the appeal of games comes from how they change the player inside. This is referred to as Serious Fun. Here a player starts in one of two emotional states and plays a game to end up feeling different. Many gamers appreciate real-world benefits from play. Some play games to become deeply immersed in a process that they hope will change them long after the game is over. (Courtesy of XEO Design. Copyright © 2005–2007 XEODesign, Inc. All rights reserved.)

Serious Fun teaches or accomplishes real work. Learning-type games, from multiplication to database administration, utilize emotion to encourage the learning of important content or to provide a mental workout, as in an effort to prevent Alzheimer's. Relaxation and excitement make it easier for the player to focus. Serious Fun provides emotions and opportunities for success unavailable to the player in real life by offering a cheaper, safer, more rewarding experience with the content or activity. Rescue simulations can train firefighters about situations that are too dangerous or expensive to do in real time. In educational games such as *DBA Day* (an Oracle workplace simulation XEODesign worked on) players role play a database administrator, including managing their own time. Gee argued that mastering any simulation requires mastering the content embedded in that simulation. By making decisions for the character in a simulation, he believed that simulation games also teach the morals and values of that character coming from their merged identities. The player makes the decisions and the game character has the special abilities to make changes in the virtual world (Gee 2003). These provide learning opportunities, whether it is values and actions of a thief in *Sly Cooper and the Thievius Raccoonus* or a restaurant owner's time and people-management skills in *Diner Dash* (Lazzaro 2005b). Serious Fun provides real benefits from play by using game-like structures to reward concentration and focus attention on an activity that is good for players. Leap Frog's *FLY* pen-top computer helps students with their Spanish vocabulary by offering a verbal translation of words written in English; hearing it spoken in another language motivates practice.

Games offer a new spin on learning by capitalizing on player emotion and interaction to create customized training. *Mavis Beacon Teaches Typing* motivates typists with typing games, such as keeping ants out of a picnic basket or driving a racecar. In addition to explicit learning games (such as Oracle's *DBA Day* or an unrelated project, *Doom DBA*), games also embed techniques to offer players more immersive instruction. The introductory experience in *Halo* not only provides a seamless introduction to the user interface by integrating it into the story, but also adjusts the controls to meet the player's preferences without a dialog box. In *Grand Tourismo*, a detailed car-racing simulation game, the opening time trials break down racing skills, such as cornering, into small, easy-to-master steps that fit together to create a more enjoyable practicing experience. By providing a motivating alternative to accomplishing an otherwise boring or unmotivating task, Serious Fun helps players accomplish real-world objectives such as getting in shape. Someone may play *Dance Dance Revolution* for the excitement of moving to the music, to lose weight by burning calories, or to learn the physical skills and coordination required to dance better. Others play *Karaoke Revolution* to learn how to sing.

Games even make work fun. Players pay for the experience of being a waitress (*Diner Dash)*, business owner (*Lemonade Tycoon*), dungeon master (*Dungeon Keeper*), professional sports player (*Madden Football*), or theme-park owner (*Rollercoaster Tycoon*). They even buy the opportunity to sort bugs by color (*Tumblebugs*), pick up their rooms (*Katamari Damacy*), or manage a city (*Sim City*). Games model life problems (*The Sims*) and improve performance during real work. In *The ESP Game*, developed at Carnegie Mellon University, people play a guessing game to enliven the otherwise boring task of providing text labels for images (von Ahn and Dabbish 2004). Idea or prediction markets use games to beat expert opinion polls. Prediction markets allow participants to express their opinions through buying and selling shares with either virtual or real money. One of the oldest, the University of Iowa's *Iowa Electronic Market*, has allegedly beat expert polls in predicting U.S. presidential elections since 1988. Players of the *Hollywood Stock Exchange* use virtual money to predict what actor, director, or film will receive an Oscar nomination. At *NewsFutures*, players compete for prizes based on their ability to predict news events. Several companies, such as Google, use internal markets to predict launch dates and job openings. Other companies such as Newsfutures/Lumenogic have created public prediction markets and led the development of enterprise-class prediction market services. In a landmark study in 2004, it was demonstrated that play-money markets can be just as predictive as real-money ones (Servan-Schreiber et al. 2004). Not without controversy (gambling is illegal in many countries), markets have even been proposed to predict terrorist attacks (Hulse 2003). Because playing prediction markets accomplishes a real purpose, it changes how participants feel about playing in general. Like offering a prize for a competition to develop a solar car, having real money or reputation on the line increases the excitement. In Serious Fun, players accomplish real work for many reasons, including to meditate, lose weight, label every image on Internet, or beat Wall Street predictions.

31.7 AMUSEMENT FROM PEOPLE FUN GAMEPLAY

31.7.1 Amusement Encourages Social Interaction

> "It's the people that are addictive, not the game."
>
> **—Bob, a hard-core sports game player**

One advantage that a computer game has is that it is ready to play when you are. No friend required. Still, for many people it is the experience of playing with friends or family that makes play worthwhile. Group gaming provides a mechanism for social interaction, a quick excuse to invite friends over, and more challenges to gameplay. People Fun creates amusement between gamers as they play to spend time with their friends. People report playing games when their friends do, playing games they do not like, and even playing the types of games that they do not like playing just to spend more time with their friends (Lazzaro 2004b).

> "Since we lost half our guild to Star Wars Galaxies it's not as fun."
>
> **—A hard-core gamer playing *Dark Age of Camelot***

People Fun is a self-motivating activity that maintains player engagement by supporting interaction with other people (Figure 31.15). People Fun encourages interaction with other players as they establish social hierarchies, joke, and develop social bonds. It creates affect by providing opportunities to cooperate, compete, and watch others play. Some emotions, such as gratitude, generosity, and *schadenfreude*, the German word for "pleasure at the misfortune of a rival" (Ekman 2003), cannot occur while playing alone. When people play together they invent new ways to interact, develop house rules, and add their own content to create more pleasure for themselves and their friends.

Gameplay that involves others to create emotion between players and increase social bonds.

FIGURE 31.15 People Fun creates emotions that increase a player's enjoyment from social interaction. The player experience profile of People Fun includes many emotions that require two people such as schadenfreude, amusement, naches, and gratitude. (Courtesy of XEO Design. Copyright © 2004–2007 XEODesign, Inc. All rights reserved.)

The most emotion from games arises when people play together in the same room. Whether playing in a living room or cyber café, the frequency, duration, variety, and intensity of emotional displays all increase (Lazzaro 2004b). The emotions of schadenfreude, amusement, and *naches* (Yiddish for the pleasure and pride felt when a child or mentee succeeds) occur more frequently when playing with others. Playing over the Internet, even with video or voice chat, elicits fewer emotional displays than when playing in the same room. A major reason behind this increased emotion is that being in the same room allows for additional interaction between players beyond what is available in the game alone. Players exchange insults and outdo each other with witty commentary. They add content and new rules as real time presence allows for more flexibility (Lazzaro 2004b). Considered in light of Ekman's nine pathways to creating emotions (Figure 31.16), People Fun uses more of them than Hard Fun, Easy Fun, or Serious Fun. In fact, the last five out of the nine in Figure 31.16 are enhanced in group face-to-face play.

31.7.2 People Fun: Creates More Emotion When Playing Face to Face

> "Enjoyment when your friends blow up."
>
> **—Pat, a PS2 gamer on his favorite game emotion**

The involvement of others increases the complexity of the game by creating cooperation and competition, which in turn increases the emotions from play. Different roles for players with shared and opposing objectives increase player interaction. Achieving a goal with a simple rule set becomes exponentially more complex when a player's opponent is another person or group. Not all players like the feelings of rivalry from competition with their friends. Many prefer to team up with their buddies to compete against computer-controlled characters. To encourage group formation, Massively Multiplayer Online Games (MMOs) often have interdependent classes of players, a design that comes from the *Dungeons and Dragons* paper-based role-playing game. In these games, such as *WOW*, character classes encourage the formation of groups, and treasure quests and dangerous dungeons require players to pool their characters' specializations such as archers, swordsmen, hunters, paladins, wizards, and healers. Improved success rates and score bonuses reward players working together in the game and help form the social bonds that increase a player's emotional attachment to the game (Figure 31.17).

Nine Pathways to Emotions

(Ekman 2003)	Example from Games
1. Auto appraisal	Explosions, fire, and boiling lava
2. Reflective appraisal	Thinking about last night's dungeon raid
3. Memory of an emotion	Remembering falling from a cliff
4. Imagination	Thinking about what happens from falling off a cliff
5. Talking about	Discussing game events with other players
6. Empathy or witnessing another's emotion	Another player's facial expression or character emote
7. Instruction by others on how to feel	Another player's assessment of an event
8. Violation of social norm	Driving over other players instead of racing against them
9. Making a facial expression of an emotion	Smiling and laughing after defeat in front of friends makes it feel more positive

FIGURE 31.16 There are nine ways to create emotions in a person.

People Fun keeps players going by providing new ways for players to interact. It provides a variety of player-to-player outcomes and bright spectacles for the audience. It provides the opportunity to perform difficult maneuvers and stunts that reward practice with which to amuse and amaze friends. In *Soul Calibur II*, players interact with each other by fighting rather than racing side by side to beat the clock. The frequency and the variety of player-to-player interaction increase commentary between players and make it more enjoyable for an audience to watch. Spectators can participate throughout with comments and criticisms. People Fun games with hidden aspects, special moves, cheat codes, and Easter Eggs (hidden games, objects, rooms, or animations) offer even more opportunity to impress friends. All of these create admiration and envy between players (Lazzaro 2004b).

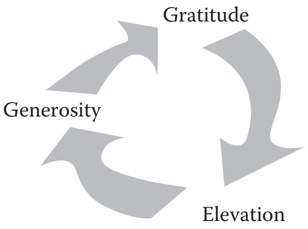
31.7.2.1 Some Emotions Require Two People

People Fun wins out over other types of gameplay with its exclusive access to emotions that require two people, such as schadenfreude and naches. The most frequent emotion in co-located group gaming is amusement. In a group context, even negative events are sources of laughter. The feeling of naches and emotional attachment created in *Nintendogs* (a puppy simulation game for the Nintendo DS) are so strong that they not only created a best-selling title, but the title's popularity increased the sales of the hardware platform as well.

People Fun in games is also present in interaction with characters on screen. It enhances emotions with facial expressions

Chain of People Fun Emotions Increases Enjoyment between Players

People Fun motivates group interaction, interpersonal relationships, and creates emotions between players.



Emotion	Common Themes and Triggers
Amusement	Something that's funny. (Ekman 2003). Regardless of the emotional tenor of the game, people in groups laugh more than when playing alone.
Schadenfreude*	Pleasure over misfortune of a rival (Ekman 2003). Competitive players enjoy beating each other, especially a long-term rival. Boasts are made about player prowess and ranking.
Naches*	Pleasure or pride at the accomplishment of a child or mentee (Ekman 2003). Players enjoy seeing friends succeed as well as the achievements of nonplayer characters they have helped, such as in *Back to Baghdad*, where players can exchange health packs.

* Schadenfreude and naches do not have universal facial gestures; however, they are frequently described by players (Lazzaro 2004b).

FIGURE 31.17 People Fun Emotion Cycle. In People Fun, some emotions link together like a chain between players, such as offering a healing spell or health pack (generosity) to a fellow player in need (gratitude). A third player feels elevation at witnessing this human kindness and becomes more likely to be generous. Next time a different player may be in need and the links on this chain would rotate. In this way, one game mechanic offers three emotions depending on who starts the chain. (Courtesy of XEO Design. Copyright © 2005–2007 XEODesign, Inc. All rights reserved.)

for nonplayer characters (NPCs) as well as for player-controlled characters. In *Diner Dash*, players not only have to react to changes in characters' facial expressions but to win the game requires managing customer emotions to prevent them from getting so angry that they leave (Lazzaro 2005b). Games such as *World of Warcraft* increase emotions between players by offering emotes and chat features. Adding voice and video communication between players increases emotions, and co-located group play takes this one step further by supporting face-to-face collaboration in addition to face-to-screen.

31.7.3 Players Modify Games to Enhance Emotions during Group Play

In People Fun, players like playing together so much that they create house rules and convert single player games to make group play more enjoyable. In order to play a *Buzz Lightyear* game together, one family assigns each person a different key to run, jump, or shoot. To share in a pirate adventure, one set of three college students plays *Sid Myer's Pirates!* game by taking turns. In a bike-racing game where players outnumbered the controllers, the winner is the player who "ran the gauntlet" and beat all challengers in the room, not by winning the race, as that would take too long, but by out-distancing each opponent. This said, some players eschew contact with other people if they mostly care about developing strategy or understanding how to play better. To them, playing a game such as *Hearts* online is better when played alone because they do not want to chat or posture with players that they do not know. Such players prefer the Hard Fun even in multiplayer games. Whether it is *WOW* or *Spades*, and depending on their mood, some end up soloing rather than joining a group.

31.8 EMOTION FROM ENTERTAINMENT INTERFACES AND INTERACTIVE PRODUCTS

The Four Fun Keys—Hard Fun, Easy Fun, Serious Fun, and People Fun—play an important role in making games self-motivating. They provide the opportunity for challenge and mastery, prospect for exploration and discovery, give a boost to self-esteem and an excuse to spend time with friends. The gameplay in games capitalizes on the interaction between human emotion, thought, and behavior. From this perspective, productivity applications have the same goal. Productivity applications take for granted that the user provides the motivation for using the tool, such as workplace responsibilities or a boss's deadline. The compelling and enjoyable nature of computer games makes the process itself enjoyable, so game designers spend a great deal of design effort to ensure that their games provide a rich emotional experience during play. Study of these interactions offers clues as to how to make productivity tools more motivating without making it a game. The importance of emotions in design is that emotions can influence when, how, and why to use a product.

31.8.1 Game-Inspired Affect Makes Product Use More Entertaining

Games offer many lessons for product-interaction design outside of entertainment, especially in the relationship between design and emotion. Software should make tasks easy by requiring just a few steps and providing appropriate emotional stimuli to focus and reward the user for completing them. One of the biggest differences between productivity software and software used for entertainment is that the pleasure and motivation come from accomplishing outside tasks, such as completing a spreadsheet or creating a database. Emotions in nongames should create enjoyment, aid decision making, focus effort and attention, and provide motivation. Like games, it is possible to design interactions that are similar to all four types of fun to create a wide spectrum of emotions in nongame software (Figure 31.18).

31.8.1.1 Playful Product Attributes Increase Emotions during Use

Many products employ novel opening techniques to increase customer appeal. Beyond "out-of-the-box" experiences, the experience of the product in use is becoming an important part of a product's competitive advantage. Similar to the way packaging frames consumer expectations and emotional associations with a product, how a product opens or switches on can create emotions and other associations every time the product is used. For example, Danger's *Sidekick* cell-phone lid spins open horizontally with a snap. The *Robo-Book* Light surprises by unfolding like a mechanical arm. The nozzle on *All* liquid laundry soap dispenser features a bright red rubber

Creating Affect through Actions for Nongames

Hard Fun

Affect to increase focus on and enjoyment of a task:
Spreadsheets
Word processing
Time management
Decision support

Easy Fun

Affect to capture attention and enjoyment:
Data mining
Searching
Multivariant problem solving
Creativity support

People Fun

Affect to facilitate the interaction and cohesion between individuals:
Cell phones
E-mail
Human-resource and project-management applications
Groupware
Presentation software

Serious Fun

Affect to help user to accomplish a lot of work consistently over time:
Learning tools
Therapies
Medical devices
Cleaning products

FIGURE 31.18 The affect from the Four Fun Keys can increase emotions and enjoyment for several kinds of productivity-software applications and consumer products. (Courtesy of XEO Design. Copyright © 2004–2007 XEODesign, Inc. All rights reserved.)

ball to squeeze for detergent. The designers at IDEO transformed the tiered old carpet sweeper to create the *Swiffer Carpet Flick*. The *Carpet Flick* combines a free-flowing universal joint at the head (Easy Fun), a transparent body so customers miss none of the action (Hard Fun's feedback on goals), and accomplishes real work in an enjoyable way (Serious Fun). The buttons on some productivity software offer Easy Fun if they glow or highlight when moused over. A hard disk defragmenting utility displays progress with an animation that is mesmerizing and game-like to watch, as the colored segments are organized and grouped together. None of these products are games, yet all of them offer Easy Fun with novelty to inspire curiosity, surprise, and a little wonder. Regardless of whether it is a productivity application or a trash can, if it creates enjoyable emotions, it will be used more often and shown off to friends (People Fun).

Breath-relaxation techniques are more effective if practiced daily. To encourage frequent use with Serious Fun the *Stresseraser* (a home-therapy device that provides bio feedback on the user's pulse and breathing exercises) uses both Hard Fun and Serious Fun. The device rewards customers with a point system and game-like chart feedback of their pulse data. The use of a display graph and a gradual increase in number of points earned per session encourages use by offering Hard Fun and Serious Fun at the same time.

> "Why not challenge yourself to see how good you can make yourself feel by getting 100 or more points a day for two months?"
>
> "A session of 30 or more points is a great way to start the day off right. Especially on days when you feel like you got up on the wrong side of the bed."
>
> **—www.stresseraser.com**

The catalog copy on the company's website frames customer expectations in terms of Hard Fun. The game-like intent of the product designers is even more evident in unreleased game modules where customers float a bird around obstacles as a reward for reducing their pulse (Fabricant 2005). Their approach to relaxation is not about building frustration to eventually succeed through their skill to feel fiero. Instead, with the *Stresseraser*, as in the Interaction Institute's *Brain Ball* game (Hjelm 2003), people win by relaxing and taking deep breaths. For these products goals and feedback allow players to monitor and change their own emotional state for Hard Fun and Serious Fun.

31.8.2 Designing Game Affect for Entertainment Access

31.8.2.1 Playful Interaction and Feedback Facilitates Entertainment Access

Game-inspired affect increases the appeal of entertainment applications such as televisions, game consoles, e-zines, and music players. Because the primary customer goal is to locate content, accessing entertainment options need not be a game in itself. However, entertainment devices can have a game-like feel. They should be even easier to use than productivity applications, because they don't borrow motivation from completing an outside task. They should also create excitement about the entertainment options they provide.

Since the beginning, graphic-user interfaces have employed metaphors such as windows, trashcans, and elevators to explain how features work. Apple's Macintosh OSX operating system established a new trend in modern interface design by going beyond the clear explanation of function to creating an experience. Mac OSX is an interface that is "fun" to use. The dock magnifies icons under the cursor to make them easier to select, at the same time creating pleasurable animation that is pure Easy Fun, even without the goal of opening an application. The genie-out-of-a-bottle animation of document windows as they expand out of a tiny icon on the dock offers more Easy Fun to create curiosity, surprise, and wonder. Operating these features entertains all by itself.

31.8.2.2 Creating Emotions in Entertainment Access: Apple's iPod Case Study

The most game-inspired device to come out of Apple is the iPod. The iPod's novel combination of hardware and software interfaces creates a new experience full of affect. The novel interaction facilitates entertainment access by offering a customer experience unlike any other. While not technically a game, the iPod uses Hard Fun, Easy Fun, Serious Fun, and People Fun to create emotional experiences for the user.

Central to the user experience of the iPod is the control wheel. It attracts attention and creates emotions of Easy Fun such as curiosity and surprise. Its novel round motion easily scrolls through long play lists. Emotions arising from exploring the free-flowing motion focus attention on finding a song. The quick feedback (including a separate speaker just for the scroll clicks) enhances the sense of mastery (Hard Fun) as a customer gains control. It feels like a game. Even without pressing play, scrolling is enjoyable because using the four directional buttons and wheel mimic a game controller. In addition to the form resembling a stereo speaker, the circular DJ Scratching action takes advantage of an action already associated with making music more exciting and even offers an opportunity to role play for more Easy Fun. The music visualizations on the companion iTunes software offer fascinating animations in time with the music.

A game of *Bricks* (similar to *Breakout*) shipped as an Easter egg (hidden game) in the first edition and later more elaborate games such as Zuma under their own games tab further established the iPod's connection to fun and enjoyment. As easy as the iPod is to use, users must experiment and might experience frustration in learning to understand the menu hierarchy. This offers opportunities for Hard Fun as customers search for their favorite track. Users may experience a feeling of accomplishment rather than fiero when they succeed, but the dancing black silhouette models in the iPod's ad campaigns frolicing with arms overhead clearly evokes fiero and other kinds of joy. That the iPod offers Serious Fun of mood-altering music and videos is a given. For additional Serious Fun, iPods also play business-audio books and offer file storage to do the real work of transporting documents and spreadsheets along with music files. The trademark white headphones offer emotions from People Fun even while separating from others auditorally by sending a clear message about the fun-loving social group to which an iPod customer belongs. These status-symbol icons create People Fun emotions from association with belonging to the "in crowd" as well as the emotions expressed in the ads. Several iPod accessories allow customers to share their music during playback. And iTunes' trading of play lists, creation of custom CDs, and podcasting all provide ways for iPod users to reach out to other people for more People Fun.

31.8.2.3 Creating Emotions in Entertainment Access: Microsoft's Xbox 360 Case Study

31.8.2.3.1 Ready to Inhale

The designers of the Xbox 360 video game platform had a specific customer experience in mind. Whereas the design inspiration for the first Xbox was like the Hulk bulging with muscles to break out of a box, the Xbox 360 was to be more of an inhale, like Bruce Lee drawing breath in preparation for play, poised, and ready to strike. Instead of a file-and-folder metaphor, the main UI for the video-game console is designed to capture a moment of preparation before the challenge. The idea was to avoid fussy animations, yet provide something interesting and intuitive to get the player emotionally ready and mentally focused before play begins. The Easy Fun of navigating the menus increases immersion. The emotions for this interface match the player's goals during this part of the use cycle.

In terms of Easy Fun, the menus for the Xbox 360's main UI curve sideways like rib bones and mimic the gesture of inhalation as they move. The menus slip from side to side in a breathing-like motion. The sounds are organic and whip-like with a satisfying thump at the end as the menu snaps into place. This novel auditory and visual experience makes the menus enjoyable to explore without becoming too complicated or intrusive. Novelty of the sideways menus creates curiosity and encourages exploration. The designers were going for playful (the attitude in games) without being so entertaining as to be a game in itself. It is about providing very simple access and a pleasurable experience that creates excitement but doesn't get in the way.

The most important way the Xbox 360 increases enjoyment of games played on its console is through the use of People Fun. To deliver more People Fun emotions and to foster connections between players, the Xbox 360 offers community features for all its titles. Gamers can create their own persistent player profile (or gamer card) that spans game titles. Personal profiles provide an in-game identity and list in-game accomplishments so friends can compare game-specific achievements, scores, and what game they are currently playing. For the nongamers in the household, the Xbox 360 allows access and display of family photos and video for a different kind of social interaction.

The emotions in these user experiences for iPods and Xbox 360s not only help customers accomplish tasks. The UIs create experiences that make the devices pleasurable to use, put users in the appropriate emotional and cognitive mindset, and capture the next level of the four pleasures that Jordan considers essential in the new human factors: (a) Physio-pleasure, (b) Psycho-pleasure, (c) Ideo-pleasure, and (d) Socio-pleasure (Jordan 2000). As the focus for HCI shifts from interface design to user experience, more accurate taxonomies for internal experiences and methods to measure these experiences are needed. The development of these tools will facilitate the design of more enjoyable player experiences. While entertainment interfaces such as the iPod and the Xbox 360 have done much to create powerful user experiences on several levels, there is still much more that is possible to do.

31.9 NEW DIRECTIONS AND OPEN ISSUES

31.9.1 New Play with Smaller, Smarter, More Flexible Devices

As technology shrinks and integrates itself into more aspects of our lives, people play more games in more places. Devices that are smaller, smarter, mobile, and contextually aware create new opportunities for electronic gaming, which until now has largely been restricted to players at home around a single screen. What happens when the services offered by a laptop become cheap enough to print on a candy wrapper? Mobile and alternate-reality gaming offer the opportunity to make things happen in the real world, which further enhances other experiences such as enjoying the company of friends and dispelling boredom while waiting in line. Games break out into the real world through geo-caching and games of tag through a city. Promotional Alternate Reality Games (ARGs), such as the *The Beast* for the movie *AI* and *I Love Bees* for the game *Halo 2*, use real-world-web-enhanced gameplay to market products and create communities of millions of players (4ourty2wo 2005). With ubiquitous computing, everything from mobile phones, to the front door, to a ketchup bottle in a diner could contain enough smarts to offer services. Will they all contain a screen and therefore the potential to host a game? Will we surf the net from our saltshaker or will it provide other opportunities to engage our attention?

Many designers chase faster hardware and better graphics, yet the emotional power of games does not occur on screen; it takes place inside the player's head. The biggest emotions that new technology will create is not through rendering blood, sweat, and tears in molecular detail. The real changes in emotional gaming will happen through supporting a more agile design process and by making gaming devices smaller, sharable, context-aware, and more accessible, such as game controllers with fewer than 12 buttons like Nintendo's *Wii*. Until we all get personal holodecks and natural language processing, the success of many new kinds of games will come from connecting the cheapest emotion generators around: a player's rivals and friends.

Life is becoming more game-like as games and elements of play inspire new dimensions of product appeal. Like games, products create experiences. Cutting-edge product designers now design customer experiences, not products, as witnessed by the iPod. Designers aim for engagement in addition to making something better/faster/cheaper and easier to use or market. Adding playful elements to goods and services increases the attraction of everything from advertising messages to Southwest Airline's in-flight safety announcements to the design of public spaces. We see the increasing importance of emotions in design of products such as the playful squid shape of the Phillip Stark orange juicer, the surprising opening rotation of Danger's *Sidekick* mobile phone, and in the pleasing octave chords produced by *Segway's* acoustically designed motors. The progress being made toward this shift toward more emotional design is even more apparent in games.

Games are already redesigning how we work and shop. Employers use games to screen potential hires for three-dimensional (3D) reasoning skills and train them to solve problems with multiple variables. Games changed consumer processes such as buying and selling on eBay or the dining experience at Dave and Busters (Chuck E. Cheese for adults). Even web software applications like Flikr (www.flikr.com) include more fun to increase appeal by sharing items between friends or by offering features to be "gamed," such as displaying the number of friends a person has in *Friendster* or *LinkedIn* (www.friendster.com; www.linkedin.com) social-networking software. Understanding how games create emotions makes products and services more engaging and enjoyable and even improves community and the quality of life.

31.9.2 Open Issues

Better design of the emotions required for and that result from interaction will unlock more human potential from using products and games by priming and rewarding users with appropriate affective states. We know that cognition and emotion walk hand in hand. We are only just beginning to discover how they support each other and how interaction creates emotion. The Four Fun Keys model starts this journey to build and examine player experiences in terms of specific emotions such as fiero from Hard Fun, curiosity from Easy Fun, relaxation from Serious Fun, and amusement from People Fun. Further measurement of specific emotions during different types of cognitive, behavioral, and emotional experiences will help piece together the role individual emotions play in cognition and activities. For example, a surprising event orients an individual's attention to determine whether the source is a benefit or a threat. Surprise does this in addition to creating internal sensations, producing facial expressions, and communicating information about the source to others. Curiosity, the lead emotion from Easy Fun, has a strong cognitive component, which also focuses attention in a pleasurable way. Satisfying curiosity especially when it results in feelings of surprise and wonder produces strong pleasurable sensations that motivate an individual to repeat the activity. Additional research will tell us how to create designs that inspire, maintain, and intensify feelings of curiosity. This is important for applications such as *Google* to improve searching the Internet or when browsing an e-commerce catalog (www.google.com). Conversely, intensifying fiero from finding the search item also improves the user experience. Informed with a deep understanding of how curiosity and frustration employ different affective states to focus attention, the design of entertainment and productivity products can achieve the next level of engagement by sculpting emotional responses that complement the tasks.

31.10 CONCLUSION

Games have the creative freedom to push technical boundaries and be light years ahead of productivity interfaces. They have been champions and early adopters of new interface techniques from joysticks to voice commands. Game interfaces lasso new hardware and experiment with dialogs and menus to deliver novel experiences with a vigor never seen in productivity applications. Mastering these innovative interaction techniques provides richer experiences that inspire a devotion to learning features. Radial menus in *The Sims*, audio menus, and draw-your-own-game interfaces in LeapFrog's *FLY* pen-top computer, the Line Rider web game, the iPod's scroll wheel, and Xbox 360's organic side-scrolling tabs are all examples of original alternatives to navigating file-and-folder hierarchies and dialog boxes. Games boast heads-up displays and voice commands to allow players to multitask (*Tom Clancy's Rainbow Six* on the Xbox) or sing (*Karaoke Revolution*). Still other games use camera interfaces that track the body's movement (*EyeToy* games, *Virus Attack* for camera phones), physical motion (*Dance Dance Revolution* dance pad, Wii Sports), and touch and gestures (*Black and White, Nintendogs, Yoshi's Touch and Go, Electroplankton, Pac-Pix*). Others use positional sensing/ubiquitous computing and motion sensors (*WarioWare: Twisted*). Games offer rich social systems for interpersonal collaboration and communication (*WOW, EverQuest*). Games even prototype future interface technology such as context-sensitive holograms to encourage cursor exploration (*Star Wars Commando*). The interface for each of these technologies supports a fresh experience.

In addition, games offer an emotional punch that has become a cultural force. The automotive industry already consults racing-game designers on how to make more exciting cars. U.S. politicians such as Howard Dean use web games to teach democracy and increase interest in their campaigns. Games are not only innovating interface design, they are also full of emotional experiments. For example, in *Fable*, the moral values expressed by player decisions change the character into a shining, blonde-haired hero or demonic devil with horns. Although not everyone plays computer games, they command a profound influence on other media and culture. Additionally, the generation raised on games (today's college students all played *Oregon Trail* in grade school) will play more games as adults than their parents did.

Games' distinct emotional processes come from what players like most during play, which informs the functional design of product and software. Unfortunately, the sole emotion goal addressed by usability is to reduce frustration. While important, this falls short of offering strong emotional rewards for accomplishing difficult tasks. Crafting these emotions contributes to user success because, when inspired by rich emotional responses, users will explore and learn more of an application's features, making them more efficient at their jobs. Over-engineering a task by making it too predictable, repetitive, and easy to complete increases the likelihood of boredom and actually reduces satisfaction over the long term. Players and workers experience huge emotional rewards for completing complex challenging tasks. It would be unfortunate if these were eliminated from the work we do as humans.

In HCI, the big mistake used to be fixing clumsy complex features with pretty background graphics. Today, the big mistake lies in believing that user experiences will improve if designers remove frustration points (usability), have the interface do all the work, and reduce the task to a series of trivial steps. Customers already have emotional reactions to their software. Designers must learn to speak this language of emotion from interaction.

The role of a good interface is to prepare users to master something difficult, then allow them to give themselves credit for mastering the difficult skill, while leaving enough ambiguity and challenge to make the task fun. What's next for user-experience design goes beyond refining features to logically support how users perform tasks. Design must also address how features motivate users through affective states to support and refresh the task at hand, not by making the software unnecessarily complicated, but by doing what games do: support sequential skill-building to achieve complex goals and encourage players to move beyond their points of failure to feel empowered masters of their own destiny. Experienced designers are already using Hard Fun, Easy Fun, Serious Fun, and People Fun by embedding emotions from goal-directed, open-ended, purposeful, and social play.

By offering life problems in miniature, games provide important clues to the relationship of emotion in human problem solving, goal achievement, and interaction with other people. Researching games clearly defines the relationships between action and emotion as well as between emotions themselves. In games, many emotions are opposites, happen in sequences, have prerequisites, and share links with others. Some emotions require people, relate to goals, or involve the future or the past. Connecting how gameplay leads to specific emotions establishes a framework for the process of creating more emotional user experiences. The Four Fun Keys Model creates effective analysis and design techniques to identify and create a wider range of emotions. It connects emotions to popular types of gameplay and demonstrates how chains of emotions are embedded or released from different activities. By harnessing play, even productivity software and workflow design can take advantage of the motivating force of game emotions.

Games are the new medium of the twenty-first century. Unlike any other design discipline, player experiences that unfold over time are more interactive than movies, painting, architecture, industrial design, literature, or fashion. Games are dynamic processes that create dynamic experiences. They are much more than a series of static impressions seen in sequence. Games offer a unique set of emotions from accomplishment and failure. At their core is the ability for players to interact with the content. The experiences that come from this interaction, the ability to create emotions, and the way that this interaction moves will separate games as an art form distinct from movies and other visual arts.

Emotions play an essential role in providing the entertainment value that captivates players. From games, we can learn how to improve the emotions that keep users engaged in activities of different types. Through player interaction and control of events, games promise to become more emotional than movies and other entertainment, but whether these are the same emotions remains to be seen. Games now include more detailed storylines to increase player engagement. However, it is clear from XEODesign's research that games create strong emotions even without stories, and it is clear that games already create more emotions through interaction with other players in the game world. Many aspects of the storytelling language of cinema apply to games and they will still move players emotionally. However, emotions from the player's goals and the things he or she cares about will likely prove to be stronger. In games, the mechanic is the moral of the story.

Releasing the full emotional potential of games will not be easy. It requires deep understanding of how emotions work, because more is known about crafting emotional entertainment experiences (such as a movie) by offering the viewer empathy with a protagonist engaged in a predetermined sequence of events. Less is known about creating emotion through being the protagonist. Viewing a prerendered video between game levels is less compelling than having the player's actions create an emotionally rich experience itself, but at the moment these mini-movies are easier to design. Going forward, these dramatic tools for creating affect should inspire rather than dictate game design. Eventually the emotional props from these cut scenes will fade from games just as title cards disappeared from old silent pictures once sound technology allowed the actors and the action to speak for themselves.

Psychology, sociology, theater, literature, film, and only recently games have all studied how entertainment engages audiences. Games are unique in that they entertain by creating emotion from interaction. Before XEODesign's research on emotion and the fun of games, none had studied how entertainment creates specific emotions and uses them to focus attention and motivate play. The Four Fun Keys Model creates the four most important sets of emotions for games. Each fun key is a collection of game interactions (game mechanics) that captivate player attention with different series of emotion that make games self-motivating. These emotion cycles create the player experience and separate best-selling games from their imitators. Based on contextual research of people playing their favorite games cross genre, platform, and gender, the Four Fun Keys describe how emotion comes from what is the most fun about games. Entertainment interfaces and products such as Apple's iPod and Microsoft's Xbox 360 already use interaction from each of the Four Fun Keys to unlock powerful emotions to increase user enjoyment and build stronger brand impressions. Interaction that generates a lot of emotion is more memorable and feels like play.

ACKNOWLEDGMENTS

Jane Booth, Brian "Psychochild" Green, Ron Meiners, Steve Meretzky, and Jeff Pobst provided detailed feedback on drafts of this chapter. 32 Motor Vehicle–Driver Interfaces

Paul A. Green

CONTENTS

32.1 INTRODUCTION

This chapter is written for professionals familiar with human–computer interaction (HCI), but not with the issues and considerations particular to motor vehicles. For non-HCI professionals, reading Chapters 1–29 of this text should provide the desired background. For automotive industry driver interface designers, this chapter should pull together information dispersed throughout the literature.

HCI is of interest to motor vehicle designers because of the rapid growth of driver information systems that utilize computers and communications, collectively referred to as "telematics." Included under the umbrella of telematics are navigation systems, cell phones, and so forth. Also important are "infotainment" systems, the combination of information systems (commonly navigation) and entertainment systems (music), a grouping that obviously overlaps with telematics. The interfaces for infotainment systems are far more complex than the two knobs, a dial, and five buttons of yore. These systems are being developed to (1) enhance public safety, (2) make transport more efficient (saving time and fuel), (3) make driving more enjoyable, and (4) make drivers more productive. It is with respect to these goals that systems are evaluated.

Although findings from research are important, this chapter emphasizes the resulting design documents and evaluation methods for driver interfaces to promote safety and ease of use. An underlying theme of this chapter is that the safety-critical and highly regulated nature of driving leads to significant departures from standard HCI practice, and to some methods, measures, and statistics that are unique to automotive applications. As this is a reference handbook, engineering practice receives more attention than scientific theory and, furthermore, given its technology focus, the design of traditional (noncomputer) motor vehicle driver interfaces (such as switches for headlights and windshield wipers) is not covered. For information on traditional interfaces, see Peacock and Karwowski (1993) or the latest edition of the Society of Automotive Engineers (SAE) Handbook (Society of Automotive Engineers 2010a,b). Readers interested in additional research literature on contemporary driver interfaces should see the proceedings from the biannual Driving Assessment conference, which occurs in the summer of odd numbered years. (For the 2009 Driving Assessment conference proceedings, see http://drivingassessment.uiowa.edu/node/17, retrieved May 22, 2010). A conference of increasing interest is the Automotive User Interfaces and Interactive Vehicular Applications Conference (see http://www.auto-ui.org, retrieved May 24, 2010).

32.1.1 What Kinds of New Features Are Likely in the Near Term?

To be able to design for systems of the future, one needs a sense of what they will be. Commonly, studies have used expert opinions to predict the future of automotive electronics, specifically telematics applications (e.g., Ribbens and Cole 1989; Underwood, Chen, and Ervin 1991; Underwood 1989, 1992; Richardson and Green 2000; Green et al. 2001). The most extensive information, however, is often contained in proprietary market surveys not for public distribution (e.g., Frost and Sullivan 2009).

Although the statistical accuracy of the proprietary market surveys is unknown, the published studies on the future are often too optimistic and, with surprising frequency, simply wrong. For example, Green et al. (2001) predicted that built-in cellular phones would be in 10% of all luxury cars in the 2004 model year. Interestingly, earlier research had rated cell phones as a low-priority feature. In part, this is because most studies are one-shot evaluations with no review of prior work to examine the basis for prior estimates and how they can be improved. Opportunities for authors to review their own estimates from previous years and generate more informed estimates are rare. Such estimates could be informed by utilizing quantitative historical sales data of vehicle various features to develop product diffusion models (Bass 1969, 2004; Mahajan, Muller, and Bass 1990, Wejnert 2002). (See also http://andorraweb.com/bass/, http://www.bassbasement.org/BassModel/.)

Although there are no firm statistics, recent research requests from manufacturers and publications in the open literature indicate there is considerable interest in audio texting/messaging and access to the web while driving for a wide range of purposes, as well as methods for music selection. A noteworthy development is real-time navigation systems for smart phones, in particular the iPhone. There is certainly the possibility that smart phones or tablets (e.g., iPad) could be the driver interface of the future. At this point, there is no evidence that these devices or applications for them are undergoing the safety evaluations required of in-vehicle devices used while driving.

32.1.2 Chapter Organization

How could one organize information on driver interfaces? In their classic paper on usability, Gould and Lewis (1985) identified three key principles to be followed when designing products for ease of use:

1. Early focus on users and tasks
2. Empirical measurement
3. Iterative design

These principles not only apply to office applications and web development, but automotive applications as well. In the automotive context, designers need to understand (1) who drives the vehicle (users), (2) what in-vehicle tasks they perform, (3) the driving task (the most important task), (4) task context, and (5) the consequence of task failures. These topics are the focus of the first part of this chapter.

Second, it is important to be able to measure driver and system performance (empirical measurement). That topic constitutes the second part of this chapter.

Surprisingly, there have been few reports of how iterative design is used in developing driver interfaces, though the approach is used. Complete attention to all three principles, however, is not common (Lee, Forlizzi, and Hudson 2008; Steinfeld and Tan 2000). Because a great deal of automotive design relies upon following design standards, that topic is the final focus of this chapter.

32.2 WHAT IS THE DRIVING CONTEXT IN WHICH USERS PERFORM TASKS?

Scott McNealy, CEO of Sun Microsystems, once said, “A car is nothing more than a Java technology-enabled browser with tires” (Kayl 2000). He is dead wrong. The author has never heard of anyone claiming, “A computer came out of nowhere, hit me, and vanished.” Yet police officers and insurance adjusters hear such claims about motor vehicle crashes every day. Likewise, the author knows of no one who has ever been killed as a consequence of operating a computer at their desk, but the loss of life associated with crashes arising from normal motor vehicle operation is huge.

According to the World Health Organization (WHO) (World Health Organization 2009), over 1.2 million people die in road traffic crashes each year, or almost 3300 per day, and somewhere between 20 and 50 million suffer injuries. WHO ranked traffic crashes as the ninth leading cause of death and the leading cause of death of adults aged 15–29. If the current trends continue, by the year 2030, traffic crashes will become the fifth largest cause of death after heart attacks, stroke, pneumonia, and lung diseases of various types.

Additional insights come from crash data for the United States, for which reliable, detailed crash statistics are available. In fact, the United States is probably the only country in the world for which its crash databases are available to anyone for free, which can lead those examining crash data to a U.S.-centric perspective of motor vehicle crash problems.

Analyses of U.S. crashes typically rely on three databases: (1) Fatality Analysis Reporting System (FARS), (2) National Automotive Sampling System (NASS), (3) General Estimates System (GES), and (4) Crashworthiness Data System (CDS). FARS (http://www.nhtsa.gov/people/ncsa/fars.html, retrieved June 1, 2010) is a database containing all fatal crashes in the United States. GES (www.nhtsa.gov/people/ncsa/nass_ges.html, retrieved June 1, 2010) is a nationally representative sample of police-reported crashes of all severities (including those that result in death, injury, or property damage). CDS (http://www.nhtsa.gov/PEOPLE/ncsa/nass_cds.html, retrieved June 1, 2010) is an annual probability sample of approximately 5000 police-reported crashes involving at least one passenger vehicle that was towed from the scene (out of a population of almost 3.4 million tow-away crashes). Minor crashes (involving property damage only) are not in CDS. CDS crashes are investigated in detail by specially trained teams of professionals who provide much more information than is given in police reports.

According to the U.S. Department of Transportation's 2008 annual traffic safety assessment (U.S. Department of Transportation 2009a), 37,261 people were killed in traffic crashes in the United States in that year. Of them, 14,587 were passenger car occupants; 10,764 were pickup truck occupants; 5,290 were on motorcycles; 4,378 were pedestrians; 677 were in larger trucks; 716 were bicyclists; and 188 were in other categories.

32.2.1 How Often and What Kinds of Crashes Are Associated with Telematics?

Crashes can occur for a wide variety of reasons (U.S. Department of Transportation 2008) and crashes are often attributable to multiple causes. It is widely accepted that some telematics tasks are distracting and that distraction can lead to crashes. The most recent analysis (U.S. Department of Transportation 2009b), based on FARS and GES concluded that distraction was reported for 11% of the drivers involved in fatal crashes, but those crashes were associated with 16% of all fatalities. Overall, the percentage of fatal crashes involving distraction has increased about 1% per year since 2004. Interestingly, the percentages of injury and property damage crashes have declined annually by a similar amount.

Additional details of distraction crashes appear in a previous analysis that utilized CDS (Wang, Knipling, and Goodman 1996) (Table 32.1). They found that distraction-related crashes primarily involved a single vehicle (41%), though rear-end crashes (moving, 10%; stopped, 22%) were also common. Intersection crashes represented another 18% of the total. Crashes tended to peak in the morning rush hour and, to a much lesser extent, in the evening rush. The overwhelming majority of the crashes occurred in good weather (86% clear, 10% rain, 4% snow/hail/sleet), and many occurred at lower speeds (40% at 0–35 mph, 40% at 40–50 mph, 17% at 55–60 mph, and 4% at over 65 mph). Thus, these data suggest that device test scenarios

TABLE 32.1
Distraction/Inattention Crashes by Crash Type

Crash Type Row (%) Column (%)	Sleepy	Distracted	Looked But Did Not See	Unknown	Attentive	Total

*Too few cases for a stable estimate.

should emphasize situations in which single-vehicle crashes (often run-off-the-road), as well as those involving rear-end collisions into stopped vehicles, are likely. (See also Stutts, Reinfurt, Staplin, and Rodgman [2001] and Eby and Kostyniuk [2004].)

32.2.2 What Kinds of Trips Do People Make and Why?

Every 5–10 years, the U.S. Department of Transportation conducts the National Household Travel Survey to obtain travel data for the United States (Hu and Reuscher 2004), and many other countries conduct similar studies as well. (See http://www.dft.gov.uk/pgr/statistics/datatablespublications/personal/ and http://en.wikipedia.org/wiki/Travel_survey, retrieved May 31, 2010.) In the most recent U.S. data (2001), people in the United States are shown to have traveled an average of 14,500 miles per year, making four trips per day. They drove an average of 40 miles per day, with most of the miles (about 35) covered in a personal vehicle. Keep in mind that these are averages, and that public transit (including school buses) prevalent in urban areas accounts for only 2% of all trips. The travel situation is likely to be different for more urbanized countries (Japan, most of Europe), where public transit is more prevalent.

According to the 2001 data (Table 32.2), the most common reason for travel is family and personal business, which includes shopping, running errands, and dropping off and picking up others, accounting for almost half of the trips.

These and other data (on trip distances, travel speeds, time of day, etc.) in the National Household Travel Survey provide information on both the tasks and information needs that driver information systems should support and the conditions (road types, speed, weather, etc.) under which safety and usability should be assessed.

In contrast to the emerging understanding of the primary driving task, less is known about the real use of in-vehicle devices while driving, in particular, the frequency and duration of various tasks.

TABLE 32.2
Summary of Trip Purposes

Purpose	Person Trips (%)
Family and personal business	44.6
Work	14.8
Social and recreational	27.1
School and church	9.8
Work-related	2.9
Other	0.8

32.2.3 Who Are the Users?

Almost any adult has the potential to drive. To do so, they need only complete limited driver licensing requirements. Thus, in some ways, the driving population represents the population of candidate users for office computer systems. In the United States, within any age group, the percentages of men and women who are licensed are within 1% of being equal except for the elderly (Figure 32.1) (Highway Statistics 2008). Elderly women are sometimes more likely to drive because they are in better health. Notice that the percentage of the United States population that is licensed hits 80% at age 21 and increases with age, reaching a maximum at age 60–64, and then begins to decline. Thus, in designing in-vehicle systems for motor vehicles, few adults can be excluded, which differs from the design of office computer systems, where the emphasis is on the working population (generally less than 65 years old). Further, because of a wide age range, skill, and experience, significant differences in individual performance can be expected. For example, in the University of Michigan Transportation Research Institute (UMTRI) telematics studies, older drivers typically required one and a half to two times longer to complete tasks than younger drivers (Green 2001d). This fact, along with the requirement to design and test for the reasonable worst-case drivers, makes testing drivers over age 65 imperative. Of course, this is all for the United States, and in places where the vehicle market is growing rapidly such as China, there is a greater predominance of younger drivers.

In contrast to computer users, operators of motor vehicles must be licensed. In the United States, the process of becoming a licensed driver begins with obtaining a copy of the state driving manual and learning the state's traffic laws. Candidates must also pass vision tests (see http://www.lowvisioncare.com/visionlaws.htm) and take a test of rules of the road to obtain a learner's permit, often on or after their sixteenth birthdays. Consistent with the increasingly common practice of graduated driver licensing, learners can drive at restricted times with adult supervision. They must generally complete a driver's education class (which often includes gory crash movies designed to convince teenagers

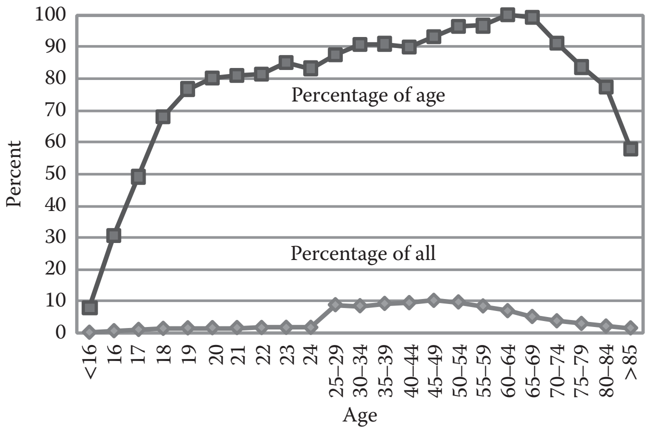

FIGURE 32.1 Distribution of driver age groups developed from U.S. Department of Transportation data.

not to drink and drive and to wear seat belts) and, after a few years, they pass an on-the-road test and obtain a license to drive. (For details, see http://www.iihs.org/laws/graduatedLicenseIntro.aspx, retrieved May 31, 2010.) The rationale for graduated licensing is to provide new drivers with more experience under less risky conditions. To put this in perspective, Mayhew, Simpson, and Pak (2003) show that crash rates per 10,000 novice drivers drop dramatically with time, being about 120, 100, and 70 after 1, 3, and 6 months of being licensed. Similarly, recognizing the increased risk of elderly drivers, some states have special renewal procedures for older drivers (http://www.iihs.org/laws/olderdrivers.aspx, retrieved May 31, 2010).

In the United States, obtaining a commercial driver's license, which is needed to drive buses, large trucks, and other vehicles, is a more complex process. Most candidates either obtain (1) on-the-job training, (2) training integrated into their lifestyle (using machinery on a farm), or (3) training at truck driving schools (Sloss and Green 2000). That population tends to be older than the working population as a whole, and is predominantly male.

Driver licensing practice varies from country to country (http://en.wikipedia.org/wiki/Driver's_license, retrieved May 31, 2010). Europe will have a common license in place in 2013 (http://en.wikipedia.org/wiki/European_driving_licence, retrieved May 31, 2010). In Japan, for example, the failure rate for the basic licensing exam is much higher than in the United States, and there is much greater use of special schools to train drivers. In some countries, obtaining a license may require minimal skill, training, or knowledge, and corruption of the licensing authority can be an issue (Bertand et al. 2008).

32.2.4 What Kinds of Vehicles Do People Drive (The Platform Question)?

For computers, people are concerned about the (1) brand, (2) amount of memory, (3) processor speed, (4) capacity of the hard drive, (5) type and version of operating system (Windows, Mac, or Linux), (6) type and version of browser, (7) the network connection speed, and so forth. The hardware and software of individual computers is in a state of flux, being constantly updated over a life span of often 3–5 years. Fortunately, the physical interface is fairly consistent—a QWERTY keyboard, mouse, and with increasing frequency, a 24-in. monitor for a desktop computer. The on-screen "desktop" is a more flexible space than the motor vehicle instrument panel, though there has been talk of personalizing instrument clusters, complete with personal photos.

Unlike personal computers, a motor vehicle is almost completely identified by its make, model, and year. Updates over an average 13-year life span are rare. (See http://www.bts.gov/publications/national_transportation_statistics/#chapter_2, Table 1-11 for the distribution of vehicles by year.) In most countries (at least where there is left-hand drive), many aspects of driving are fairly consistent: the (1) input devices (steering wheel, brake, and throttle), (2) method of operation, (3) location, and (4) primary displays (windshield and mirrors). In contrast, there is no consistency in the controls or displays for telematics interfaces. Furthermore, although new motor vehicle models are offered once per year, major changes typically occur every 5 years. Computer software and hardware model upgrades occur almost continually. Thus, the hardware lifecycles of the two contexts are quite different, and motor vehicle software is never updated unless there is a product recall.

As of 2008, there were 942 million vehicles in operation worldwide of which about 668 million were cars and 274 million were commercial vehicles (Wards Automotive Group 2009). Data on motorcycles and motorbikes was not provided. Of the world vehicle fleet, 296 million (31%) are in North America (mostly the United States), 238 million (25%) are in Western Europe. As of 2008, there were only 47 million vehicles in China, and 60% of those vehicles were commercial. That number is far less than Japan, with 74 million vehicles. However, there has been a huge change in the Chinese market for vehicles over the last few years. In 2008, there were 9.5 million vehicles produced in China (mostly for the Chinese market) and production has grown 1 million vehicles per year for the last several years. Sales of vehicles in China now exceed vehicle sales in the United States. However, relative to the United States and Europe, very little has been published about Chinese drivers or travel behavior.

Beyond the overall production and sales data, the vehicle sizes and types sold vary among countries, and even regions within a country. People on the east and west coast of the United States think of cars as the primary means of personal transportation. Yet, in other parts of the country, trucks, especially pickup trucks, predominate, and that is reflected in the U.S. sales shown in Table 32.3. Readers should keep in mind that these sales volumes represent a substantial change from a few years ago. Not only have total sales declined, but the sales of pickup trucks are half their totals from 5 years ago.

32.3 WHAT ARE SOME OF THE DEVICES OF CONCERN (AND SOLUTIONS)?

Driver distraction is a topic that has received considerable attention in government reports (e.g., Ranney 2008), has been a series in the *The New York Times* (topics.nytimes.com/top/news/…to_distraction/index.html, retrieved June 1, 2010), has become a cause on *The Oprah Winfrey Show* (a popular TV show in the United States), and even has its own government web site (www.distraction.gov). Although there are many potential distractions a driver might encounter, this chapter focuses only on those related to human–computer interfaces.

In addition to these external influences, the auto industry is strongly influenced by customer feedback on their products, especially as expressed in the J.D. Power Initial Quality Survey (measured at 90 days of ownership) and the Vehicle Dependability Survey (after 3 years of ownership). In the case of J.D. Power surveys, the focus is on the relative ratings of a particular manufacturer's products relative to the competition, not the absolute product ratings. The questions relating to navigation system characteristics receive considerable attention.

TABLE 32.3
Top 20 Selling Vehicles in the United States in 2009

Rank	Make	Model	Sales
1	**Ford**	**F-series**	**413,625**
2	Toyota	Camry	356,824
3	**Chevrolet**	**Silverado**	**316,544**
4	Toyota	Corolla	296,874
5	Honda	Accord	290,056
6	Honda	Civic	259,722
7	Nissan	Altima	203,568
8	Honda	CR-V	191,214
9	Ford	Fusion	180,671
10	**Dodge**	**Ram**	**177,268**
11	Ford	Escape	173,044
12	Chevrolet	Impala	165,565
13	Chevrolet	Malibu	161,568
14	Ford	Focus	160,433
15	Toyota	RAV4	149,088
16	Toyota	Prius	139,682
17	Hyundai	Sonata	120,028
18	GMC	Sierra	111,842
19	**Toyota**	**Tacoma**	**111,824**
20	Chevrolet	Cobalt	104,724

Note: Bolded terms are pickup trucks.

32.3.1 Cell Phone Problems

Because driver information systems are new, the data on device-related crashes is limited. This lack of crash data has hampered progress in understanding the risks of such devices, especially cell phones, which receive the most attention. At the time this chapter was written, many (but not all) states record whether cell phones are causal factors in crashes, with most just starting to collect this information recently. For a variety of reasons, identification of phone use as a causal factor is believed to be underreported. Eight states currently ban talking on a cell phone while driving, with 26 banning texting (http://www.iihs.org/laws/CellPhoneLaws.aspx, http://www.ghsa.org/html/stateinfo/laws/cellphone_laws.html, retrieved May 31, 2010). Bans on texting are becoming more common. Currently, 6% of all drivers are using cell phones at any moment (U.S. Department of Transportation 2009). However, given increased feature content (MP3 support, text messaging, broadcast TV), cell phone use could increase in the future.

There have been several studies that have examined vehicle crash risk related to cell phone use by drivers. The most often cited study of cellular phone use is Redelmeier and Tibshirani (1997; see also Redelmeier and Tibshirani 2001). They examined data for almost 700 drivers who were mobile phone users and were involved in motor vehicle crashes that resulted in substantial property damage. Each driver's mobile phone records for the day of the crash and the previous week were examined. Redelmeier and Tibshirani reported the risk of a crash was 4.3 times greater when a mobile phone was used than when it was not. Interestingly, handsfree units had a greater risk ratio (though not significant) than handheld units (5.9;1 vs. 3.9;1). Other data (Koushki, Ali, and Al-Saleh 1999; McEvoy et al. 2005; Violanti and Marshall 1996) suggested similar risk ratios. In contrast, data from Dingus and Klauer (2008) suggests a much lower risk. Meta-analyses and other reviews show drivers taking longer to respond to brake lights of lead vehicles, departing from the lane more often, and exhibiting other undesired characteristics while using a cell phone (Caird et al. 2006; Horrey and Wickens 2006; Mccartt, Hellinga, and Bratiman 2006; Collet, Guillot, and Petit 2010a,b). In contrast, more recent research shows no changes in crash risk or claims associated with cell phone use (Highway Loss Data Institute 2009; Farmer, Braitman, and Lund 2010).

In addition to the overall issue of crash risk, there has been some concern relating to manual dialing, answering the phone, conversation, or other tasks, and under what conditions these tasks occur. Useful data appear in Green, George, and Jacob (2003). One interesting data point comes from Nowakowski, Friedman, and Green (2001) who found that while driving in a simulator, most people answered a ringing phone in a few rings almost independently of the traffic situation. Answering the phone should not usually be more important than driving, but people behave otherwise out of habit.

Talking on the phone is different from talking to a passenger, especially an adult in the front seat. Often, that adult behaves as a codriver, looking both ways at intersections and checking the mirrors during lane changes, and speaking less in higher risk situations (Drews, Pasupathi, and Strayer 2004; Crundall et al. 2005). When drivers move their heads to scan an intersection or expressway entrance or exit, passengers often stop talking. People on the phone have no knowledge of the driving situation, and just keep talking. Admittedly, the situation can be complex, as talking to passengers can be distracting, but the most recent evidence suggests that speaking to callers (who are unaware of the driving situation) is worse (McEvoy, Stevenson, and Woodward 2007). The effects of conversation with others may very well depend upon a driver's age (teenagers are very susceptible to distraction) and the gender of the passenger (young men may drive less aggressively when young women are passengers) or called party, as well as the number of passengers. Technology could assist in reducing the scope of this problem, for example by providing cues to inform callers of the driving situation and alerting drivers of the call duration or their driving performance. In fact, a number of applications are appearing that block calls to phones when the phones are moving faster than a walking pace, primarily intended for parents who do not want their teens to talk on the phone or text while driving. Keep in mind that most of the time in the United States, vehicles have only one occupant—the driver.

32.3.2 Problems with Navigation Systems

The tasks associated with navigation system destination entry when performed using a visual-manual interface generated the initial concerns about driver distraction (e.g., Steinfeld et al. 1996; Nowakowski, Utsui, and Green 2000; Farber et al. 2000). These concerns continue today. (See http://www.cbc.ca/marketplace/2010/gps_distraction/main.html, GPS distraction, aired January 1, 2010, retrieved May 31, 2010.) More specifically, the concern is for entry of street addresses and intersections, and points of interest. For the street address, the driver is required to enter the city and the state, as well as the street name, building number, prefix (east, north, etc.) and suffix (street, road, drive, etc.). Not only does this require a significant number of keystrokes, which can take 40 seconds to 1 minute to enter, but often the driver may not know the complete address, in which case several alternative variations of the address need to be entered before the desired address is found. ("They live at 1015 Peachtree. Is that Peachtree Road, Avenue, Boulevard, Place, or something else?")

With points of interest, people often do not know in which category they will find their desired destination, so they end up exploring many dead ends. (e.g., is Cobo Hall in Detroit a civic center, a community center, or is it listed in some other category?)

32.3.3 Menu Interface Problems (Especially for Music Selection)

The iPod and other devices provide people with access to large music libraries. iPods with 4000 songs are not unusual, and that number will surely increase several fold in the future. The problem is that drivers try to retrieve songs, albums, and playlists while driving, and not just from one device, but potentially from an iPod or some other MP3 player, a USB drive, a hard disk drive, or a CD player, all of which can be connected at the same time. Drivers may need to go through multiple menus to get to the desired selection. Furthermore, selections can be shuffled, transferred, renamed, and sorted, all while driving. For current research on this topic, see Salvucci et al. (2007); Bayly, Young, and Regan (2008); Chisholm, Caird, and Lockhart (2008); Garay-Vega et al. (2010).

32.3.4 Web Access Problems

At this point, web access while driving is not very common, in part because access to the web in a moving vehicle is a recent occurrence. However, given the number of keystrokes required to enter a URL and the amount of information to be read on a web page, use of the web while driving in a manner typical of an office or home setting will be problematic.

32.3.5 Speech Interfaces—Are They the Future?

There are some who believe that speech interfaces are the solution to the problem of information access while driving. There is good evidence to suggest that speech interfaces can be less distracting than visual-manual interfaces (Tsimhoni, Smith, and Green 2004; Barón and Green 2006; Shutko, Mayer, Laansoo, and Tijerina 2009; Garay-Vega et al. 2010; Owens, McLaughlin, and Sudweeks 2010), though they are not without their problems (Chang et al. 2009). At this point, use of speech interfaces is uncommon because recognition performance is not very good. However, the considerable success of Ford Sync® and opportunities to process speech off board may change the situation.

32.3.6 Workload Managers—Are They the Future?

Given the concern for overload, one potential solution is to measure the primary task workload and then regulate the secondary tasks a driver can do at any moment using a workload manager (Michon 1993; Green 2000b, 2004; Hoedemaeker, de Ridder, and Janssen 2002; Piechulla et al. 2003). As initially conceived, such systems would use data from four sources: (1) the navigation system (such as lane width and radius of curvature), to assess the demands due to road geometry, (2) the adaptive cruise control system (headway and range rate to vehicles ahead), to assess traffic demands, (3) the traction control system, to assess road surface friction, and (4) the wipers, lights, and clock, to assess visibility. This information—along with information on the driver (e.g., age) and the specific visual, auditory, cognitive, and motor demands of each in-vehicle task—could be used to schedule the occurrence of in-vehicle tasks. Thus, when driving on a curving road in heavy traffic in a downpour, incoming mobile phone calls could be directed to an answering machine and the 30,000-mile maintenance reminder could be postponed. When the driving task demand is low, drivers could have access to a wide range of functions. Being able to reliably predict the momentary workload of driving, however, has proven to be very difficult.

As some vehicle engineers have realized, drivers are most likely to be overloaded when maneuvering or about to maneuver. Maneuvering includes (1) changing lanes, (2) merging onto an expressway, (3) turning at an intersection, (4) parking, (5) braking in response to a lead vehicle, (6) accelerating from a traffic light, and so forth. These situations are much easier to identify than the overload situations described earlier and, furthermore, are situations when drivers are less likely to desire additional tasks (such as responding to an incoming call) and would likely lead to much greater market acceptance of a workload manager (Eoh et al. 2006).

32.4 WHAT MEASURES AND STATISTICS OF SAFETY AND USABILITY ARE OF INTEREST? (THE EMPIRICAL MEASUREMENT ISSUE)

As was noted earlier, usability is difficult to achieve without empirical measurement. Superficial impressions suggest that the measurement of usability of office computer and web applications, and the measurement of the usability of driver interfaces are quite similar. In an office, one measures task completion time, errors, and ratings of ease of use. A typical usability lab has (1) a one-way mirror, (2) cameras, (3) video editing equipment, (4) audio mixers, and (5) at least two rooms, one for the subject and one for an experimenter. (See Chapter 53.)

TABLE 32.4
Some Driving-Specific Usability Measures

Category	Statistic
Lateral	Number of lane departures
	Mean and standard deviation of lane position
	Standard deviation of steering wheel angle
	Number of steering wheel reversals
	Time to line crossing
	Steering entropy
Longitudinal	Number of collisions
	Time to collision
	Standard deviation of gap (time or distance to lead vehicle)
	Mean and standard deviation of speed
	Speed drop during a task
	Heading entropy
	Number of braking events over some g threshold
Visual	Number of glances
	Mean glance duration
	Maximum glance duration
	Percentage of off-road glances greater than 2 s
	Total eyes-off-the-road time

Note: For definitions of some of these measures, see SAE J2499 (Society of Automotive Engineers 2010a).

In a typical laboratory for examining driver interfaces, the same measures may be obtained. However, other driving-specific measures, as listed in Table 32.4, may also be obtained, especially in driving simulators and on-the-road tests. (See Green [1995a,b,c].) A major problem is that most researchers do not define how these measures are collected, making studies difficult to compare, and when they are defined, definitions are inconsistent. For example, a lane departure could be determined with respect to the outside edge of the exterior mirror or the outside of a tire. The boundary could be with respect to the inside, middle, or outside edge of pavement marking. Together, these two factors alone alter the determination of a lane departure by a foot. Similarly, headway can be measured to the front or rear of a lead vehicle, a difference of about 15–16 ft. for a car and 55 ft. for a tractor trailer, all substantial differences. Ideally, in the future, authors will use the definitions in SAE J2499 (Society of Automotive Engineers 2010a,b) for consistency.

In addition to the standard measures of driving performance, a host of other performance measures are often collected in driving studies, which include: (1) ratings of workload (National Aeronautics and Space Administration Task Load Index [NASA TLX]), (2) measures of situation awareness, and (3) measures of object and event detection (pertaining to traffic). (See Roskam et al. [2002]; Tijerina et al. [2003]; Johansson et al. [2004].) In fact, simulator and on-road studies of telematics typically involve anywhere from 10–30 dependent measures, though in operational field tests the collection of several hundred measures in real time is not unusual (General Motors Corporation 2005; LeBlanc et al. 2006). Because the user is engaged in concurrent performance of manual control and information management tasks, the situation in some ways is similar to that described by Landry in the aerospace chapter. (See Chapter 33.)

A major challenge in assessing the safety and usability of telematics is dealing with the trade-offs that drivers naturally make. The impression is that when preoccupied with an in-vehicle task, drivers lose awareness of the driving context—that is, situation awareness. Drivers attempt to compensate by slowing down (to make driving easier), allowing for larger gaps and, if very preoccupied, paying less attention to steering (so lane variance and the number of lane departures increase). However, drivers can respond in strange ways. For example, if asked to use two different in-vehicle systems, one of which is not well designed, they might attempt to maintain equal performance on both: slow down more for the more difficult interface, but compensate by having better steering performance for the poorer interface. Assessment is difficult because the trade-off functions for all of these measures are unknown. One strategy used to overcome the trade-off problem is to minimize the opportunity for trade-offs. For example, this might include using cruise control to fix the speed (and in some cases, headway) and provide incentives and feedback to maintain driving performance, so only task time and errors might trade off.

32.5 HOW ARE DRIVER INTERFACES EVALUATED?

The assessment of mobile applications often occurs in contexts other than simulators and real roads as suggested above. Table 32.5 provides a summary of the contexts and their strengths and weaknesses. (See Green [1995a] for additional details.)

Over the last decade, enormous improvements have been made in the quality of the tools available for human factors evaluations of driver interfaces. These include

1. Reductions in the size of video cameras (to that of a postage stamp) and their cost
2. Significant improvements in the fidelity, along with significant reductions in the cost, of wide field-of-view driving simulators
3. Electronic innovations that allow packaging compact instrumentation systems in vehicles and that reduce power consumption (and heat generation)
4. GPS systems for precise tracking of vehicle location
5. Digital cellular phones for remote downloading of vehicle data

Two specific developments of note are the custom driving monitoring systems and low-cost vehicle data logging systems. The best known of the monitoring system is Drivecam (www.drivecam.com, retrieved May 31, 2010), which consists of two video cameras, one aimed forward and one facing the driver, mounted in front of the rearview mirror. Recording occurs when lateral or longitudinal acceleration exceeds some threshold. Drivecam is commonly used by vehicle fleet operators to monitor their drivers and parents to monitor their teenagers.

TABLE 32.5
Evaluation Contexts

	Method and Equipment	Advice and Comments
Focus groups	Groups of 8 to 12 people demographically similar to customers sit around a table and discuss a product or service guided by a facilitator. Camera is often behind one-way mirror. Generally done in multiple cities (one or two groups/city). Often conducted by a marketing firm.	Useful in getting ideas for product concepts, but not predictions of the safety or usability of new products because the products have not been used. Approach is sometimes used by manufacturers when a usability test might be more appropriate. Generally no quantitative data. Essential to report actual quotes from participants, not what the facilitator recalls.
Clinics	Customers in various cities are given the opportunity to experience a new product and its competition, often two or three vehicles, side by side. Customers say which product or feature they prefer.	Only exposes users to a limited number of options. Performance data often not collected. Approach is commonly used by industry. Because the results are highly proprietary, published studies are rare.
Part task simulation	A sample of users operate the device (e.g., computer simulation of a new radio) and user task times, errors, and comments are recorded. Test facility is not sophisticated.	Not done that often. Relatively less common now than in the past as simulators have improved and instrumented vehicles have become more common.
Driving simulator	Typically driving simulators are fixed base (no motion) and cost $25,000 to $250,000 each, but the major cost is for a full-time engineer (or engineers) or several graduate students to operate the simulator. Simulators at manufacturers tend to be in 1–3 million dollar range, though some are much more (e.g., Ford is about $10,000,000). One to five projectors with total 40–210 degree forward field of view, real vehicle cab, steering system with torque feedback, and realistic sound. Rear image may be projected or mirrors may be replaced with small LCDs. For advice, see Green et al. (2003); Green (2005).	Operation requires considerable experience. Simulator sickness is a major problem, especially for wide field of view and older driver. Each experiment requires construction of a test road/world and scripting the behavior of vehicles and pedestrians. Facility can require considerable space (e.g., 1000 ft.^{2}). Generally requires large number of fixed small (lipstick or smaller) cameras. Best-known vendors in the United States are Systems Technology Inc. ($5,000–$25,000, http://www.systemstech.com/content/view/23/39/), Realtime Technologies ($75,000–$150,000), www.simcreator.com, GlobalSim Corporation, ($75,000–$150,000, http://www.drivesafety.com/), and OKTAL in Europe (http://www.scaner2.com/php/).
Instrumented vehicle on test track or public roads	Production vehicle (usually a car and often in the past, a station wagon) is fitted with cameras aimed at driver, forward scene, instrument panel, and lane markings, and with sensors for steering wheel angle, brake pressure, speed, and headway. Eye fixation system may also be provided. System of interest is also installed. In a typical experiment, the driver is asked to follow a test route while a back seat experimenter operates the test equipment.	Typical cost is at least $100,000–$250,000 though some low-cost systems may utilize a single camcorder on a vertically mounted curtain rod in the back seat aimed at the instrument panel. Problem in the past has been finding enough space and power for the equipment, which has been solved by laptops and lipstick cameras. Commonly, instrumented research test vehicles are used, though there is increasing use of systems that can be installed in the subject's own vehicle.
Operational field test	Compact instrumentation is installed in a fleet of vehicles (10–50). Each vehicle is borrowed by a potential user for a week, a month, or even a year. Driving performance is surreptitiously recorded by the vehicle. Unlike an instrumented car, continuous video is not recorded. In addition to data recorded by the instrumented vehicle, GPS-determined location is also recorded. Vehicles are periodically polled for data (and data is automatically dumped) by an independent digital cellular phone. Test is confined to a single metropolitan area but tests in multiple areas are being planned.	Each test requires unique instrumentation. Tests are very expensive ($10,000,000 to $40,000,000) and can only be conducted with significant government support. Experiment generally lasts several years. Planning stage for experiments takes several years. At any given time, there may be only one operational field test in progress in the United States.

LCD = liquid crystal display; GPS = global positioning system.

There are several low-cost devices that plug into the onboard diagnostic II (OBDII) connector of the engine computer (often under the dash), to allow for easy recording of speed, engine RPM and other driving measures. The best-known product is Carchip (www.carchip.com, retrieved May 30, 2010). In some cases, these may be a substitute for CANalyzers, commercial data loggers that record all information on the controller–area network (CAN) bus, the bus containing all of the speed, throttle, brake, and other driving data. Those not familiar with driving research should be forewarned. CAN bus codes are manufacturer specific and proprietary, and obtaining access to the codebooks is not easy.

The data that most researchers often wish they had concerns where drivers are looking. Development of better, lower cost eye fixation systems is still needed, though the leading vendors of hardware for driving research, Seeing Machines, the manufacturers of FaceLab (http://seeingmachines.com/), and Smart Eye (http://www.smarteye.se), are making progress. Challenges include enhancing accuracy and ability to hold calibration, dealing with glasses (common for older drivers), and operation in bright sunlight.

32.6 WHAT DESIGN DOCUMENTS EXIST FOR DRIVER INTERFACES?

32.6.1 What Types of Documents Are There?

Although feedback from the empirical measurements just described is important, automotive design is strongly influenced by industry and government regulations, and international standards. For office applications, compliance with design guidelines, commonly called style guides, is achieved by providing application program interfaces in the operating system that assure that widgets such as windows, menus, and so forth all work in a consistent way. (See Chapter 41 by Mayhew and Follansee for related information on requirements specification.) For driver interfaces, publicly available, product-specific interface guidelines do not exist, but there are other types of important written materials (Green 2001a,b; Schindhelm et al. 2004). Automotive design documents fall into five general classes: (1) principles, (2) information reports, (3) guidelines, (4) recommended practices, and (5) standards. Principles give high-level recommendations for design and are similar to those found in office HCI applications, such as “design interfaces to minimize learning.”

Information report is a term used by the SAE to refer to a compilation of engineering reference data or educational material useful to the technical community. Information reports do not specify how something should be designed, but provide useful background information.

Guidelines give much more specific advice about how to design an interface element. For example, guideline 9 in Chapter 7 of Green (1995c, p. 41) stated, “Turn displays should show two turns in a row when the turns are in close proximity,” where close proximity means 0.1 miles apart or less. The impact of guidelines can depend on the issuing organization. For example, automotive design guidelines written by research organizations have no real authority. Guidelines written by the International Organization for Standardization (ISO), although technically voluntary, can become requirements, because in some countries, type approval (approval for sale) requires compliance with ISO guidelines. For vehicle models sold worldwide, global manufacturers find that building common vehicle systems that comply with ISO standards to be less costly than building noncompliant, country-specific systems. In Japan, the Japan Automobile Manufacturers Association (JAMA 2004) has a set of guidelines for navigation systems. Although theoretically voluntary, “requests” from the National Police Agency make the JAMA guidelines a requirement for all original equipment manufacturers (OEMs) in Japan.

Recommended practice, a term used by SAE, refers to specifications for a material, product design, or design or test procedure that are intended to guide standard engineering practice, often because they have not gained broad engineering acceptance. Commonly, a recommended practice is followed. A product liability action against a product (especially in the United States) is extraordinarily difficult to defend if the product design and evaluation deviate from recommended practice.

In some sense, a standard is a recommended practice that is a broadly accepted engineering practice, and must be followed. In the SAE context, “must” has an unusual connotation, because an SAE standard is technically voluntary because SAE has no enforcement powers. However, in a product liability context, a product not complying with an SAE standard is almost not defendable, and is unlikely to be purchased from a supplier by an OEM.

32.6.2 Non-ISO Documents

Table 32.6 provides a summary of the design document activities till date excluding those of the ISO (described later). As indicated in the table, the EU guidelines are quite brief and are merely statements of very general principles (e.g., those interfaces should be simple to operate), though they serve as the basis of the Alliance guidelines described later. Most of the early guidelines (Battelle, Harmonization of ATT Roadside and Driver Information in Europe [HARDIE], Technology Readiness Level [TRL], UMTRI), though they are quite detailed and still valuable, are rarely used because there are no requirements to use them. Documents that are followed are JAMA (as was described previously), the Alliance guidelines (because the Alliance members agreed to follow them, possibly to avoid government regulation), and SAE and ISO guidelines (both of which are accepted industry practice and are described in the Sections 32.6.3 to 32.6.5). For all of these guidelines, see http://www.umich.edu/~driving/guidelines/guidelines.html for unofficial electronic copies. (To avoid copyright problems, only draft versions have been posted for SAE and ISO documents.) Readers are cautioned that all of these documents are updated every few years, and they should verify that they are using the most recent version with the authoring organization.

TABLE 32.6
Major Non-ISO Telematics Guidelines and Recommended Practices

Common Document Name	Reference	Size (Pages)	Comments
Alliance guidelines	Alliance of Automobile Manufacturers (2006); version 3	90	Elaboration of the EU principles with details on the method and rationale, used by almost all manufacturers in the United States; key sections are principles 2.1 and 2.2, which still need development.
Battelle guidelines	Campbell, Carney, and Kantowitz (1997)	261	Voluminous document with references to interface design, emphasis on trucks. User interface has been said to have a Windows OS flavor, includes physical ergonomics information (e.g., legibility, control sizes) which are not included in the UMTRI guidelines.
EU guidelines	Commission of the European Communities (2007)	42	Mostly “motherhood” statements.
HARDIE guidelines	Ross et al. (1996)	480	Early set of European guidelines, less data than UMTRI or Battelle.
JAMA guidelines	Japan Automobile Manufacturers Association (2004)	15	First set of detailed design guidelines for driver interfaces. These guidelines are voluntary in Japan but followed by all OEMs there and sometimes by aftermarket suppliers. Some aspects are particular to Japan. Device location restrictions are important.
SAE J2364 (“15-second rule”)	Society of Automotive Engineers (2004a)	13	Specifies the maximum allowable task time and test procedures for navigation system tasks performed while driving for systems with visual displays and manual controls; also describes an interrupted vision (visual occlusion) method as well; see also SAE J2365.
SAE J2365 (SAE calculations)	Society of Automotive Engineers (2002)	23	Method to compute total task time for tasks not involving voice, used early in design to estimate compliance with J2364.
TRL guidelines	TRL Limited (2004)	56	Expansion of simple checklist.
UMTRI guidelines	Green, Levison, Paelke, and Serafin (1995)	111	First set of comprehensive design guidelines for the United States. Includes principles, general guidelines, and specific design criteria with an emphasis on navigation interfaces.

EU = European Union; UMTRI = University of Michigan, Transportation Research Institute; HARDIE = Harmonization of ATT Roadside and Driver Information in Europe; JAMA = Japan Automobile Manufacturers Association; OEM = original equipment manufacturer; SAE = Society of Automotive Engineers; TRL = Technology Readiness Level.

32.6.3 ISO Documents

Much of the ISO activity over the last decade has occurred under the auspices of ISO Technical Committee 22, Subcommittee 13 (ISO TC 22/SC 13-Ergonomics Applicable to Road Vehicles, in particular, Working Group 8 [WG8—Transport, Information, and Control Systems or TICS]; Green 2000a). WG8 has about 50 delegates from the major vehicle-producing nations, with the most 15 active members appearing at meetings held two to three times per year, usually in Europe.

Table 32.7 shows the standards and technical reports developed (or in progress) by WG8 that pertain to telematics. (For the complete list, go to the ISO TC 22/SC 12 portion of the ISO website [www.ISO.org].) Most of the standards can be quite general, sometimes not containing the detail found in the Battelle, HARDIE, or UMTRI guidelines. For a variety of reasons, ISO documents emphasize measurement methods and organization over specifications and safety limits. To promote international harmonization, national standards organizations, technical societies (e.g., SAE), and government organizations (e.g., U.S. Department of Transportation) often permit ISO standards to supersede their own standards, so ISO standards are very important.

Note: ISO documents follow a very well-defined, 3-year process through several stages (Preliminary Work Item [PWI], Committee Draft [CD], Draft International Standard [DIS], Final Draft International Standard [FDIS], and International Standard [IS]) as they are passed from the working group to the subcommittee to the technical committee, and finally, to the secretariat for review and approval. The major hurdles are the working group and subcommittee, where passage requires two-thirds of the nations participating. The emphasis of this process is on building a voluntary consensus. Some items that are more informational in nature become technical reports instead of standards. Because of the limited number of experts available, WG8 is very selective in adding items to its work program.

TABLE 32.7
ISO TC 22/SC 13/WG 8 Work Program

Effort	Summary	Status
Dialogue management principles and compliance procedures	Provides high-level ergonomic principles (compatibility with driving, consistency, simplicity, error tolerance, etc.) to be applied in the design of dialogues that take place between the driver of a road vehicle and an in-vehicle information system while the vehicle is in motion. Provides general directions on how to test for compliance.	Std 15005
Specifications and compliance procedures for in-vehicle auditory presentation	Provides requirements for auditory messages including signal levels, appropriateness, coding, and so on, along with compliance test procedures.	Std 15006
Measurement of driver visual behavior	Generally describes video-based equipment (cameras, recording procedures, etc.) and procedures (subject descriptions, experiment design parameters, tasks, performance measures, etc.) used to measure driver visual behavior.	Std 15007, part 1 and TS part 2
Legibility (visual presentation of information)	Provides requirements for character size, contrast, luminance, and so on, and specifies how they are to be measured.	Std 15008
Warning system messages	This state-of-the-art literature review (circa 2002) of warning systems covers topics such as alarm theories; the design of visual, auditory, and tactile warnings; redundancy; and so on. The report contains summaries of a significant number of studies.	TR 16352
Message priority	Provides two methods for determining a priority index for in-vehicle messages (e.g., navigation turn instruction, collision warning, low oil) presented to drivers while driving. For one method, priority is based on criticality (likelihood of injury if the event occurs and urgency [required response time]), determined on four-point scales by experts.	TS 16951
Suitability of TICS while driving	Generally describes a process for assessing whether a specific TICS, or a combination of TICS with other in-vehicle systems, is suitable for use while driving. It addresses a user-oriented TICS description and context of use, TICS task description and analysis, assessment, and documentation.	Std 17287
Occlusion method to assess distraction	Describes how the visual demand of a display can be assessed by periodically blocking (occluding) the driver's view of the display. Includes requirements for number and training of subjects, test hardware, viewing and occluded periods, and two metrics for data analysis.	Std 16673
Lane change test	Proposes a procedure for testing the demand of telematics devices using a PC-based driving simulator. Subjects perform a number of lane changes, some of which occur while using an in-vehicle device. The test is based on results of the ADAM project. Complements SAE and AAM procedures.	Proof Std 26022

TICS = Transport, Information, and Control Systems; ADAM = Advanced Driver Attention Metrics; SAE = Society of Automotive Engineers; AAM = Alliance of Automobile Manufacturers.

32.6.4 SAE J2364 (The 15-Second Rule)

Of the design documents in the literature, few have generated as much discussion as SAE Recommended Practice J2364, also known as "The 15-Second Total Task Time Rule" or "15-Second Rule." SAE J2364 establishes two procedures for determining if a navigation system–related data entry task involving visual displays and manual controls is excessive while driving (Society of Automotive Engineers 2004a,b; Green 1999c). The practice applies to OEM and aftermarket products. The practice does not and should not apply to voice interfaces or passenger operation because the task demands are fundamentally different. There is no reason why the requirements should not be applied to all visual-manual tasks, not just navigation, given its performance basis.

In developing this practice, criteria were selected to be related to crash risk, likely to lead to design improvements, and easy to measure. Some suggested this document should contain design criteria, such as a specification for a maximum number of items on a menu. To be nimble and allow for changes in technology, a performance-based practice was developed instead. Many measures were then proposed, with eyes-off-the-road time being most popular. The logic behind this measure is simple. If drivers are not looking at the road while driving, they are more likely to crash, with the likelihood of a crash increasing with increased eyes-off-the-road time. As shown in Green (1999d), this is reflected in the following equation:

$$\begin{aligned}&\text{No. of U.S. deaths in 1989}\\&\quad = \text{market.penetration.fraction} * [-0.133 + (0.0447 *\\&\qquad (\text{mean glance time})^{1.5} * (\text{No. of glances}) * (\text{frequency}))]\end{aligned}$$

where *market.penetration.fraction* is the fraction of vehicles with a system (10% -> 0.1), *mean glance time* is the number of seconds drivers looked away from the road, *no. of glances* is the number of times the device is looked at for each use sequence, and *frequency* is the number of use sequences per week.

As an example, a task—say, entering an address—could have a mean glance duration of 2.7 seconds, require an average of 27.5 glances per entry, and be performed twice per week.

Unfortunately, eyes-off-the-road time is time-consuming and expensive to measure, and requires specialized equipment and skilled personnel. Measurement also requires a fully functional system installed either in a simulator or test vehicle, something that is only available late in design. Invariably, problems are identified so close to production that few, if any, changes can be made. One of the key lessons from the Gould and Lewis design principles from HCI is that feedback from early on in the design process is critical.

A review of the literature at the time the practice was being developed (Green 1999d) found that task time while driving was highly correlated with eyes-off-the-road time, a finding that has been repeatedly observed. Looking at in-vehicle systems is time shared with driving, so the more the driver needs to look, the longer the task will take. Further, dynamic (on-the-road) task time and eyes-off-the-road time are correlated with static task time, the time to complete the task when the vehicle is parked (e.g., Green 1999d; Farber et al. 2000; Young et al. 2005). Static task time is easy to measure and can be done using prototypes available early in design.

The current SAE J2364 test procedure (Society of Automotive Engineers 2004a) requires that 10 subjects between the ages 45 and 65 be tested. Each subject completes five practice trials and three test trials in a parked vehicle, simulator, or laboratory mockup. The test cases to be examined (addresses for destination entry) are to be representative of what is planned for production. Interestingly, the choice of the address can have a marked impact on the task time.

In the static method, the subject performs the task, with the duration being from when the subject is told to start until the goal is achieved. Timing is continuous except for computational interruptions equal to or greater than 1.5 seconds, a time period during which the device is computing (e.g., a route). If feedback is provided to the driver, that period is excluded from the 15-second task time limit. The interface complies with J2364 if the mean of the log of the task times is less than the log of 15 seconds. (Logs were used to reduce the influence of long outliers.)

It must be emphasized that the 15-second limit is for a static test. On-the-road drivers will take 30%–50% longer overall, and furthermore alternate between looking inside the vehicle and looking at the road. The test procedure does not suggest that drivers can safely look away from the road continuously for 15 seconds.

Some have argued that use of static task time fails to identify interfaces requiring long glance durations. However, analysis of real products shows the primary risk is from tasks that take too long to complete. In fact, it is very difficult to think of driver tasks for navigation systems that have short total task times but very long glance durations. In real driving, people truncate glances to the interior when the glances become too long but tend to complete tasks, even if they are unacceptably long. In practice, eliminating tasks with long completion tasks (the worst tasks) also eliminates many of the tasks with long glance durations.

Nonetheless, J2364 provides an alternative method involving visual occlusion. In that method, either the subjects wear special liquid crystal display (LCD) glasses, or vision to the device is otherwise periodically interrupted, simulating looking back and forth between the road and the device. (Unlike driving, though, subjects do nothing in the occlusion interval.) The device is visible for 1.5 seconds and occluded for 1–2 seconds, with 1.5 seconds being recommended. Compliance is achieved if the sum of the log of the viewing times is less than the log of 20 seconds.

32.6.5 Alliance Principles

The Alliance of Automobile Manufacturers (AAM), the trade association of 11 major manufacturers of automobiles in the United States (GM, Ford, Toyota, Mercedes, etc.) has devoted considerable effort to developing design guidelines/principles (Alliance of Automobile Manufacturers 2006). Although the document scope states that it applies only to "telematic devices," (p. 7), it should apply to all types of driver interfaces (except speech), since the low-level tasks (reading displays, pressing buttons, etc.) and the manner in which those tasks interfere with driving are the same for all systems. Some, if not many, of the manufacturers verify that their products meet the Alliance guidelines and request that their suppliers document that products sold to them also comply.

The Alliance guidelines are a detailed elaboration of the 24 principles in the EU guidelines (e.g., Principle 1.1: "The system should be located … in accordance with relevant … standards.…" "No part … should obstruct any vehicle controls or displays …"), (p. 13). Those guidelines seem obvious at a high level, but defining precisely how they can be met is quite difficult. Each principle has four parts: (1) rationale (usually quite detailed), (2) criterion/criteria, (3) verification procedures, and (4) examples.

The most important principle is 2.1: "Systems with visual displays should be designed such that the driver can complete the desired task with sequential glances that are brief enough not to adversely affect driving" (p. 39). Two alternative sets of criteria are offered. Alternative A says that "single-glance durations generally should not exceed 2 seconds," and task completion "should not require more than 20 seconds of total glance time." (Notice use of the words "should," not shall.) There is debate as to what the percentile criterion for a single glance and the maximum task time should be (Go et al. 2006). Verification can be achieved by a visual occlusion procedure (1.5 seconds viewing time, 1.0 second occlusion time), or by monitoring eye fixations directly using either a camera aimed at the face or an eye fixation monitoring system in either a divided-attention or on-road test.

Alternative B requires that the number of lane departures "should" not exceed the number associated with a reference task such as manual radio tuning, and that cars following headway "should" not degrade under those conditions, either. The verification procedure is stipulated to be driving on a divided road (either real or simulated) at 45 mph or less in daylight, on dry pavement, with low to moderate traffic. Additional details are provided describing the location of the radio, the stations to choose among, what constitutes a trial, subject selection (equal numbers of men and women between the ages of 45 and 65), and so forth.

Although both procedures seem well described on the surface, additional details and constraints are needed to make those procedures repeatable. For example, the differences in performance between driving in "low" and "medium" traffic could be quite considerable and need to be quantified such as in Schweitzer and Green (2007). Also needed are additional specifications for acceptable levels of variation in speed and lane position, criteria that could be developed from the data in Lai's (2005) dissertation or from Jamson et al. (2008). For many tasks that involve database searches (of address lists, song files, etc.), compliance with the principle will depend on the size of the database and the subject's familiarity with it. Nonetheless, the principles represent a reasonable first step in developing a test protocol. On the other hand, on-road and simulator tests are extremely expensive and time-consuming, often impractical, and occur too late to have a useful impact. Therefore, the author strongly prefers simpler evaluation procedures such as J2364, and the task time estimates determined using SAE J2365 and Pettitt's calculation procedures described in the Section 32.7.2.

32.7 WHAT TOOLS AND ESTIMATION PROCEDURES CAN AID TELEMATICS DESIGN?

32.7.1 SAE J2365 Task Time Calculations

SAE J2365 (Green 1999a) was developed to allow designers and engineers to calculate completion times early in design, when the design is still a concept that can easily be modified. As with J2364, J2365 is for in-vehicle tasks involving visual displays and manual controls evaluated statically—that is, while parked (or in a bench-top simulation). SAE J2365 applies to both OEM and aftermarket equipment. Though intended for navigation systems, J2365 should provide reasonable estimates for most in-vehicle tasks involving manual controls and visual displays.

The calculation method is based on the Goals, Operators, Methods, and Selection rules (GOMS) model described by Card, Moran, and Newell (1980) with task time data from several sources. (See Kieras' Chapter 57 for background information on GOMS.) The keystroke data was drawn from UMTRI studies of the Siemens Ali-Scout navigation system (Steinfeld et al. 1996; Manes, Green, and Hunter 1998). Search times were based on Olson and Nilsen (1987–1988), and the mental time estimates were drawn from the Keystroke-Level Model (Card, Moran, and Newell 1983) and UMTRI Ali-Scout studies. Thus, the times shown in Table 32.8 have been tailored for the automotive context. (See also Nowakowski, Utsui, and Green [2000].)

The basic approach involves top-down, successive decomposition of a task. The analyst divides the task into logical steps. For each step, the analyst identifies the human and device task operators. Sometimes analysts get stuck using this approach because they are not sure how to divide a task into steps. In those cases, utilizing a bottom-up approach may overcome such roadblocks. For each goal, the analyst identifies the method used.

The analyst is advised to document each method using paragraph descriptions and then convert those descriptions into pseudo code. All steps are assumed to occur in series; multiple tasks cannot be completed at the same time. Furthermore, most drivers are assumed to use only visible, noncognitively loading shortcuts. Invisible shortcuts are likely to be used only by experts.

Next, the pseudo code task description is entered into an Excel spreadsheet. The analyst looks up the associated time for each operator listed in Table 32.8 and sums them to determine total task time. To assist in understanding the process, the practice provides a step-by-step example of entering a street address into a PathMaster/NeverLost navigation system, a popular U.S. product. For background on the calculation method, see Green (1999b).

The J2365 approach shares a number of assumptions, many of which are also shared with the basic GOMS model. For example, the model assumes error-free performance, which while not likely, can be adjusted for (say by increasing the computed value by 25%). Further, activities are assumed to be routine cognitive tasks, with users knowing each step and executing them in a serial manner. Again, adjustments in computed time can account for users sometimes forgetting what is next.

Though many of these assumptions are not true, adjustments can be made for them, and many times the adjustments are small. Furthermore, violations of assumptions tend to affect all interfaces equally, so decisions about which of several interfaces is best still hold. As a practical matter, the estimates are good enough for most engineering decisions. Readers should keep in mind that J2364 only requires the use of 10 subjects at most, so there is some error in those estimates. Those errors are likely to be as large as variability among analysts and among J2365 estimates.

TABLE 32.8
SAE J2365 Operator Times

			Time (seconds)	
Code	**Name**	**Operator Description**	**Young Drivers (18–30)**	**Older Drivers (55–60)**
Rn	Reach near	From steering wheel to other parts of the wheel, stalks, or pods	0.31	0.53
Rf	Reach far	From steering wheel to center console	0.45	0.77
C1	Cursor once	Press a cursor key once	0.80	1.36
C2	Cursor twice or more	Time/keystroke for the second and each successive cursor keystroke	0.40	0.68
L1	Letter or space once	Press a letter or space key once	1.00	1.70
L2	Letter or space twice or more	Time/keystroke for the second and each successive cursor keystroke	0.50	0.85
N1	Number once	Press the letter or space key once	0.90	1.53
N2	Number twice or more	Time/keystroke for the second and each successive number key	0.45	0.77
E	Enter	Press the Enter key	1.20	2.04
F	Function keys or shift	Press the function keys or Shift	1.20	2.04
S	Search	Search for something on the display	2.30	3.91
Rs	Response time of system scroll	Time to scroll one line	0.00	0.00
Rm	Response time of system new menu	Time for new menu to appear	0.50	0.50

Note: The keystroke times shown include the time to move between keys. System response times to display new menus may be empirically determined.

32.7.2 Pettitt's Occlusion Time Calculation

In his dissertation, Pettitt (2008) (see also Pettitt, Burnette, and Stevens [2007] for one of several summaries) developed a similar method for estimating occlusion task times. In the occlusion procedure (ISO 16673, SAE J2364), subjects are allowed to intermittently look at a display while performing a task, simulating looking back and forth between the road scene and an in-vehicle system. Typically, this is accomplished by having the subject wear goggles with LCD shutters, which alternate between the two states (viewable, occluded) every 1.5 seconds, the duration of a typical glance.

Pettitt's calculation is quite similar to that of SAE J2365, with additional rules to determine what can be done during occlusion intervals.

Rule 1: During the vision interval (assumed to be 1.5 seconds), the task progresses normally without interruption.

Rule 2: Operators that do not require vision (e.g., mental) begun during vision can continue during occlusion.

Rule 3: Only operators that do not require vision can begin during occlusion (e.g., a key can be pressed if the finger is already resting there).

Also, there are fewer operator times than in J2365 and except for reaching for the device (Rf = 0.31 seconds), the times are slightly different (M = 1.25 seconds, H = home/move to key = 0.62 seconds, K = press a key = 0.2 seconds).

Using these methods, Pettitt, Burnette, and Stevens reported estimates to be 10% high (range 2%–22%) for static task time (estimate for 6 tasks from 12 drivers) and 13% high (range 2%–12%) for total shutter open time in an occlusion procedure, a reasonable approximation for engineering estimates. Keep in mind that the data from drivers is not the true time, just another estimate.

32.7.3 In-Vehicle Information System Estimates

A more complex estimation procedure, the In-Vehicle Information System Design Evaluation and Model of Attention Demand (IVIS DEMAnD) model, described by Hankey et al. (2000a,b). The model, which runs under Windows 98 or Windows NT, allows analysts to calculate a wide range of performance characteristics for proposed user interfaces. (The CD can be obtained from the U.S. Department of Transportation, Federal Highway Administration, Turner-Fairbank Highway Research Center in McLean, Virginia.)

The model assumes there are five basic human resources: (1) visual input, (2) auditory input, (3) central processing, (4) manual output, and (5) speech output. Overload of any one of these resources will affect task performance. The more demanding an in-vehicle task, the greater the likelihood of a crash. The model does not include a haptic component because haptic displays are rare in contemporary vehicles. Although many have developed models of human performance that partition human resources more finely, a five-component model is sufficient for most in-vehicle analyses. The data in the model were based on four experiments: (1) Gallagher (2001), (2) Blanco (1999), (3) Biever (1999), and (4) research conducted by Westat, a consulting company. These experiments concentrated on reading visual displays while driving, though there was work on auditory information as well.

To use the model, analysts need to create a description of each task drivers perform. Generally, that involves selecting the task in question from a large library of tasks in the database, modifying an existing description, or creating one from scratch. Tasks are grouped into seven categories: (1) conventional, (2) search, (3) search-plan, (4) search-plan-interpret, (5) search-plan-compute, (6) search-compute, and (7) search-plan-interpret-compute. Analysts need to select the driver age category (or specify all ages), the traffic density, the road complexity, the reliance on symbols/labels, the location of the display, and other characteristics.

The output of the model includes about 20 parameters, such as (1) the expected number of glances, (2) total task time, (3) ratings of mental demand and frustration, (4) total task demand, and so forth. In addition, the model output specifies if design thresholds are exceeded. The model proposes two sets of thresholds: (1) yellow-line and (2) red-line. Yellow-line thresholds were sets of points at which there was a measurable degradation in driving performance ($p < .05$) from baseline driving in the research conducted to support model development. Red-line thresholds indicated that a composite group of surrogate safety measures of driving performance was substantially affected. The red-line values were determined primarily from the literature and expert opinion. Table 32.9 shows those thresholds.

Quite frankly, IVIS DEMAnD is an orphan model that is not used, though it is certainly interesting. Unfortunately, the IVIS DEMAnD source code has not been widely distributed and the results from IVIS DEMAnD modeling have not been independently validated. Currently, the development of many other human performance models is better funded and they are used more often (GOMS, Adaptive Control of Thought—Rational [ACT-R], Executive-Process Interactive Control [EPIC], State, Operator and Result [SOAR], Operator Model Architecture [OMAR], etc.).

In particular, two modeling tools have garnered more interest than others, Distract-R (Salvucci et al. 2005; Salvucci 2009; www.cs.drexel.edu/~salvucci/distract-r/, retrieved May 31, 2010) and Cogtool (Teo and John 2008, http://cogtool.hcii.cs.cmu.edu/, retrieved May 31, 2010). Distract-R is a Macintosh-based application that allows for prototyping and evaluation of driver interfaces. Interfaces are prototypes from a pallet that includes displays, buttons, microphones, and speakers. Tasks are created by demonstration and described in an ACT simple framework. The key actions are: press a button (100 milliseconds preparation time plus a movement time determined by Fitts' Law, move a hand from the steering wheel (610 milliseconds), look at and encode information (150 milliseconds), begin to speak (300 milliseconds), begin to listen (300 milliseconds), rotate a knob (2 ms/degree), and think (1250 milliseconds). Also important in Distract-R is an ACT-R driver model that realistically emulates how drivers negotiate curves, change lanes, as well as where they look. Distract-R also has features that allows for the specification of driver characteristics (young and old), driver steering style, various driving scenarios (straight and curved roads, if a lead vehicle brakes), and then allows those simulations to be run and viewed. Running a simulation involves the ACT-R code to execute the secondary task, the ACT-R code to drive, plus addition code to coordinate the two tasks. Notably, there has been a modest level of effort to validate Distract-R, including one effort in collaboration with Ford.

Cogtool is a general-purpose user-interface prototyping tool that automatically generates the ACT-R code listing describing the human performance of a task being examined. There are versions of Cogtool for both Macs and PCs. Cogtool in many ways resembles Distract-R, though it uses a storyboard to create the interface. However, Cogtool has features for generating a wide variety of widgets (e.g., cascading menus) that do not appear to yet be supported in Distract-R. In contrast, Cogtool only supports the determination of device task times and does not have the driving features of Distract-R. There is a fair amount of support information for Cogtool, including instructional videos.

TABLE 32.9
In-Vehicle Information System Yellow- and Red-Line Thresholds

Measure	Affected (Yellow)	Substantially Affected (Red)
Single glance time	1.6 seconds	2.0 seconds
Number of glances	6 glances	10 glances
Total visual task time	7 seconds	15 seconds
Total task time	12 seconds	25 seconds

32.8 CLOSING THOUGHTS

This chapter makes the following key points:

1. Driving is quite different from sitting at a desk in an office because of the concern for crash risk. People die while driving, lots of them.
2. Nonetheless, driver interface design should follow the same golden Gould and Lewis principles used to design ordinary office applications—(1) early focus on users and tasks, (2) empirical measurement, and (3) iterative design.
3. Drivers can range widely in age, and at least in the United States, almost all adults drive. Outside the United States, there is little literature on how drivers are licensed, and in some cases, there are doubts about how strictly licensing procedures are followed. Thus, there are significant gaps in knowledge of the user population, drivers. Nonetheless, it is important to include older drivers (over age 65), the least capable users, in safety and usability tests. Demographic data on drivers outside the United States is limited, with data on Chinese drivers being a special need.
4. The largest market for motor vehicles is now China. In the United States, which has been the largest market for a long time, the number of cars and trucks sold has been often equal, in part because of the popularity of pickup trucks and sport-utility vehicles. Worldwide, commercial vehicles continue to make up a large fraction of the world's fleet.
5. Trips are made for a wide variety of purposes that need to be considered in assessing driver interfaces.
6. A large number of new applications have appeared and will continue to appear in vehicles over the next few years, especially on phones and tablets for navigation, audio text messaging, and web access. New applications could substantially reshape the driver's task, providing the driver with a flood of information, especially if the driving task is more automated. The current major concerns are tasks related to cell phone use (especially conversation), navigation destination entry, and music selection.
7. This flood of information has the potential to distract drivers from driving. Distraction is associated with specific types of crashes (single vehicle run off road, rear end) that are most common under generally good driving conditions.
8. Workload managers and speech interfaces may be a long-term alternative to legislation to reduce distraction that leads to crashes.
9. In assessing safety and usability, a wide variety of statistics describing longitudinal and lateral control, per SAE 2499, are used in addition to task completion time, errors, and subjective ratings of ease of use. It is not unusual for there to be 30–50 dependent measures in a driving simulator study, and hundreds in an on-the-road study. A major challenge in motor vehicle interface evaluation is dealing with performance trade-offs between measures.
10. Over the last few years, there have been significant advances in driving simulators and instrumented vehicles that have improved their quality and reduced their cost for safety and usability evaluations. However, the cost of these systems may be out of the range of most laboratories, especially those in academic settings, though low-cost options for on-the-road evaluation (DriveCam, Carchip) are becoming more common.
11. The key design and evaluation documents are the Alliance guidelines, SAE J2364 and J2365, and a collection of standards from ISO Technical Committee 22, Subcommittee 13. In Japan, the JAMA guidelines are important.
12. SAE J2365, Pettitt's method, CogTool, and Distract-R can and have been used to predict task performance time, a simple measure for evaluating telematics safety and usability. The IVIS DEMAnD model can also serve that purpose, but it is not used.

Thus, while the HCI literature provides a framework for test methods and evaluation, a great deal is specific to the motor vehicle context because of the safety-critical nature of the context and the timesharing not found in office activities. To meet the needs of the future, the cost of the methods needs to be reduced, and reliable tools, especially for recording eye fixations, are needed. Significant research is needed to support the development of driver performance models (and workload managers) and understand how drivers use real driver interfaces.

33 Human–Computer Interaction in Aerospace

Steven J. Landry

CONTENTS

33.1 HUMAN–COMPUTER INTERACTION IN AEROSPACE

Aviation's interest with concepts relevant to human–computer interaction (HCI) began with the need to understand how pilots could interact with mechanical displays that indicated such things as airspeed, altitude, aircraft orientation, heading, and bearing from a radio navigation aid. When aircraft technology progressed and displays became more numerous and more complex, the interface issues became more pronounced. As travel by aircraft was commercialized, the consequences of these interface issues became more severe. When modern air traffic control was introduced, a new arena for human interface issues was opened. By the 1970s, computers were in commercial aircraft, and air traffic control was utilizing radar displays and automated flight data processing. This progression has not stopped, as higher levels of automation and new types of interfaces have been steadily added to flight decks and air traffic control rooms over the succeeding decades.

This continuous progression of displays and automation has taxed the capabilities of researchers to fully investigate the vast and varied challenges associated with aviation HCI. This chapter discusses the efforts that have been made, are being made, and also those issues which are just now on the horizon.

33.1.1 Basic Challenges, Solutions, and Principles

Human-factors issues related to aviation displays were recognized as early as 1923, as indicated by the following quotation from a National Advisory Committee for Aeronautics (the predecessor to NASA) report:

> The reaction of the aviator to his instruments has to be considered, as well as the operation of the instruments themselves. This is evident enough in the case of appliances such as oxygen apparatus, intended solely for the comfort and efficiency of the aviator, or in the case of complicated instruments such as bomb sights. But it is equally true with the more simple, direct-reading instruments. It is not enough for such instruments to be mechanically correct; they must be, in the case of service instruments, readily intelligible to the pilot. The manipulation of the instrument must not make an appreciable demand on his time or attention. The visibility must be satisfactory both day and night. Finally, service instruments must be "fool-proof." Although much can be accomplished by technical instruction courses for aviation personnel, still the personal prejudice of the average pilot has to be reckoned with. If the instrument for any reason fails to appeal to the individual pilot, he will take great chances rather than trouble to look at it. On the other hand, if the instrument pleases his fancy, he may grow so attached to it that he will claim he could not fly safely without it, even though the instrument is scientifically known to be incorrect. Curious examples of this circumstance were found in the popularity of the earlier liquid type Pitot tube among the British pilots and the spinning-top inclinometer among the French (Hersey 1923, pp. 8–9).

Another early example of aviation cognitive engineering research was in 1939, when an Applied Psychology Unit at Cambridge University in England, headed by Frederic Bartlett, began studying the design of aviation equipment (Bartlett 1943). Bartlett's group studied manual control performance, the interrelationship between controls and displays, and human vigilance. Also in 1939, the National Research Council in the United States created a Council on Aviation Psychology. The U.S. Army and Navy created programs on aviation psychology in 1940 and 1945, respectively.

World War II provided a wealth of aviation experience, and, after the war was over, aviation-savvy graduate students entering universities on the GI Bill. At the same time, advances were being made in navigation systems technology, cathode ray tube (CRT) displays, aircraft instrumentation, and control technology. The rapid increase in civil aviation made the development of air traffic control a priority as well, and the advent of radar displays peaked interest in cognitive engineering issues for air traffic controllers.

These developments led to an explosion of research in the 1950s, both in the United States and in Europe. One of the more influential reports was a 1951 blue ribbon committee report titled "Human Engineering for an Effective Air-Navigation and Traffic-Control System" (Fitts 1951b). This paper summarized the state of research as it concerned air transportation and identified key areas of future research. As such, it provides a convenient milepost for a discussion of the history and progress of aviation cognitive engineering research.

This chapter will begin from a historical perspective, covering the major issues conceived of in the 1950s and how they were addressed in the succeeding decades, if at all. Following that will be a discussion of modern concerns, which grew out of the computerization of flight decks and innovative display concepts such as heads-up displays (HUDs). Lastly will be a discussion of the future challenges for aviation and air traffic control displays.

One concern for researchers in the 1950s regarded the display of information on "transitory displays," mainly dials and gauges. As such the main focus was on whether (and how) to integrate information on a single display, how to arrange displays, how displays, controls, and the comprehension of spatial information were related, and even what types of displays were best for certain functions.

Many of these questions have been successfully addressed and provide today's engineers with some of the most concrete guidance that cognitive engineering has to offer. Some of them continue to be fascinating topics of research to this day, and, of course, many new topics related to information display and assessment have arisen over the years.

33.1.1.1 Single-Sensor Single-Instrument Displays versus Integrated Displays

The problems inherent in single-sensor single-instrument (SSSI) displays have become increasingly obvious as the number and complexity of sensors and other information sources has increased. This has been particularly noticeable in aviation, where flight decks have undergone significant changes since 1951, but has also been true for nuclear plants, which were just beginning to be tested in 1951. Interestingly, air traffic controllers have only recently begun to encounter this problem as the number of displays, and elements on those displays, provided to a controller and in the Traffic Management Unit has increased substantially.

SSSI displays have been gradually replaced or incorporated into multifunction displays as display technology has improved, although there are still examples of traditional SSSI displays on older aircraft and plants. (It is an expensive venture to replace them with graphical displays.) It seems clear from the research however, that fewer displays are better than many displays, although the former is not without its own problems.

The reason that SSSI displays are generally considered to be worse than an integrated display seems, in part, to be related to the fact that a person's ability to monitor dynamic information is very low, even when only keeping track of a few items (Monty 1973). Also, operators of aircraft have demonstrated that they have difficulty in integrating a large amount of displayed information from different sources (Murphy et al. 1978). These findings mean that it is difficult for an operator to maintain comprehension of a dynamic situation when forced to scan from display to display.

A study of the operation of manipulators showed subjects performed 30%–40% better using two displays as opposed to four displays, despite a greater amount of information in the four-display case (Bejczy and Paine 1977). This result extended a much earlier finding showed that there would be fewer missed detections if there were, for example, five times the error rate on one display compared with five displays each with one-fifth the error rate (Conrad 1951).

The presence of large numbers of displays also increases the amount of irrelevant data, also called "clutter," through which the operator must sort. Almost by definition, SSSI displays must, at every moment, display all the information that may be needed in any state of the system. Because of this, there must be irrelevant information present at any given time, and the operator must filter out this irrelevant information. As the quantity of irrelevant information increases, operator performance decreases, particularly if the information is similar (Dorris et al. 1977; Hodge and Reid 1971; Well 1971).

In addition, relevant data may be spread out over different, and often physically separated, instruments. In such a case, the information may need to be integrated mentally to obtain a higher-order representation. This operation can be cognitively intensive, and during situations of stress or short time constraints, it may not be possible (Vicente and Rasmussen 1992).

In the next section, these issues—general design principles, arrangement of displays, and clutter—will be discussed in more detail. Many of the same or similar principles can be noticed in Chapter 14 of this volume.

33.1.1.2 Basic Display Principles

In examining the question of whether fewer displays containing integrated information were better, and how information may be integrated, researchers have developed a number of principles for the design of displays. In particular, researchers have studied problems related to discerning the direction of motion of a pointer, and in the use of multipointer displays, which have been used in altimeter designs (Fitts 1951a). Since then, a number of design principles with regard to such quantitative displays have been put forth (Sanders and McCormick 1993).

One study compared digital speedometers with dials and curvilinear displays, all of which were generated electronically. For accuracy and speed of reading, the digital display performed consistently better (Simmonds, Galer, and Baines 1981). In general, digital displays have been found superior when a precise numeric value is required, and when the values presented remain visible long enough to be read.

Fixed-scale displays with moving pointers are better in the opposite cases—where precision is not required or the values are changing quickly. They are also better in cases where direction and rate of change of the values are important. For the design of analog displays, the following guidelines have been generally accepted (Heglin 1973):

- A moving pointer against a fixed scale is preferred.
- Small changes in quantity are more visible with a moving pointer display.
- If the quantity to be read is analogous to some physical interpretation, horizontal, or vertical fixed scales with moving pointers should be used to provide a zero reference.
- Do not mix multiple moving-element indicators when they are related to the same function, as this can cause reversal errors.
- Moving scale displays can be used where the scale is too great to be displayed on the face of an instrument.
- If a control changes the quantity on the display, it is less ambiguous for the pointer to move than the scale.

In addition, for quantitative displays, the numeric progression and length of scale units affect the speed and accuracy of quantitative reading (Whitehurst 1982), and scale progressions should be in increments of 1s or 5s (to ease determination of readings in multiples of 1 and 5). Unusual progressions and decimals should be avoided. It was also found that the distance between graduation markers should not be less than 0.05–0.07 inches apart (greater under low-illumination conditions), that scale markers should be used, and they should have graduation marks for the lowest unit to be read, but in no case lower than one-fifth or one-tenth (Cohen and Follert 1970). Bar-type displays should only show one segment of the bar, should not have the bar extended to zero, and should not be used where a need for an indication at zero is needed (Green 1984).

Altimeter designs were of particular concern in the late 1940s due to a spate of accidents related to misreading them. One of the early altimeters responsible for some of the problems violated one of the principles above: it had three pointers on the same scale. The operator would have to read three pieces of information and integrate them to get altitude. In 1968, a study determined that an integrated vertical display of altitude was best in terms of time and accuracy of reading (Roscoe 1968). In explaining the results, the researcher indicated that key factors were the analogy of the vertical instrument to altitude and the integration of all elements of altitude into one display.

Computers have changed how instruments are driven; instead of mechanical devices, sensors provide digital input to computers, which drive displays. However, despite the nature of the digital computers driving them, modern graphical displays often show representations of analog-like displays for instruments. This is because analog displays were found to be more quickly read for this purpose, and contributed less to workload, compared with digital displays (Hanson et al. 1981).

In addition to quantitative displays, aviation instruments may be used for check reading or qualitative purposes (Sanders and McCormick 1993). These instruments, and some principles for their design, are discussed in Sections 33.1.1.2.1 and 33.1.1.2.2.

33.1.1.2.1 Check-reading Display Research

Researchers demonstrated that for a number of instruments configured together for check reading, the pointers on round instruments were best positioned at 9 or 12 o'clock (Sanders and McCormick 1993). When all pointers are showing nearly identical readings, the grouping of the instruments and positioning of the pointers appeal to the similarity gestalt of human cognition. Violation of the gestalt is immediately and reliably recognized. Further research indicated that the addition of a line joining the instruments at their null position improved or added to the gestalt and improved performance (Dashevsky 1964).

33.1.1.2.2 Qualitative Instrument Research

The distinction does not appear to have been made between quantitative and qualitative, perhaps a subset of which is check reading, instruments before 1960. Qualitative instruments are distinct from quantitative in that the specific numerical value is irrelevant; instead the approximate value, its value in relation to some standard, its rate, or its trend are of interest. The difference may have first been noticed in a study that examined two types of readings of an instrument using three types of scales. In that study, subjects had to either read the quantitative value, or read high, low, or OK. Open window displays (see Figure 33.1) were read the quickest for quantitative values, but vertical scales were read quickest for the qualitative assessment (Elkin 1959).

Qualitative scales also typically have some identification of ranges. This can be done through the use of color, or by the addition of coded markings that have some association to the meaning of the range (Sabeh, Jorve, and Vanderplas 1958).

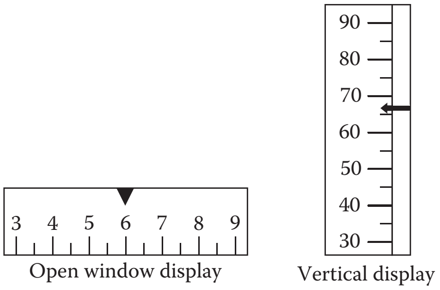

FIGURE 33.1 Display types.

33.1.1.3 Arrangement of Displays

A second question brought up in the Fitts report (1951b) regarded the organization of the display elements. A number of advances in relation to this arrangement problem were made shortly after its publication. Extensive studies, most notably one in which Fitts himself participated (Fitts, Jones, and Milton 1950), were underway examining visual scanning patterns to determine the optimal layout of instruments. These studies led the Civil Aeronautics Board (later to become the FAA) to establish a standard arrangement for flight instruments, commonly referred to as the "basic T," in 1953 (Civil Aeronautics Board 1953). It included six basic instruments, namely airspeed, attitude, altitude, direction, "climb," which is taken here to mean vertical speed, flight path deviation, and their required arrangement. This was later reduced to just the first four instruments (Civil Aeronautics Board 1957).

The analysis used in relating visual scanning patterns to display positioning was referred to as "link analysis." In this analysis, a "link" was sequential fixations on two items. The more occurrences of sequential fixations there are between two items, the stronger the link is considered to be. Items strongly linked should then be located next to one another, a technique and principle used in other fields, such as in operation centers onboard naval vessels (Chapanis 1959). Other studies of eye movements determined that the best location for important information is just above or below the glareshield of a vehicle (Cole, Milton, and McIntosh 1954). Since then, advances have been made in automating information organization (Mendel and Sheridan 1986) and instrument panel layout (Pulat and Ayoub 1979), although methods of this sort are not widely used.

The layout of the instruments not only serves to reduce the time to scan the instruments, but can also affect workload. A principle of display design called the "proximity compatibility principle" states that, when attempting to integrate two sources of information from two locations, greater workload is induced by greater separation, as the physical proximity of the sources should mimic the cognitive proximity of the information (Wickens and Carswell 1995).

Multifunction graphical displays (MFDs), common in modern aircraft, have remained consistent with the basic T and other principles, despite the substantial difference in technology, although notable differences exist between MFDs and SSSI displays. MFDs provide, in one viewport, a number of elements that may need to be integrated frequently, satisfying the proximity compatibility principle (Seidler and Wickens 1992). The content of the MFD can be manually controlled, providing the opportunity to present a wealth of information for which there was no physical space previously.

However, two problems arise. First, information that is not currently displayed is unavailable to the pilot. If that information changes, then the pilot will not be aware of it. Second, the "depth" added to the display presents the problem of navigation, although this can be mitigated through good organization and minimal depth of the pages (Allen 1983; Francis 2000; Schneiderman 1998). However, if these principles are not met, there is the possibility that the operator will become lost in the database. In addition, there is workload and heads-down time associated with the controls for the display.

33.1.1.4 How Much Information Can Be Displayed Effectively?

The problem of how much information can be fit on a display has significantly evolved since 1951, but is still a topic of debate and research. A large body of work on visual processing has been amassed over the years, and many of the theories are still hotly debated. What is certain is that the distinguishability of items on a display is overwhelmed by the somewhat limited perceptual processing capacity of the human. Without going into a great amount of detail, some of the findings with respect to this issue will be summarized.

There are two fundamental limits on extracting information from a visual scene: processing and attention. At any time, only a small amount of the information available to the retina can be processed (although all of it is perceived). The mechanics of processing are still being determined, but it appears likely that some high-level representation is quickly obtained, followed by a "weeding out" of some portions of the image (VanRullen and Thorpe 2001). Scene processing allows a variety of information to be extracted, but specific objects of interest may or may not be extracted in sufficient detail. Focused attention captures this detail, but objects can only be processed serially, and subsequent processing of these objects is inhibited (Tipper and Driver 1988). (This effect is referred to as "negative priming.") The combination of these effects yields an effective capacity of four to six items (VanRullen and Koch 2003). This number represents how many items can be represented in visual awareness at any one time. Objects/information may then be transferred to long-term memory, a process that has also been researched extensively.

How much information can be fit on one display, then, is dependent on the task and environmental factors. If one is reading a depiction of an instrument approach with the intention of memorizing details, and there is no time pressure, a great deal of information can be displayed and recalled effectively. If an air traffic controller has a fraction of a second to glean track information from a radar display, he or she is unlikely to extract more than four to six pieces of information from that display. Moreover, what information would be extracted from that display is unclear, although factors of the displayed information, such as salience, size, and color, can influence selective attention.

One further question remains with regard to information display that we will address here—the rate at which information can be extracted. This also is complex, dependent on physiological factors, features of the display, complexity of the information to be extracted, and other factors. Simple responses to visual stimuli can occur within 30–60 milliseconds (Iwasaki 1996), but more complex objects such as text can require a great deal more time.

In summary, the answer to the question of how much information can be fit on a display is—it depends. The question has become even more relevant as electromechanical displays have been almost universally replaced with electronic displays driven by computers, which can display a great deal of information in one place. These displays are also three dimensional (3D) in the sense that they can contain pages of information, which adds a new task—navigation of a display and their contents can be modified by the user or automation.

33.1.1.5 Clutter

Clutter is a significant issue for multifunction displays, such as modern air traffic control and flight deck displays that show combined depictions of route, weather, and traffic, as well as for HUDs. The source of the clutter is different in the two cases. In the former case, a large quantity of data is being overlaid on the display, whereas in the latter the display is overlaid on a source of great clutter—the outside world. In both cases, the problem is the same: response time for a stimulus is increased with the proximity of nonstimulus items (Eriksen and Eriksen 1974). Additionally, clutter can increase the time it takes for the pilot to locate an item, or even obscure items of interest (Wickens 2003). Clutter has also been mentioned by pilots in subjective ratings for some time (Abbott et al. 1980).

The solution to this problem is to provide the operator with decluttering capability—that is, the ability to remove information from the display, either manually or automatically. However, if the information is no longer present, it cannot be integrated with other information, and changes to the information, which could be important, will of course not be noticed. This is in addition to the workload required to remove or add information to the display, which could be considerable, particularly in the case of navigating a multifunction display.

33.1.1.6 Displaying Spatial Relationships

The Fitts report (1951b, p. xvii) suggested that: "studies should be made to determine principles governing the effective display of information about the relative position of aircraft and ground objects in tri-dimensional space." Specifically, the committee felt that research should be directed at determining the best types of projections for displaying spatial relations, and how symbolic and pictorial displays are best used for this purpose. In addition, more studies were called for to determine what display characteristics were required when control manipulation resulted in changes in the display. For example, turning a control yoke results in changes in bank and heading indications.

Aviation displays is a natural place for interest into the display of spatial relations to develop. Air traffic controllers must gauge both absolute and relative position and motion of aircraft in at least two dimensions (often three), and provide spatial control guidance to pilots. A pilot must, through use of instrumentation, determine relative and sometimes absolute position in 3D coordinates, and keep track of 3D orientation. This is accomplished through the use of an attitude indicator (ADI), which shows pitch and bank; a heading indicator, which shows absolute orientation; a turn indicator, which shows yaw rate; and one or more instruments showing relative position and bearing (e.g., altimeters, radio magnetic indicator, course deviation indicator, vertical deviation indicator, distance measuring equipment).

One problem which almost certainly drove the recommendation in the Fitts report (1951b) regarding the display of orientation was the problem of the ADI. In particular, what should move—the aircraft or the earth? Several principles related to this question have been put forth in consideration of the body of research into interfaces (Roscoe, Corl, and Jensen 1981) as follows:

- Principle of pictorial realism: The display should be pictorially analogous to the real world.
- Principle of compatible motion: The part that moves in the real world should be the part that moves on the display.
- Principle of integration: Related information should be integrated on the same display.
- Principle of pursuit presentation: A display should allow pursuit tracking versus just compensatory tracking; that is, if a target moves both absolutely and relatively, both sources of movement should be displayed.

A moving aircraft on an ADI or an air traffic controller's radar scope would be compatible with the principle of compatible motion. However, while the radar scope also complies with the principle of pictorial realism, from the pilot's perspective the moving aircraft would (loosely) violate it—it appears from the pilot's perspective that the horizon is banked, that is, the earth moves, as opposed to the aircraft. Although designers have settled on the moving earth model for ADI design, the debate was never satisfactorily resolved. Experiments based on a proposal to integrate the two models (Fogel 1959) showed improved performance (Beringer, Willeges, and Roscoe 1975). Researchers have argued that the moving earth ADI has continued to be used only because of the lack of interest on the part of pilots to change it, despite evidence that it is has been causing accidents for decades (Bryan, Stonecipher, and Aron 1954; Roscoe 1997).

In addition to the orientation question addressed mainly by the ADI, there are questions about how best to portray relative position. This is a common problem for both air traffic controllers, who must assess relative bearing and range between aircraft, and pilots, who must frequently assess their relative bearing and range from some navigational fix. More recently, the question of vertical navigation has received attention.

A typical horizontal navigation problem for a pilot is common to anyone familiar with basic instrument flying. From any given position, a pilot could be asked to fly to a "fix," whose position is defined by bearing and range relative to a radio navigation aid (e.g., a very high frequency omni-directional radio range, or VOR). Although this can be calculated from current heading and the ownship's bearing and range to the VOR, it is not a trivial task. A simpler task is to fly inbound on a course to a VOR or outbound on a radial from a VOR. Another example is the task of determining the position of the ownship given access to several radio navigational aids.

Recent research has qualified the difficulties inherent in these operations as "representational" problems (Zhang and Norman 1994). The theory follows from the argument that the information to accomplish many tasks is distributed between the external stimuli (the interface) and internal cognition (in this case of the pilot) (Norman 1993). Furthermore, the information representations may have different scales: ratio, interval, ordinal, or nominal. Efficient external representations reflect all the categories of information present in the "real-world" object. Deficiencies in external representations would require that information be distributed to the internal cognition of the operator, whereas surplus information, here defined as information present in the display that is not in the object, could be misleading.

Application of this theory to the problem of horizontal navigation shows that different equipment requires different levels of internal cognition. A simple automatic direction finder (ADF) or VOR system requires internal computation of angular differences and range. However, a map type display explicitly represents these, simplifying the task.

An extreme example of this representational problem is the difficulty in determining relative position from terrain or weather on a paper map (or even presented aurally!) from their knowledge of absolute position as given by the flight instruments. It is difficult and time-consuming to accurately comprehend this situation. This was apparently recognized, resulting in the display of "minimum safe" altitudes, which changes the nature of what needs to be comprehended (i.e., the pilot only must know his or her position with respect to that altitude, a one-dimensional, relative task).

33.1.1.7 Situation Awareness

It is a notable theme that modern research attention has turned from information display, as described above, to information assessment. As complex automation has been added to flight decks and air traffic facilities, and as more information has been provided to operators, accessing and comprehending that automation and information has become problematic. Researchers began to understand that not only did they need to know how to display information, but also how operators represented and utilized that information, to provide a better match between technology and the human.

Interest in information assessment has lead to a significant body of research into situation awareness (SA). This has been a particularly important concept in aviation, because safe and successful operation in aviation requires a great deal of knowledge about the environment outside an individual aircraft. Many aviation accidents can be attributed to a lack of knowledge of the environment external to the aircraft (e.g., collisions with aircraft and the ground). For air traffic controllers, their knowledge of the "big picture" includes not only the states of the aircraft in their own sector, but those of neighboring sectors, airports, weather, and much more. Attempts to understand how pilots and controllers obtain and maintain this "big picture" have been the focus of SA research.

Military aviators, since as far back as the First World War, have understood the importance of SA, and instructed their pilots in developing and maintaining good SA. One of Germany's top World War I fighter aces, Oswald Boelcke, listed among his "dicta" that "the pilot must acquire the habit of 'taking in' unconsciously the general progress of the whole multiaircraft dogfight going on around the individual combat in which the pilot will become involved … (so that) no time (is) wasted in assessment of the general situation after the end of an individual combat" (Hacker 1984). Boelcke also prescribes knowledge of one's own machine, the enemy's machine, and navigational fixes. SA has been a significant part of aeronautical training since that time.

As a research topic, however, the concept was mostly ignored by researchers until the 1980s. Due to increasing flight deck and air traffic automation, pilots' and air traffic controllers' role as supervisor of these systems was increasing, reducing the time they could spend in developing SA. At the same time, a great deal of new sensor information was becoming available to designers of aviation automation, information that could be used to reinforce the controllers' and pilots' SA. Researchers began looking into what SA is, what affects an operator's ability to construct SA and to keep it, and how it might be measured.

Many definitions of SA exist, with most agreeing that SA is, at least in part, the comprehension of elements of the environment that have (or may have) some bearing on the task being accomplished. Some efforts have viewed SA as a static, information-driven product; some have viewed it as a dynamic process, whereas others have viewed SA as a high-level description of certain aspects of task behavior. A significant body of work has also gone toward determining how to measure SA.

One of the most widely quoted definitions of SA is: "… the perception of elements in the environment within a volume of time and space, the comprehension of their meaning, and the projection of their status in the near future" (Endsley 1988, p. 97). Another researcher has called SA "… an integrated understanding of factors that will contribute to the safe flying of the aircraft under normal or non-normal conditions" (Regal, Rogers, and Boucek 1988, p. 65). These definitions attempt to describe SA as a product, something that an operator either has or does not have. As such, errors resulting from a lack of SA can be studied. Researchers have found that controllers, viewing recorded air traffic files, were unable to recall many details about traffic when asked about them during the scenario, including call signs, control level (who has control of the aircraft), altitude, speed, heading, and often even failed to report that some aircraft were present at all (Endsley and Rodgers 1996). Other researchers studying error report databases have found that in only about 20% of serious operational air traffic errors were controllers aware of the problem developing (Gosling 2002).

Researchers who view SA as a product often defer the process of obtaining and maintaining SA to a separate process, often referring to it as "situation assessment." This type of SA has been described as "(an) adaptive, externally-directed consciousness" (Smith and Hancock 1995, p. 137) and "the integration of knowledge resulting from recurrent situation assessments" (Sarter and Woods 1991, p. 45). Here, the sources of information important to SA (visual, auditory, tactile, other sensory input, knowledge of procedures and regulations, etc.) are diverse and often clearly identifiable. The operator's ability to obtain SA begins with the most fundamental cognitive processes (detection), and progress to very sophisticated concepts (comprehension and projection).

Some researchers have called into question the utility of the SA concept. Many feel it is a high-level concept that does not have sufficient granularity to really explain anything. SA has been referred to as a description of observations of humans operating complex systems in a dynamic environment (Billings 1995) and as simply equivalent to expertise (Crane 1992). As such, SA is a description of a set of cognitive processes that are used together, and is really only useful in categorizing or grouping behaviors and errors. Some researchers feel that considering SA as a causal agent can be counterproductive to understanding operator behavior (Flach 1995).

No one set of measures has been clearly identified for SA. Typical measures can be broken into three categories: (1) explicit (or knowledge-based), (2) implicit (or performance-based), and (3) subjective (Vidulich 1992). Examples of explicit methods include participants' recall of a situation (post hoc), an ongoing narrative provided concurrently with the task, or freezing a scenario and questioning the participant about the decisions, events, or the task environment. These measures can be compared with actual state of the system to provide a better measure, but have been criticized as too subjective (in the case of recall) (Fracker 1991), or too intrusive (in the case of freezing a scenario) (Sarter and Woods 1991).

Implicit measures examine task performance, and correlate that with SA. These measures are generally unobtrusive and objective and can be used in conjunction with explicit measures. It has been suggested that these measures can succeed where explicit methods cannot, particularly in situations where a determination of the timing of events is important and where the subject may be unaware of his or her deficiency (Pritchett, Hansman, and Johnson 1995). These measures may examine performance at the task overall, or alter the task to determine whether the subject notices the change.

Subjective ratings are assessments of SA made either by an observer or by the subject. These ratings can use a number of different scales, and can be either direct or relative (such as by comparing SA in one situation with SA in another situation). Although these ratings can be affected by a number of factors, including task performance, one technique that has been studied extensively is the situation awareness rating technique (SART) (Taylor 1989). This technique has the operator rate 10 constructs on a seven-point scale. The constructs are grouped into three categories: (1) attentional demand (which includes the instability, variability, and complexity of the situation), (2) attentional supply (including arousal, spare mental capacity, concentration, and division of attention), and (3) understanding (which includes information quality and quantity, and familiarity). SART has been found to be more sensitive than overall subjective measures of SA (Selcon and Taylor 1989), although some researchers feel that SART confounds SA with workload (Jones and Endsley 2000).

33.2 FROM THE EARLY YEARS TO TODAY: APPLYING HUMAN–COMPUTER INTERACTION PRINCIPLES TO AVIATION

In addition to research concerning information display and assessment, much was being learned about automation in general. The Fitts report (1951b) mentioned the need to understand how tasks should be allocated between human and machine, and this was the subject of some effort on the part of Fitts himself. Computer technology was in its infancy, and little was known in the 1950s about what limits there may be on the ability of machines to assist humans. Many thought that these machines would gradually replace all functions of the humans. Researchers now understand better the different ways in which we can describe the relationship between human and operator, although this relationship is changing as new types of automated assistance are being added to aircraft and air traffic systems.

This section will discuss the concept of allocating roles to automation and humans, beginning with some of the early concepts, then progressing to more recent characterizations of the roles of humans and automation. Following this will be a discussion of how cognitive engineering has helped shape early systems, consisting mainly of control automation, and how it is significantly involved in newer types of systems, consisting mainly of information automation.

33.2.1 Function Allocation Principles

The "Fitts list" shown in Table 33.1 served as the launching point for studies on the allocation of tasks to humans and automation. Automation for the control of aircraft had been around for decades by 1951. However, not much more was automated until the late 1960s and early 1970s, when some systems, navigation, and automated alerting were added. The early 1980s saw the advent of graphical displays, flight management systems, and the removal of flight engineers. The late 1980s introduced the concept of glass cockpits—replacing nearly all electromechanical "steam gauges" with graphical displays (Billings 1997).

TABLE 33.1
Fitts List

Humans Are Good At	Machines Are Good At
Sensory functions and detection	Speed and power
Perceptual ability	Routine and repetitive work
Flexibility and improvisation	Computation
Judgment and selective recall	Short-term storage
Reasoning	Simultaneous operations
Long-term memory	Short-term memory

Over the decades, there have been several different attempts at methodologies for allocating function. This section will be organized around those efforts: the Fitts list, the "automate everything" philosophy, supervisory control, guidelines for automation, and levels of automation.

33.2.1.1 Fitts List

To discuss the advantages and disadvantages of this approach, but without rehashing Fitts' discussion of them, we will first discuss the contents of the list, and findings surrounding the truth or fallacy of the claims. Then, we will give examples of applying the Fitts list to automation, examining the strengths and weaknesses of the approach. Finally, examples of criticism levied at this method of function allocation will be discussed.

Many of the items in the list still appear to be true. Very little argument can be made with the assertion that machines can generate more power than humans, and they can perform many tasks faster than humans. On the other side of the list, humans are still much more capable of improvisation and making judgments, and computers are not able to reason in any meaningful way, despite significant advances in computer technology.

Yet, some comparisons appear to be more complicated than suggested by the Fitts list. Although a human's perceptual ability is quite impressive, there are machines capable of remarkable feats of detection—thermal imaging systems that can "see" through walls, satellites that can read individual license plates, microscopes that can image individual atoms, explosive detection equipment that can "smell" tiny amounts of specific chemicals, and so on. Despite this, it still requires a human to interpret the results. Machines still have only primitive (and brittle) abilities to deal with recognition (particularly of symbol systems, faces, and expressions, etc.).

In general, it appears humans are "wired" for rapid operation in a highly uncertain and diverse environment, whereas machines are still generally relegated to rather specific operations in a well-regulated and defined environment. So while machines may be better at routine and repetitive work, they are generally unable to deal with events or circumstances outside of the expected operating regime. Humans, however, are able to operate in the face of such events, leading to the notion that humans are suited for "supervising" automation, which will be discussed in Section 33.2.1.3.

In practice, Fitts lists have been difficult to apply in allocating function (Sheridan 1998). One reason is likely that a Fitts list approach requires automation to be assigned to a particular function. In reality, most functions require some aspects to be done by human operators and some part to be done by the automation. Since the functions are shared between humans and automation, any distinction of human or machine for a function is likely to be sub optimal.

33.2.1.2 The "Automate Everything" Philosophy

Although this method of allocation seems unjustifiable on its face, it has had its proponents, and its reasons. Humans typically have been seen as the source of a majority of error in the system. Replacing them with "trustworthy" automation, which also came with the benefits of lower cost and more efficient operation, did not seem quite so ridiculous several decades ago. Officials of two different aircraft manufacturers have been quoted as adhering to some form of this approach relatively recently (Billings 1997). In addition, these thoughts came at a time when the growth of technology appeared to be facilitating the design of automation.

It was becoming apparent by the late 1970s that humans and automation had trouble getting along. Among the problems frequently cited were (Wiener and Curry 1980) as follows:

- Crew errors exacerbating automation errors
- Improper setup of automated systems
- Improper response to alerts
- Failure to monitor
- Loss of proficiency

In truth, however, the hurdles for an entirely automated aircraft have been, so far, too great to be surmounted. For one, the current social and political climate would have to undergo significant changes. Furthermore, it has become apparent that automation is not as reliable as had been believed at the time. Examples of failures in automatic equipment have been common and persistent (Wiener and Curry 1980).

In addition, under this strategy, the operator would be left with any functions that could not be automated (Parasuraman, Sheridan, and Wickens 2000). The result is that ill-defined, difficult tasks may be assigned to an operator that is significantly detached from the operation of the system. It is unlikely that the operator could perform well under these circumstances.

In such a system, the operator may be left with the task of monitoring the system, with the resumption of control should the automation fail. Unfortunately, the skills necessary to do so would likely be degraded from nonuse. In addition, retrieval from long-term memory is more difficult if information goes unused for long periods of time, and the model of the system required for diagnosis and action is unlikely to be present in an operator who rarely actively controls it. These last few points have been referred to as "ironies of automation," since the more advanced the automation, the more valuable may be the operator's function, but the less able the operator may be to fulfill that function (Bainbridge 1983).

33.2.1.3 Human Supervisory Control

About the same time as automate-everything approach, a concept of interaction between humans and automation was being discussed, called human supervisory control (Ferrell and Sheridan 1967). This was an offshoot of research into how humans could control a remote vehicle (specifically vehicles on the moon). It became apparent that under the 3-second delay for information to be sent to and return from the moon, that some control loops would have to be closed by the automation, with the operator acting as a supervisor of the automation (Sheridan 1992).

The concept reflected the growing role of automation, and the changing of the human's role from operator to manager of automation. As shown in Figure 33.2, several levels of supervisory and control loops exist, with the human closing the supervisory loops, and each control loop being able to be closed by either the automation or the human.

Designers could now use control theory concepts to the human-automation problem. The role of humans was essentially defined by this paradigm, and the designer could then look at lower level tasks and turn to questions such as what human resources are required for each task, how much time

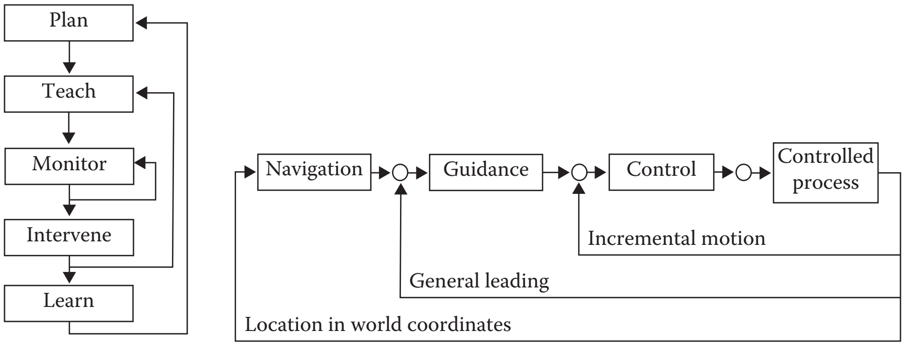

FIGURE 33.2 Sheridan's supervisory and control loops. (Adapted from Sheridan, T. B. *Telerobotics, Automation, and Human Supervisory Control,* Figures 1.2 and 1.3 © Massachusetts Institute of Technology, published by the MIT Press, 1992.)

and effort is required, how much time and energy is available, and what the consequences are of accomplishing or not accomplishing an action (Sheridan 1992).

Sheridan goes on to describe the limitations of humans and automation, and the implications of this for applying the concept. However, these admonishments went unheeded and automation was steadily added to the flight deck and control rooms, with the expectation that the operators would handle the additional managerial workload.

33.2.1.4 Levels of Automation

Parasuraman, Sheridan, and Wickens (2000) proposed a new model for allocation of automation functions across four classes and along a continuum of low automation to high automation. The four classes are: (1) information acquisition, (2) information analysis, (3) decision and action selection, and (4) action implementation. The level of automation can be allocated for each of these four levels, and can be adapted "on the fly" during operational use. The overriding consideration in determining level of automation is the consequences for human performance in the wake of that automation decision.

Information acquisition automation relates to the "sensing and registration of input data." This includes such things as moving sensors (low level of automation), organizing information (moderate), highlighting information (moderate), and filtering information (could be a high level of automation).

Information analysis automation relate to the requirement to integrate and/or transform information. Low-level examples include showing track predictions or trends. At higher-levels data may be integrated, displaying only high-level information to the operator.

Decision and action selection automation assists in determining courses of action and in making decisions. Low-level automation in this class may simply recommend courses of action. At higher levels, the automation may perform the action that it feels is appropriate. The difference is demonstrated by the Ground Proximity Warning System (GPWS), which recommends an action and is at a fairly low level, and the ground collision avoidance system, which is at a significantly higher level as it automatically takes control to avoid a ground impact if the pilot does not take action.

Action implementation automation performs actions for the operator. The level is determined by the amount of manual control left to the human operator. For example, an autopilot on heading hold may still require heading changes using a turn controller and speed control using throttles. This would be a lower level of action implementation than a fully coupled autopilot.

The appropriate level of automation for different classes should then be decided upon by examining possible solutions at different levels of automation and applying primary and secondary criteria in a possibly iterative fashion. The primary criteria are based on aspects of human performance such as mental workload, SA, complacency, and skill degradation. The secondary criteria are based on more practical concerns such as reliability of the automation and the costs versus benefits of automation decisions.

33.2.1.5 Adaptive and Adaptable Function Allocation

In addition to the other automation-related deficiencies mentioned in Section 33.2.1.2, it was noted that when certain functions of pilots were automated, those pilots suffered from increased complacency and reduced SA. To combat these problems, researchers investigated a concept whereby functions could be allocated dynamically between pilots and automation. This concept is referred to as "adaptive" function allocation when the allocation is controlled by automation, and as "adaptable" function allocation when the human operator controls the allocation (Miller and Parasuraman 2007).

Automation can alter the allocation of functions by monitoring physiological signals that reflect the workload, stress level, or engagement of the operator; by monitoring the performance level of the operator; or by reference to a model of the task. Based on a change to one of these levels, functions may be wholly allocated to automation (complete reallocation), allocated to a predefined level of automation (partial reallocation), or moved up or down by one or a few levels of automation (partial transformation) (Lagu and Landry 2011). Each of these methods has been used in research settings, although no operational dynamic function allocations have been implemented.

A pilot's general workload or stress level can be inferred from changes in heart rate or the interbeat interval (Rani et al. 2002; Wilson and Russell 2007). A pilot's cognitive workload can be inferred from changes in heart rate variability (Acharya et al. 2006). A pilot's engagement can be inferred from electro-encephalograph measurements (Bailey et al. 2006). Triggers for allocating automation to and from automation can be established on the basis of these measurements.

Performance-based measures either monitor overall performance or performance at particular, critical tasks. Should operator performance drop below a threshold, this is used as a trigger to allocate functions to the automation; if performance increases above the threshold, functions are allocated back to the human (Parasuraman et al. 1993). Critical task methods have been found to be insensitive to overall performance (Parasuraman and Byrne 2003).

Models of a task may be used to predict when workload is exceeding the capability of the operator, and when the operator may be under-loaded. These predictions can be used to trigger allocation between human and automation. A study of model-based triggers failed to find any difference between model-based and performance-based triggering methods (Parasuraman et al. 1993).

33.2.1.6 Ecological Allocation

Advocates of this approach (although they do not use this term to describe it), regard function-based representations of work as inadequate representations of the actual workplace. The workplace is complex, and there is interplay between technology and work—that is, just as the workplace is changed by automation, the use of the automation may be changed by the workplace. The claim is then that one cannot adequately allocate function without fully comprehending the work environment and the situations that arise therein.

Suchman (1987, p. 28) stressed that work is "situated," and as a result the system must "incorporate both a sensitivity to local circumstances and resources for the remedy of troubles in understanding that inevitably arise."

Moreover, the situations that arise can fundamentally change the work environment. In a discussion of previous work, Wright, Dearden, and Fields (1998) related three themes that emerged from their (and other related) studies:

> The first is that divisions of labor are often dynamically reallocated on the basis of local contingencies on an occasion of practice. The second is that the processes by which such working divisions of labor are achieved are a significant component of that work. The third themes (sic) is that even where divisions of labor are precomputed and reified in such mechanisms as standard operating procedures, there is still work to be done in making those procedures work (p. 339).

Often, due to the changing nature of work, organization, and even situation, the underlying functions of automation can change. In a study of two incidents in the London Underground (subway system) in which trains left their drivers behind, it was discovered that the operators had altered one of the two controls required to operate the train (Wright, Dearden, and Fields 1998). One automated control requires the doors of the train to all be shut before the train will move. A second control is simply a button for the operator to push to start the train moving. The operators, apparently believing that the second control was redundant, taped the button in the on position. The two incidents happened when operators left their station to fix stuck doors. When the doors were closed, the "circuit" was closed, and the trains began moving.

Wright, Dearden, and Fields (1998) argue that the operators had unknowingly changed the allocation of functions. Their function had been removed—the automation now had sole control to operate the vehicle. Yet, these types of changes to function are not only the result of errors. Pilots make use of automation in ways that change their function as well—stall warning systems as angle of attack indicators, situational awareness instruments as navigation sensors.

For this reason, it may be desirable to allocate functions dynamically, as it is done in normal social work contexts. In this concept, the (adaptable) allocation of function would depend on the context of each occasion of use (Scallen, Hancock, and Dudley 1996). In this case, designers would have to examine the consequences of improper configuration of the automation and how to mitigate the likelihood of that occurring (Dearden, Harrison, and Wright 1998).

One method of obtaining the richer representations of the work context called for in this concept would be the use of scenarios (Dearden, Harrison, and Wright 1998), as discussed in Chapter 54. Other methods include ethnographic approaches (Hughes, Randall, and Shapiro 1992) and contextual design methods (Beyer and Holtzblatt 1998), which are discussed in detail in Chapters 51 and 50, respectively. The former finds researchers immersing themselves in the work environment under study to attempt to understand the social organization of the work. In the latter, the work environment is viewed from different perspectives (e.g., user, cultural relationships, sequences of actions, information artifacts, physical layout) to define roles and tasks.

33.2.1.7 Guidelines for Function Allocation

Over the years, a number of efforts at establishing guidelines for automation have been described. Several of these, by notable authors are discussed here.

Wiener and Curry (1980) first presented guidelines for automation. They advised designers to create automation that was comprehensible to the operator, so that the operator could detect and properly react to failures in the system. They also advised that the system should appear to perform the task in much the same way as the operator, allowing for individual styles of operation while not affecting overall system performance. They suggested that operators should be well trained on the setup of the system as well as nominal and off-nominal operation, emphasizing its use as an aid rather than as a replacement. Operators should also be trained on the alerts of the systems, which should be able to be validated by the operator, and should clearly indicate both the source of the alarm and the severity of the situation. Wiener and Curry also suggested that monitoring may be an important task for the operator, who should be trained and motivated to monitor, and whose workload should be kept at a moderate level to avoid both high- and low-workload situations.

Billings (1997) agreed with many of these findings, but stressed that the automation should never have control over the system. The operator should be in control and even should not be automatically prevented from exceeding normal operating limitations. Billings also warned against overautomation, the tendency of complex automation to become incomprehensible, and the resulting system being too complex for the operator to control in the case of automation failure.

Parasuraman and Riley (1997) added to these guidelines by pointing out the possibility that in certain situations operators can "over-rely" on automation, whereas in other situations operators can "under-rely" on the automation. These situations generally occur when the operator does not have sufficient knowledge about the automation or the situation, or when confidence in the automation is misplaced (either high or low). They found that sudden alerts do not adequately allow the operators to prepare to respond, and suggested the use of preparatory, or "likelihood" alerts. They warned that automation in many cases replaced operator error with designer error, which can occur if designers do not incorporate knowledge of operational practice into their design, and do not allow for some nonintended uses of the automation.

33.2.2 Autopilots

The autopilot's development began in 1914 when Lawrence Sperry created a gyroscopic device capable of stabilizing an aircraft's flight without input from the pilot. This lead to the design of a fully automatic aircraft by 1915, and a fully automatic pilot by 1916, although it would not be until 1931 that an autopilot was licensed to operate with passengers on board (Davenport 1978). An automatic landing system was invented in 1937 by Capt. Carl Crane, and since then there have been numerous refinements in control theory which have been applied to autopilots.

One particularly interesting addition to control theory was the finding that the behavior of human–machine systems with simple feedback control systems (such as an aircraft under nominal flight conditions) can be modeled using a simple control law (McRuer and Graham 1965). McRuer attempted to model just the pilot as a controller of the system, in a manner consistent with the development of automatic controllers, such as the autopilot. Such automatic controllers have a mathematical transfer function that outputs control movements when provided with deviations of system state from the desired state as input. However, McRuer could not construct such a mathematical model of the pilot. Instead, a simple delay-and-integrator control system model was found for the combination of the system and operator; because the pilot could adapt to the dynamics of the system, the control function of just the pilot was inseparable from the plant dynamics. As stated by Sheridan, "the right way to model the human was to model the whole closed loop: the human and the airplane, or whatever system he was controlling, together as a single entity ... this was a great insight" (Gerovitch 2003).

In general, autopilots have been amazingly successful. They relieve pilots of a great deal of manual workload, particularly during routine phases of flight such as cruise. Autopilots are also capable of increased accuracy at navigation, which is reflected in their ability to land aircraft in poor weather, including when poor visibility completely obstructs the pilot from seeing the runway. Autopilots are an excellent example of the successful introduction of automation to replace manual work in a complex human-integrated system.

However, autopilots are not exempt from HCI issues. Most notably, pilots may experience confusion regarding the mode of the autopilot; the concept of "mode confusion" is discussed in Section 33.3.1.

However, in one sense the challenge of introducing autopilots is not as great as the next generation of challenges. The autopilot automates a task that the pilot can still perform; if the system fails, the operator can detect the failure and resume manual control. In this way, it is much like the cruise control in an automobile. In future systems, it is desired to introduce automation to allow the system to perform beyond the limits of manual control. In such systems, operators will not be able to detect failures or intervene should the system fail. (Such control systems exist for aircraft that are inherently unstable, such as the X-29 and the Eurofighter.)

33.2.3 Aviation Checklists and Procedures

Aviation operations are highly proceduralized, and nearly all aspects of the operation of an aircraft involve the use of checklists. In safety critical environments such as aviation, such proceduralization is common. Recognizing this, engineers who design flight deck instrumentation consider procedures when developing new avionics. However, there has been relatively little human factors work on the design and utilization of the procedures themselves (Degani and Weiner 1993).

Among the work that has been done, general design principles and considerations have been described by Degani and Weiner (1990, 1997). De Brito (2002) and Endsley and Garland (2000) found that experience will influence whether and how pilots follow procedures. However, the specific effect is not straightforward, as inexperienced pilots tend to deviate from procedure improperly, whereas experienced pilots tend to deviate from procedure when the circumstances dictate that the procedure is not appropriate. Ockerman and Pritchett (2004) recommend that the detail of the procedure is limited to force experienced operators to rely on their knowledge of the situation, and that the boundary conditions of the procedure are explicitly presented. Findings from both aviation and other domains indicate that enforcing compliance to procedures through management action may lead to worse performance (Dien 1998; Graeber and Moodi 1998; Parker and Lawton 2000).

33.2.4 Air Traffic Control

Efforts at controlling air traffic began quickly after the advent of aircraft. These early efforts consisted of drafting procedures for safe operation of aircraft, and were undertaken by private companies until the 1930s (Gilbert 1973). As aviation grew, the efforts undertaken by dedicated professionals to track aircraft and ensure their separation from one another increased.

This process was, and to a surprising degree still is, a highly manual process. Initially, aircraft had contact via radio with their companies, who relayed position and timing information to a central control facility. The controllers in that facility would record this information on a large blackboard, and manipulate aircraft markers (also called "shrimp boats") on a map table. They would analyze this information in an attempt to predict potential conflicts between aircraft. This ability to mentally project aircraft states is still relied on today when radar displays fail.

Progress from these modest beginnings was slow compared with the progress of aircraft technology. The two most significant advances in air traffic technology occurred after World War II. At least partially due to their experiences in the Berlin Airlift, air traffic personnel adopted the practice of speaking directly to aircraft. In addition, the development of radar allowed controllers to track aircraft in real time.

33.2.4.1 Early Radar Displays

Although the application to air traffic control is obvious, early efforts at controlling aircraft using radar were troubled. Early radar displays displayed the position of each aircraft relative to the radar station, but did not display other critical information, such as aircraft identification, speed, or altitude. Because of this, associating targets with radar returns was difficult, and projecting their status into the future was still a largely cognitive process. The recognition of this helped bring about the introduction of secondary surveillance radar, in which a transponder on board each aircraft transmits an identification code and altitude to a ground receiving station (Gilbert 1973). This information can then be correlated with the radar returns, eliminating the need for map tables.

33.2.4.2 Flight Strips and Strip Bays

Controllers gradually replaced the blackboard with small strips of paper on which information about each flight was recorded. These would be placed in a rack (or bay) in temporal order, and even passed from controller to controller as the flight progressed. As computers were added in the 1960s and 1970s, one of their first tasks was to automate this flight data processing, including printing flight strips.

This proved to be a rather difficult task. The physical manipulation of the flight strips, such as controllers moving the strip from one position to another or literally handing it off to another controller, contained significant meaning (Bentley et al. 1992; MacKay 1999). This meaning was lost when the strips were no longer physically present. Since this time, data strips have been automated within the User Request Evaluation Tool (URET), but the manner in which the deficiencies were overcome, or the resulting performance of controllers, has not been documented.

33.3 MODERN CHALLENGES, SOLUTIONS, AND PRINCIPLES

The first 50 years of aviation saw significant changes and innovations in both aircraft and air traffic control. Recent developments, such as complex flight management systems, multifunction displays, highly integrated information systems, alerting and warning systems, and sophisticated automatic control capability have presented even more complex challenges for aviation professionals and researchers.

33.3.1 Glass Cockpits, Flight Management Systems, Mental Models, and Mode Confusion

Beginning in the 1970s, airliners were being equipped with flight management computers, which would assist pilots in numerous tasks, including flight path management, navigation, and fuel burn management. The interface to the flight management computer is through a control display unit, which consists of a small alphanumeric keyboard, several function keys, and a small display screen, all of which fits into about a 6 inch by 10 inch space. On this unit, pilots must enter navigation information, select information to be displayed, and navigate through menus. By the 1980s, flight management computers were integrated with CRT displays, creating flight decks mostly devoid of gauges, also called “glass cockpits.” An example of a glass cockpit (from NASA’s Atlantis orbiter) is shown in Figure 33.3.

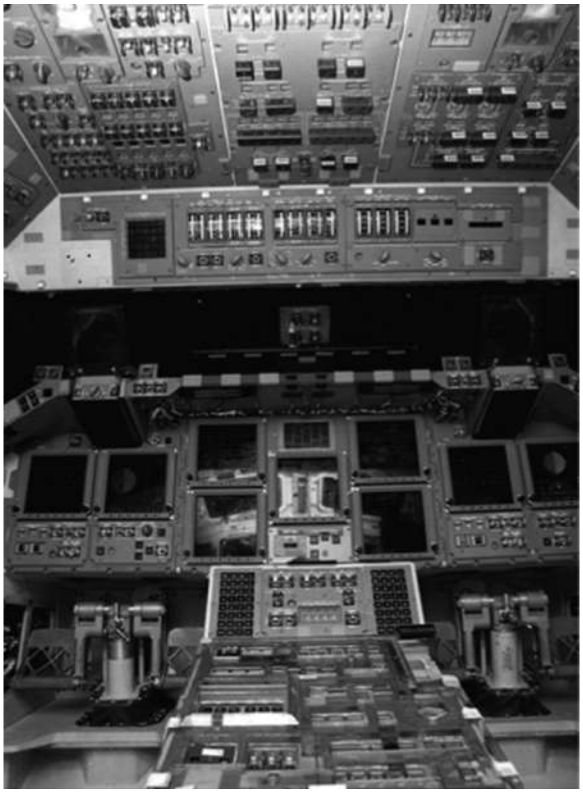

FIGURE 33.3 Orbiter glass cockpit. (Image courtesy of NASA, obtained from http://www.nasa.gov/mission_pages/shuttle/main/shuttle_evolves.html.)

Such systems integrated the operation of the aircraft with navigation, resulting in a “fundamental shift in aircraft automation” (Billings 1997, p. 107). Although such displays provided the benefits of a highly integrated display, there is a cost in terms of workload, crew coordination, error management, and vigilance (Wickens et al. 1998). In addition, a number of accidents have been associated with pilots misunderstanding the state of the automation. These accidents have been attributed to the pilots lacking an accurate “mental model” of the automation.

Mental models, described in detail in Chapter 4, are a conceptual representation of a system posited cognitively. The precursors to mental model research date back nearly a century. These early inquiries (Craik 1943; Wittgenstein 1922), and a significant body of recent work, argue that cognition is inherently imagistic, so that mental models are a theory of how people think. This theory is a topic of contentious debate in the psychological community, with many researchers vehemently denying that people think in these “pictures in the head,” but rather that thought consists of formal rules of inference (Pylyshyn 2003).

Undeniably, however, people at least think about such imagistic models. In doing so, operator’s reason about their system based on these models. There is convincing evidence that such models correlate well with certain operator errors, and point to ways in which good design can mitigate these errors. As such, we will try to skirt the contentious issue of whether mental models are theories or models, and stick to how the concept has been deployed in support of cognitive engineering.

Mental model research was borne out of the observation that many people use analogy to understand complex phenomena. This idea became more formalized in the cognitive science literature, highlighted by a flood of papers and books on mental models in the early 1980s (Gentner and Stevens 1983; Johnson-Laird 1983). If one believed that a person's knowledge of a complex system was a product of that person's model of the system, then an understanding of the limitations of these models was crucial to explaining behavior and errors.

Nowhere did mental models seem to fit in better than in explaining a number of human-automation interaction failures. Flight deck automation was becoming increasingly complex, taxing the abilities of pilots to accurately model it. Where such inaccuracies exist, error is likely. Several particularly prominent examples of this have occurred in the last 15 years. In 1988, a Boeing 767 was inadvertently put into a vertical speed mode, nearly resulting in a crash. A similar situation occurred in an Airbus 320, when a crew mistakenly selected a descent rate of 3300 feet per minute instead of on a 3.3° downward slope and flew into terrain. In 1994, a China Airlines Airbus 300 aircraft crashed after pilots tried to continue a landing while the autopilot had been inadvertently put into a go-around mode. Also in 1988, an Airbus 320 was flown into terrain by an aircrew during an air show; the crew believed that the envelope protection of the aircraft would prevent a stall, but the aircraft was in a mode where that protection was not provided.

These incidents indicated that one piece of flight deck automation particularly prone to such mental model inaccuracies is the flight management system, which interacts closely with the autopilot. Researchers had been aware of mode problems in HCI for some time, and in due time, these issues arose in the interaction of the pilot with the computer that operates the autopilot. This aspect of the problem—as a computer interface issue—has significantly affected the research on mental models in aviation.

In addition to calling for training for pilots to better understand their systems, much effort has been put into creating models of the pilot's interaction with the flight management system in an effort to understand how systems might be designed to mitigate these model inaccuracies.

33.3.2 Heads-up Displays

To minimize the need to view instruments inside the cockpit, "heads-up" displays were superimposed on the windscreen, providing at least the basic T information. The same method can be used to superimpose images on the inside of the visor of a helmet (known as helmet-mounted displays). HUDs have moved from the military, where they found their first application, to commercial aircraft and even automobiles.

One major difference between the instrumentation on a HUD and the same instrumentation on a traditional instrument panel is that the world can be viewed through the HUD. This allows for the possibility of integrating real external images with the instrumentation without violating the proximity principle. However, the flip side of this is that the world peeking through the HUD provides a great deal of clutter to the display, although some research indicates that this is not a significant increase in difficulty (Ververs and Wickens 1998). Overall, the HUD has a number of advantages that make it superior to conventional positioning of displays. The HUD enhances the operator's ability to switch between near and far domains (Levy, Foyle, and McCann 1998), although strangely this reverses to a detriment for the detection of unexpected events (Wickens and Prevett 1995).

33.3.3 Information Automation

The rapid rise in computer and display technology has allowed engineers to develop systems that alleviate some of the information burden on the operator. These systems perform automated monitoring (such as conflict alerting and prevention), provide information to assist the pilot's decision making, and help provide coordination between different operators.

33.3.3.1 Alerting Systems

In the late 1970s, aircraft were undergoing a rapid expansion in terms of warnings and alerting systems. One survey found general agreement that there were too many warnings and also standards and guidelines were needed for warning system design (Cooper 1977). Another researcher determined that the number of visual alerts and flags had doubled, whereas the number of aural alerts (see Chapter 10) had increased by 50% since the beginning of the commercial jet age (Veitengruber 1977). Based on the data at the time, researchers were recommending that alerts be reduced, prioritized, and inhibited during critical phases of flight.

Since then alerting systems have grown significantly in capability and complexity. Current alerting systems may utilize multiple sensors, ground communications, large knowledge databases, and may have sophisticated algorithms for alert threshold and guidance recommendations (Pritchett 2001).

One of the most widely analyzed problems in alerting system technology relates to problems with conformance to the GPWS. The GPWS was a complex alert designed to warn of something extremely hazardous—proximity to or closure to terrain. It was complex in that closure to terrain can be caused by a number of things, including landing, and the system had to discriminate these events. In part due to this complexity, and in part due to poor design, the system frequently produced false alarms. A high rate of false alarms generally has the effect of reducing operator trust in the automation and causing under reliance (the pilots would not believe the alert), a phenomenon known as the "cry-wolf" effect (Breznitz 1984).

High false alarm rates can also be caused by improper setting of thresholds for alerts, a process that is analogous to signal detection. The threshold for an alert can be based on the system operating characteristics curve, which is in turn a function of the sensors (Kuchar 1996). Setting the threshold is then a tradeoff between missed detections and false alarms. Typically, this means that the fewer the false alarms, the more the missed detections. Interestingly, some researchers have warned against having too low a false alarm rate (Farber and Paley 1993). If the false alarm rate is too low, not only will the occurrence be infrequent and unexpected, but it will likely require a later alert, compounding the difficulty of reacting to the alert.

The problem of false alarms is further exacerbated by the low base rate of incidents requiring an alert (Parasuraman and Riley 1997). In these cases, the relative rate of false alarms is increased. Yet in many cases, the cost of a false alarm is considered much lower than a missed detection, leading designers to err on the side of economy, and/or safety.

These (generally) are cases where the alerting system is functioning as a signal detector or a hazard detector, the latter being a more complex version of the former. Alerting systems have also added hazard-resolving logic, such as in Traffic Collision and Avoidance System (TCAS) II (Kuchar and Drumm 2007) and NASA's Advanced Airspace Concept (Erzberger and Paielli 2002). The benefit of such an approach is that the resolving maneuver can be incorporated into the alerting logic, resulting in a reduction of false alarms. However, such a system relies heavily on the pilot performing the maneuver appropriately. It is also possible that the maneuver may actually induce a collision, by creating a problem where none actually existed.

33.3.3.2 Decision-Support Systems

In addition to alerting systems, there are also systems on board aircraft and, to an even greater extent, in air traffic control which are considered decision-support tools (see Chapter 26 for a discussion of design approaches for decision-support systems). These tools do not warn or alert, but provide information to support decision making. This information is often integrated from several sources, or enhanced in some way.

One fairly simple example of a decision-support system on a flight deck is the weather radar system. This system provides no discrete alert, but rather shows the pilot where hazardous weather exists to help pilots determine how to deviate to avoid it. With no weather radar, pilots had to rely on visual means, which can only detect gross features, such as height, darkness, and the presence of lightning. However, weather radar not only shows rates of precipitation (an indication of severity), but can also show the lateral and vertical extent of the weather.

Another decision-support system is the Engine Indication and Crew Alerting System. Although some aspects of this system are more correctly considered an alerting system, much of the system is simply decision support. This display shows pilots the status of most of the systems on board. It can be configured to depict engine instruments or other graphical depictions of the operation of the systems on board the aircraft.

As mentioned, there are a number of decision-support tools being used in air traffic control. In fact, the number of such displays are increasing at such a rate that the FAA is attempting to integrate these systems to reduce the sheer number of separate systems operating in air traffic facilities.

33.3.4 Near Term Air Traffic Control Issues in Human–Computer Interaction

The current air traffic control system, while reliant on computer resources, has been designed to be resilient to the loss of such resources. Computers are still used for display of primary and secondary radar information, and flight data processing. The upgrading of these capabilities from the 1970s has been slow, impacted by the widespread replacement of experienced controllers following the air traffic controller strike of 1981, and the failure of the Advanced Automation System (AAS) program of the late 1980s (Lee and Davis 1996). On the heels of the AAS system, however, have come a number of advances, including attempts to automate flight strips and the introduction of automation aids.

33.3.4.1 Automated Flight Strips

Flight strips have proven remarkably resilient to change. Many controllers still use flight strips, and flight strip bays are still used in air traffic control facilities. Recently, however, manual flight strips are being replaced with electronic flight strips, most notably in the URET, which took 25 years to implement (Arthur and McLaughlin 1998). Similar efforts to replace flight strips were undertaken in Europe (Berndtsson and Normark 2000). The reasons for their slow demise are highly instructive of some of the problems with automating some forms of human work.

Despite the significant workload of the manual process of dealing with flight strips, controllers have been reluctant to part with them, or to use suggested replacements. This is, in large part, due to the flight strips contribution to the controller's SA. For a controller, whose job is still to a large degree cognitive, their SA is crucial (Whitfield and Jackson 1983). Researchers have found that controllers indicate that flight strips are a primary means of establishing and maintaining their SA (Harper and Hughes 1991).

33.3.4.2 Decision-Support Tools in Air Traffic Control

One of the most significant areas of improvement within air traffic over the last two decades has been in decision-support tools. Over the years, a number of automation tools have been slowly added to the air traffic control system, and others have been considered and failed. These advancements have included the introduction of two conflict prediction systems, the failed attempt to provide sequencing and runway selection aids, and the introduction of centrally scheduled time-based metering tools.

The first conflict prediction system was created in the early 1980s as a quality assurance program. The "operational error detection program" (OEDP) was designed to identify when two aircraft had come closer to one another than allowed under FAA regulations. If the OEDP was set off, a record was made of the transgression, and investigation took place. This is obviously highly undesirable for controllers, who have nicknamed the system "the snitch patch." Controllers routinely pad separation between aircraft, in part to ensure that the snitch patch does not activate (Cotton 2003).

The conflict alert system gives a 3-minute warning that a violation is going to occur, although the system is not considered highly reliable by controllers due to its high false alarm rate (Wickens et al. 2009). Part of the reason for the system's unreliability is that its predictions are based on simple extrapolations of the current states of the aircraft involved, without consideration of intentions (such as its intention to stop climbing or to change course).The system's unreliability has led to several efforts to replace it. The URET system mentioned previously includes a "conflict probe," which examines the predicted flight path of aircraft and gives an indication of the potential for collision (Brudnicki and McFarland 1997).

In the 1990s, NASA undertook an effort to provide automation tools for controllers and traffic managers. The suite of tools, called the Center-TRACON Automation System (CTAS), was based on combining radar position and speed data, aircraft flight plans, weather data, and models of aircraft flight characteristics. The models were based upon those used in the flight management systems in aircraft, which are known to be highly accurate. One of the first tools proposed was the Final Approach Spacing Tool (FAST). This system was to be used by controllers handling aircraft close to busy airports. These controllers transition aircraft from intermediate altitudes and about 50 miles out from an airport and coordinate their arrival to the runway. This is a very complex task, requiring controllers to predict the proper sequencing and merging of aircraft from several directions. FAST generated advisories for sequencing, runway assignment, headings, and speeds to ease the merging and spacing of aircraft (Lee and Davis 1996). Although deemed acceptable by controllers (Lee and Sanford 1998), the system was ultimately not implemented. One of the likely factors was that although the system was extremely accurate in its predictions, it was not perfectly so, and controllers may have felt that the workload and distraction of the few inaccurate predictions outweighed its benefits.

Another part of the CTAS suite of tools is the Traffic Management Advisor (TMA), which provides a similar service as FAST for controllers handling aircraft further out from the airport (out to about 300 miles). This system provides delay advisories for each aircraft approaching a busy airport. Controllers are then responsible for slowing aircraft to meet the assigned delays, utilizing the same techniques they use to space aircraft normally. The main shift between the current method and TMA is that the spacing TMA provides is time-based, versus the distance-based method currently used. Time-based metering in this fashion has been shown to be more efficient than distance-based (Sokkappa 1989; Vandevenne and Andrews 1993), and TMA has shown significant benefits where it has been adopted (Knorr 2003). Similar efforts focused on runway sequencing and scheduling have been developed in Europe, Canada, and Australia (Barco Orthogon 2003; Ljundberg and Lucas 1992; NavCanada 2003; Robinson III, Davis, and Isaacson 1997). More advanced systems are also being developed which move some separation authority to the flight deck (Prevot et al. 2003).

33.4 FUTURE CHALLENGES

Aviation has undergone a great deal of change since its inception, although predictions of its development path have not always been accurate. Forty or fifty years ago predictions of where the air transport system would be probably have included much more automation of air traffic control, high reliance on satellite systems, with larger and faster aircraft than were then utilized. These aspects have largely not been realized to the extent expected. The aviation system of the future will undoubtedly hold other unexpected developments, but a few challenges for researchers, engineers, and practitioners are clear.

33.4.1 Three-Dimensional Displays

To overcome the limitations of two-dimensional (2D) displays, several alternatives to providing three dimensions in a display have been investigated. Air traffic and navigation displays are both trying to represent three dimensions in a 2D display. Inevitably, some information is lost in the display in this case. This can be accomplished through binocular, stereoscopic, or holographic devices (Mountford and Somberg 1981), but practical problems make this unlikely. Also unlikely due to the cognitive demands of integration is using time-frame compressions (a display of sequential images) (Roscoe, Corl, and Jensen 1981). However, significant research has been accomplished in using perspective illusion displays, where the illusion of three dimensions is given through the use of perspective.

Three dimensional displays can portray a variety of viewpoints, to different effect (Wickens and Prevett 1995). In testing such displays, 2D displays, with either some analog display of altitude or an additional profile view, are used for comparison. This adds complexity to testing these displays, since often additional information has to be added to current displays to isolate the 3D presentation from the additional information provided by the display.

In addition, dual panel 2D displays, although they may contain the same information as 3D displays, have an additional cost—that of scanning and integrating. So, it would seem that 3D displays adhere to several tenets of good display design: proximity compatibility, integration, and pictorial realism.

However, if the airplane is not navigating vertically, the 3D display may impose a clutter cost as the operator must sort through the irrelevant altitude information. This is in addition to the problem of ambiguity of position of objects along the line of sight of the display (McGreevy and Ellis 1986). Lastly, if the 3D perspective is immersed (the perspective is as the world looks from the cockpit), no information concerning the world to the side or behind the aircraft is presented, resulting in a "keyhole" view of the world (Woods 1984).

For judgments requiring mapping between the world and the display, a 3D display with a viewpoint outside the cockpit seems to provide the best performance (Olmos, Wickens, and Chudy 1997). This benefit is again tied to the principles of realism and integration, and is generally viewed as providing better overall SA than immersed 3D views.

33.4.1.1 Tunnels and Tubes in the Sky

Enhancements to the immersed viewpoint of a 3D display can present the operator with a highly integrated pathway, or "tunnel in the sky." Superior performance in navigation and tracking has been demonstrated using this display (Wickens and Prevett 1995), although they are currently still in development. The biggest obstacle to the deployment of such automation seems to be the cost of certification rather than any technical or cognitive issues. It appears that these displays only suffer from effects similar to those found on other perspective displays (confounding of distance along the line of sight) and on HUDs (difficulty in detecting unusual events due to the compelling nature of the display) (Wickens 1998).

Proposals that would segregate airspace by the level of equipage of the aircraft in that airspace often use the notion of "tubes in the sky," where the tube is a region of airspace in which only aircraft that have particular equipment are allowed to fly (Sridhar et al. 2007). Tubes and other proposals, such as dynamic airspace reconfiguration (Kopardekar, Bilimoria, and Sridhar 2007), would have significant consequences for air traffic controllers. The effect of such proposals is not yet known.

33.4.2 Coordination Support Systems

One type of information system which is likely to become prevalent in the future is what is referred to here as a coordination support system (for a further discussion of computer-supported cooperative work, see Chapter 28). It is becoming more common that work, including in the air traffic system, is distributed across organizations. For example, alerts generated by an aircraft's TCAS system have to be coordinated between the two aircraft in the conflict pair to avoid having the aircraft's resolutions conflict. Also, coordinating arrivals into airports involves affecting aircraft many hundreds of miles away from the airport, across air traffic control organizational, and even facility boundaries.

One approach to enabling such cooperative work is to actively share information between organizations through procedural means. Such an approach means that one organization, with localized information of interest, distributes that information to other parties. However, in the air traffic system, the great majority of the information needed for collaborative work is present in the task environment, or relates to the impact of other organizations' decisions on the traffic situation. If such ecological information could be provided, then collaborative work would happen naturally.

Such an approach is supported by the concept of a common information space (CIS) (Schmidt and Bannon 1992). A CIS is a source of information shared within and across organization boundaries to conduct coordinated work for common purposes. Instead of passing information from one organization to another, information is made available through the CIS, which can then be accessed and manipulated by any interested party. Moreover, objects can be created within the CIS that serve as translators across different communities. These objects, referred to as boundary objects, are entities in which decontextualized information resides in a particular form (Starr and Griesemer 1989). The distinction which defines boundary objects is their purpose in acting as translators, or, as defined by Bannon, they are a "means for sharing items in a common information space" (Bannon 2000, p. 5). Information, devoid of context, is presented in a form that allows users from different communities of interest to comprehend it within their own context. This object is accessed by users in different communities of interest to conduct their particular portion of the work. The information in boundary objects is contextualized only within each community of interest, and this context differs in each separate community.

33.4.3 Technologies Needed for 3x Air Traffic: Human–Computer Interaction Issues

The rate of growth of air traffic has been consistent for a number of decades, and is not expected to change significantly in the next few decades. Such a rate of growth would double or triple air traffic, a level which some researchers feel is unsupportable by the current method of air traffic control.

Such a conclusion is consistent with the historical development of the air traffic system. To grow beyond its capabilities in the 1940s, radar was added, reducing the workload of the controllers, which enabled them to deal with more traffic and higher aircraft speeds. To continue to grow, computerized flight data processing was added, further reducing workload and allowing controllers to handle more traffic. Increases in staffing, reduction in sector sizes, strategic control, and other innovations have allowed further increases in air traffic levels. To further continue these increases, researchers argue that a more fundamental shift is needed, by sharing some of the air traffic responsibilities between the current authority (air traffic controllers) and the flight deck, by allowing automation to accomplish some current tasks of the controllers, or some combination of these.

33.4.3.1 Data Communications

To date, much of the communication that occurs in the air transportation system is by voice, with the exception of communications between airline operations centers and their aircraft, which happens using a form of electronic mail. Voice communication is considered the primary means of controlling aircraft; controllers worry more about losing voice communication than radar. Specific procedures have been developed for aircraft to follow should communications be lost.

However, voice communication channels have limited bandwidth. The commands a controller issues to a pilot are stated in clear, standardized phraseology, and each command must be "read back" to the controller to ensure it has been heard correctly. Frequencies can become jammed with such communications, which is why commercial aircraft are required to simultaneously monitor the air traffic control frequency and an emergency frequency. Controllers in very busy areas, such as the airspace near a major airport, can encounter "frequency congestion," where the controller no longer waits for the read back, but instead issues streams of commands to different pilots back-to-back without pause. In such conditions, the capacity of the airspace is effectively capped to the number of aircraft with which the controller can communicate.

Because of this, and due to problems associated with miscommunication, it has been proposed to replace some, or even most, voice communications with data communications (Erzberger 2004a; Kerns 1991). In some early studies, however, controller's responses were slower when using data communications (Latorella 1998; Wickens, Miller, and Tham 1996). In addition, pilots were found to use information from communications to other pilots, referred to as "party line" information, and this information would be lost if the switch were made to data communications (Midkiff and Hansman 1993). Nonetheless, due to the need to increase capacity, it is generally assumed that data communications will replace at least some of the voice communications currently in use (Djokic, Lorenz, and Fricke 2010).

33.4.3.2 Four-Dimensional Contracts: Future Changes in the Roles of Pilots and Controllers?

The flight management systems used by the current generation of commercial aircraft is capable of meeting arrival times over points in its flight path, subject to the constraints of the flight envelope. The logic behind these flight management systems is also available to ground-based systems, and is in fact the heart of CTAS, a suite of air traffic management tools developed by NASA (Erzberger and Nedell 1989).

These ground-based systems can use the flight management algorithms to make predictions of arrival times for all aircraft in the National Airspace System (NAS). This has been accomplished for flights arriving at a number of the busiest airports in the United States in the TMA system (Swenson et al. 1997). This capability is being expanded to regional or national airspace, and for scheduling aircraft over any congested point in the NAS (Landry, Farley, and Hoang 2005).

One proposal for increasing the capacity of the air traffic system is to allow such a system to negotiate "4D contracts," indicating navigational waypoints, altitudes, and times of arrival at those points for all aircraft. The flight management systems would then be responsible for adhering to the contract. These contracts would ensure conflict-free routes, and coordinate arrivals into congested resources, including airports.

Such a system would radically alter the roles of pilots and controllers in relation to their automation. Pilots and controllers would be monitors of a highly automated system, in comparison with their current roles of actively controlling the flight paths of aircraft. As such, this presents enormous challenges to the aviation HCI community.

33.4.3.3 Automating Separation Assurance

The primary responsibility of an air traffic controller is to provide separation assurance between aircraft. Even if data link and 4D contracts were established, the controller is still limited by the cognitively intensive process of monitoring for conflicts. This task is also under consideration for automated assistance, either on the flight deck or through a centralized system.

One proposal is to equip flight decks with a Cockpit Display of Traffic Information system, and utilize an advanced form of the current TCAS. A second proposal is to utilize a centralized system for providing alerts (Erzberger 2004b). Such a system would coordinate resolutions automatically, and provide for an independent backup in case of failures to resolve. In both cases, automation would detect conflicts, identify resolutions, and (perhaps) automatically perform the resolutions. Such systems overcome the latencies in the human detection, communication, and action cycles. However, as the human operators are pushed back further from the actual operation of the systems, their ability to intervene in the case of automation failures wanes. Because of this, such automation must be highly reliable for the system to succeed.

33.4.4 Uninhabited Aerial Vehicles in the Airspace System

The rapid development of uninhabited aerial vehicles (UAVs) will also greatly impact the air traffic system of the future. To date such vehicles have been mostly constrained to special uses, such as the military. However, it seems likely that these vehicles will need to be integrated into the air traffic control system as their uses expand (Wegerbauer 2005).

The difficulties in introducing UAVs into the airspace system, from the perspective of the air traffic controller, include their unpredictable response to system failures and the substantial difference in performance between UAVs and commercial aircraft. As mentioned, procedures exist for cases in which systems failures, such as radio failure, occur. If such a failure occurs, controllers can manage the other aircraft assuming that the procedure is followed. Even under unusual circumstances, controllers can usually predict the behavior of the pilot and control other aircraft accordingly. However, if radio links to the UAV are lost, control of the vehicle would resort to a set of automated routines, which may not perform in a predictable manner. Moreover, without the ability to "see and avoid" other aircraft, UAVs pose a collision risk in such circumstances.

From the pilot's perspective, flying a UAV is substantially different than flying an aircraft. Many subtle, but important, proximate cues available to the pilot of a manned vehicle, such as vestibular and auditory cues, are not available to the pilot of a UAV. Instead, all information available to the UAV pilot is mediated by a computer display and data communications link, which may include some delay.

In addition, automatic landings, and landings using video and instrumentation, are not available for all UAVs. When visually landing such aircraft, the perspective is no longer egocentric, as with a pilot on the flight deck, but rather exocentric and from different perspectives, such as in front of the aircraft, behind it, or off to the side. These different perspectives make precision control of the vehicle, generally necessary for landing, difficult. As a result, accident rates for UAVs are high; although this does not usually involve loss of life, there is substantial cost in terms of material.

33.5 CONCLUSIONS

Fitts (1951b) and his colleagues described the research challenges in visual displays as of 1951. The document is remarkable in that it spurred (or foresaw) a great deal of research that continues to this day. Some of that can be attributed to the general nature of the questions, but many of the specific research questions and methods have been examined and used over the last 40 years. What was noticeably (and understandably) absent from the discussion of transitory displays was any reference to higher cognition. In some ways, this is indicative of the progress made in aerospace human–machine system research. Many of the difficulties associated with these concepts originated as higher levels (and greater amounts) of automation were added to the flight deck.

The progression of research has also followed this model. Early research resulted in a number of principles for integrating displays, for determining the form of displays for different purposes, and for the positioning of displays. Later work has concentrated on higher level cognitive issues such as mental models and SA. Also, work has been done on understanding how to apply automation, resulting in a number of principles regarding automation use and allocation of function. Most recently, new types of displays and automation such as warning systems and decision-support systems have been introduced, yielding a new set of problems for researchers to tackle. As the air transportation system matures and the demand for ever greater levels of capacity increases, it seems that greater reliance on automated systems will be required. For such a system to be successful, such automation must be based on sound principles.

34 User-Centered Design in Games

Randy J. Pagulayan, Kevin Keeker, Thomas Fuller, Dennis Wixon, Ramon L. Romero, and Daniel V. Gunn

CONTENTS

34.1 INTRODUCTION

The application of user-centered design (UCD) methodologies has had a tremendous impact on the aviation, medical, and technology industries over the past several decades (Preece et al. 1996; Salas and Maurino 2010; Wickens and Hollands 2000). UCD principles and evaluation methods have successfully made our interaction with tools faster, safer, and more efficient. Yet, there has been growing interest in the adaptation of these techniques to make products more pleasurable (Jordan 2000). Instead of focusing on making tools faster, safer, and more efficient, greater emphasis has been placed on making them enjoyable to use (Norman 2005). For more than a decade at Microsoft, we have been applying, refining, and inventing new UCD techniques to improve not only the *usability* of our games, but, more importantly, the *enjoyability*. The purpose of this chapter is to review some principles and challenges in applying UCD techniques to game improvement and evaluation. First, we discuss why games are important followed by a differentiation between games and productivity software. Next, we discuss the principles and challenges that are unique to the design of games. That discussion provides a framework to illustrate the core variables we think one should measure to aid in game design testing and evaluation. Finally, the chapter will conclude with some examples of how those variables have been operationalized in methods used by Studios User Research at Microsoft Studios.

34.2 WHY GAMES ARE IMPORTANT

In the 1950s, computers imposed a technological and economical barrier to entry that was not easy to overcome for the general population. Only scientists, engineers, and highly technical persons with access to universities or large companies were able to use these machines (Preece et al. 1994). As computers became less expensive, more advanced, and more reliable, the technology that was once available to only a small subset of the population began proliferating throughout society and became integral to everyday life. In order to make this transition possible, well-designed interfaces between the user and the technology were required. Video games come from similar origins and appear to be heading down a similar path. Some early attempts at making commercial video games failed due to unnecessarily high levels of complexity. As Nolan Bushnell (cofounder of Atari) states, “No one wants to read an encyclopedia to play a game” (Kent 2000, p. 28). In retrospect, some of the most successful video games were the ones that were indeed very simple. The more recent adoption of “broadening interfaces” such as Nintendo’s Wiimote, Microsoft’s Kinect, or Sony’s Move, as well as the large number of people buying games, shows a similar proliferation of games in society. This too is only possible with well-designed interfaces between the user and technology.

34.2.1 Games Industry Generates Enormous Revenue

Within the first 24 hours of its release, the video game *Halo 3* generated approximately $170 million dollars in sales, in the United States alone, rivaling the film industry's opening day record for *Spiderman 3* as well as the book industry's opening day record for *Harry Potter and the Deathly Hallows* (Chalk 2007; Microsoft 2007). Video games are one of the fastest growing forms of entertainment to date, and today the video games industry generates enormous revenue. According to the Entertainment Software Association (ESA), revenue from computer and console games has grown from 2.6 billion dollars in 1996 to 11.7 billion dollars in the year 2008 (ESA 2009). Approximately 298 million games were sold in 2008 and approximately 43% of Americans purchased or planned to purchase one or more games in 2009 (ESA 2009). These statistics do not even consider the international importance of video games. To put this into perspective, the combined U.S./Canada movie box office for 2008 was $9.6 billion (MPAA 2009), which is approximately $2 billion less than the revenue from computer and console games from the United States alone.

34.2.2 Games Are Not Just for "Gamers" Anymore

The revenue created by the games industry, one that rivals the U.S. film industry, suggests that gaming appeals to more than just a niche market. In fact, video games are no longer associated with the stereotypical image of a gamer as an adolescent male; women aged 18 and older represent a larger portion of the game playing population (34%) compared to boys aged 17 and younger (18%), and the average age of those who play video games is 35 (ESA 2009). In addition, gaming has become increasingly more popular with the older population with 25% of all gamers being over the age of 50 (ESA 2009). All together, a majority of American households play computer or video games and with game revenue rivaling the motion picture revenue, it is no wonder that the people who play games are as diverse as the games they play.

34.2.3 Games Push Technology and Research

In addition to driving revenue, video games have also helped to shape and drive technology and research. For example, during the early 1980s, IBM commissioned Sierra Online to develop a game to show off the advanced graphics capabilities and three channel sound of their upcoming IBM PCjr computers. While the PCjrs didn't fare well in the marketplace, Sierra's creation actually might have helped IBM's competition. The resulting game, *King's Quest*, arguably helped drive sales of the PCjr compatible Tandy 1000 computer by showcasing its enhanced graphics and sound capabilities. A more recent example of games driving technology can be seen in the Xbox 360 Xenon processor developed by IBM and the Sony cell processor developed by Sony, Toshiba, and IBM. These processors were purposefully built for the Xbox 360 and Playstation 3, required several years of design, research, and iteration in order to build, and pushed the then current microprocessor technology to its limits—all for the primary goal of providing these consoles with the computing power required to support next generation games (Shippy and Phipps 2009).

34.2.4 Games Are a Source of Interface Innovation

Productivity applications typically strive for interface consistency from one version to the next. In that market segment, learning a new interface is considered a cost by business and a burden by users. Changing interfaces should only be done if the gains in efficiency outweigh the costs. Indeed, even the input devices associated with productivity applications have been relatively consistent for a long time. Yet, while the mouse and keyboard have stayed essentially the same for 30 years, game controllers evolve and many new games use new and novel input devices (e.g., guitars, game mats, Nintendo Entertainment System power gloves, Microsoft Kinect). In fact, gamers demand novelty, and, consequently, these evolving and novel devices create game design and ergonomic challenges that are very important to study. Moreover, each interface innovation developed for a game can potentially touch millions of people. This creates a chance to extend the interface innovation out of the games market and into other venues. For this reason, games can and should be viewed as an experimental interface testing ground.

34.3 GAMES VERSUS PRODUCTIVITY APPLICATIONS

As the games industry matures, games become more complex and varied making them difficult to narrowly define. Articulating a clear and succinct set of principles that capture the essence of games is not straightforward. Yet, shedding some light on the difference between games and productivity applications might make it easier to see how traditional UCD techniques must be adapted in order to have the most impact on games. When comparing games to productivity software, there are principles and methods that can be successfully applied to both. Regardless of the domain, the same techniques would be applied to understand a misleading button label or a confusing process model. At the same time, there are fundamental differences between productivity applications and gaming applications. Some of the differences can be fairly clear; games are usually more colorful, wacky, and escapist than productivity applications, with the inclusion of interesting story lines, or animated characters. Others may not be. In productivity applications, unclear labeling in the user interface (UI) is affecting my *productivity*; in games, the unclear labeling in the UI is affecting my *fun*.

UCD principles have not reached game makers to the degree that they have influenced other electronic applications.

Sections 34.3.1 to 34.3.4 will describe some differences that have important implications for user research on games.

34.3.1 The Goals Are Different

At a very basic level, the design goals, as well as user goals, are often quite different between games and productivity applications. If approached from a tools perspective, productivity applications are tools that help consumers be productive whereas games help consumers have fun. This perspective is useful because it allows us (1) to prioritize usability and enjoyability issues based on their impact on fun; (2) to see why the role of designer intent is so important in usability/enjoyability testing of games; and (3) to focus on the similarities of UCD principles between tool and game testing to more clearly see how traditional UCD techniques can be adapted to game development.

Because productivity applications are focused on making the user productive, the focus of design and usability is to allow the user to produce an improved work product or result with less effort, higher quality, and greater satisfaction. However, games are intended to be a pleasure to play. Ultimately, games are like movies, literature, and other forms of entertainment. They exist in order to stimulate thinking and feeling. Their outcomes are more experiential than tangible. This is not to say that word processors or other tools cannot be a pleasure to use, or that people do not think or feel when using them, but pleasure or other feelings are rarely their primary design intention. In a good game, both the outcomes and the journeys are rewarding. This fundamental difference leads us to devote more of our effort to measuring perceptions while productivity applications focus more on task completion.

34.3.2 The Role of Designer Intent

The general design goal for productivity applications is to *enable users to be productive*; for games, the goal is to *enable users to have fun*. For testing purposes, it is generally easier for usability practitioners to spot user deviations away from designer intent within productivity applications than it is in games. Most people can easily see when productivity is blocked; determining if, and when, fun is blocked is a bit more elusive. For example, it is unlikely that the designer intends for users to take four attempts to print their work so that it does not appear cropped in a productivity application. If the blockers to more efficient performance could be identified and removed, and users could successfully print on average with just one attempt, the redesigned application would make the users more productive and map better onto the designer intent. However, in games, four attempts at beating a boss might map perfectly onto the designer's intent. In fact, defeating a boss with only one attempt might actually be a blocker to fun if it is perceived as too easy. Six attempts might make the game too hard, but four attempts might be "just right." Moreover, four attempts might be just right for *some* users and not others. Thus, for games, we must rely more heavily on mapping user behavior against explicit designer intent. The designer holds the vision for their creation as well as the vision for what makes their game fun. User research on games requires close collaboration with design in order to spot deviations away from intent that could impact fun.

34.3.3 Games Must Challenge

Perhaps the most important distinction between games and productivity applications is the complex relationship between challenge, consistency, and frustration. Productivity applications, and usability testing efforts associated with them, strive to remove blockers to productivity—challenging flows, difficult navigation, unclear labeling, and so on. With games, we strive to remove blockers to fun—cumbersome weapon changing, uncomfortable controller mappings, confusing gameplay, and so on. Yet, certain kinds of gameplay challenges and difficulty don't block fun but are intentionally placed there by the designer to enhance it; they add to the *enjoyability*. To illustrate this difference, consider the following example. It has been said that the easiest game to use would consist of one button labeled "Push." When you push it, the display says "YOU WIN." This game would have few, if any usability issues; but it would not be fun either. Indeed, it has enjoyability issues galore: lack of challenge, lack of strategy required, lack of gameplay trade-offs, lack of interesting goals, and lack of replayability (to name just a few) all conspire to make this a pretty stale game. With user research in games, testing efforts should focus more on mitigating those factors that most impact enjoyability and impede fun. One should ensure that challenge adds to enjoyability and doesn't detract from it and that it is part of an intentional gameplay element and not a usability issue.

34.3.4 Industry Competition Is Intense

Competition within the games industry is more intense than other software domains. Games compete with each other as well as many other forms of entertainment for your attention. Pretend that you have to write a book chapter. For that task, there are a limited number of viable tools: hand writing, dictation, a typewriter, or a limited set of software applications. But, imagine that you've got a few hours to kill and you want to avoid productivity at all costs. You could read the biography of Nikola Tesla, argue politics with your best friend, watch a mystery film, or race your Ferrari 458 Italia 160 mph down Nürburgring in *Forza Motorsport 4* (Microsoft 2011). This element of choice, combined with the large number of games, means that many games will fail (just as many films, and TV shows fail). In contrast, a productivity application that is the "standard" will enjoy massive and sustained success.

Many of the characteristics mentioned above are not unique to games. But all of these characteristics are relevant to the discussion of the ways in which user research must adapt to be useful for game development. Later, we will discuss how these differences create particular challenges for both the design and evaluation of games.

34.4 TYPES OF GAMES

Below we review some common gaming platforms and game types.

34.4.1 Platforms

One of the simplest classifications of games is by the platform or hardware that they are played on. Cassell and Jenkins (2000) differentiates games played on a PC from those played on a console. Crawford (1982) divides games into even finer categories: arcade/coin-op, console, PC, mainframe, and handheld. Different gaming platforms can be differentiated by their technical capabilities, physical control interface, visual interface, and the context in which they are played.

34.4.1.1 Personal Computer

A useful distinction can be made between PC games that are normally acquired through retail outlets on a CD/DVD, persistent world games in which much of the content "lives" on the Internet, and casual, web-based games. While there are many technical differences between these kinds of games, the important distinction is the business model and level of investment required by the players. Most retail games need to rely heavily on flash, reputation, and recognizable novelty to attract users to a relatively large investment. Continued investment in the game is only useful to build a reputation or to convince customers with higher thresholds that they will get their money's worth from the game. But massively multiplayer online (MMO) persistent worlds require continued user investment to obtain monthly subscription fees. The long learning curves and reinforcement schedules in MMO are tailored to make players invest more time, money, and effort for long-term rewards. Many casual gamers are attracted to free, familiar games. For these casual users, game play is squeezed in between activities that are more important to them. As a result, games with very little learning investment are very appealing to casual gamers. Removing penalties for setting aside the game (for minutes, hours, days, or forever) can mean the difference between successful and unsuccessful casual games. See Section 34.4.2.2 for more details.

34.4.1.2 Console

For user research purposes, the most important unique characteristic of console video game systems is the advantage of a fixed set of hardware. By contrast with PC games, there is very little game setup, minimal maintenance efforts (e.g., few software patches, video card conflicts, and so on), and a consistent set of input device capabilities. Some game genres are more popular on console than PC. This difference in popularity can usually be attributed to differences in the input devices that are typically associated with each platform. It's hard to enter text using a controller. Thus, most popular MMO games are still published for PCs in spite of the fact that fast internet connections and hard drives are becoming more popular additions to console systems. This may change as it becomes easier to attach other devices such as keyboards or voice command hardware to consoles, which would make communication more robust.

More recently, casual games are also available for all console systems, including Xbox 360, where consumers can download, try, and purchase casual games directly from the console via a broadband connection.

34.4.1.3 Portable Devices

First released in 1989, the Game Boy and Game Boy Color (1998) combined to sell over 118 million units, and this success has only accelerated with the Game Boy Advance (2001; 80 million+ units) and Nintendo DS (2004; 125 million+ units) (Business Week 2006; Nintendo 2005). Nintendo succeeded largely by catering to the massive mainstream demand for accessible games; starting in 1989 by selling a whopping 35 million units of *Tetris* and 14 million units of *Super Mario Land*, and later selling more than 34 million *Pokemon*-related cartridges (Nintendo 2005). In fact, the portable gaming market is littered with devices that have tried to beat Nintendo with higher tech devices and more action-oriented games. More recent trends point to an impending explosion in mobile phone gaming. Since 2005, *Tetris*, now 26 years old, has sold to more than 100 million cell phones (Maximejohnson 2010). As mobile phones becomes more accessible and improve the visual display, gaming upon them becomes more and more popular.

Consumers primarily view mobile phones as communication devices, which are not meant to replace the gaming experience available on handhelds such as the Nintendo DS and Sony PSP (Moore and Rutter 2004). Unlike handheld gaming devices, mobile phones are generally carried at all times. This creates an opportunity to provide gaming at anytime, anywhere (Hyman 2005; IDGA 2005). However, with mobility comes the greater need to design for time, location, social, emotional, and motivational context (Sidel and Mayhew 2003).

34.4.2 Game Types

34.4.2.1 Retail Games (National Purchase Diary Classifications)

The National Purchase Diary (NPD) Group (a marketing company) uses a fine grained classification scheme for game type which is referred to quite often in the games industry. They offer the following classes and subclasses, as shown in Table 34.1. Games can also be categorized in a more granular fashion by splitting each genre into a subgenre. For instance, action games can be divided into Action Driving Hybrid (*Crackdown 2, Saints Row 2*, etc.), Action combat (*Tom Clancy's Splinter Cell: Conviction, Tomb Raider: Underworld*, etc.), and Platformer (*Ratchet & Clank Future: A Crack in Time, Super Mario Bros Wii*, etc.). In general, the genres represent types of gameplay mechanics, themes, or content.

TABLE 34.1
The National Purchase Diary Group Super Genre Classification Scheme for Games

Category	Description
Action	Control a character and achieve one or more objectives with that character.
Fighting	Defeat an opponent in virtual physical hand-to-hand or short-range combat.
Racing	Complete a course before others do and/or accumulate more points than others while completing a course.
Shooter	Goal is to defeat enemies in combat with ranged weapons (first-person shooters, third-person shooters).
Strategy	Strategically manage resources to develop and control a complex system in order to defeat an opponent or achieve a goal. The goal is to defeat opponent(s) using a large and sophisticated array of elements.
Role playing	Control a character that is assuming a particular role in order to achieve a goal or mission. Rich story and character development are common.
Family entertainment	The primary objective is to interact with others and/or to solve problems. This genre includes puzzles and parlor games.
Children's entertainment	Same as family entertainment but geared to a younger audience.
Sports	Manage a team or control players to either win a game or develop a team to championship status. Involves individual, team, and extreme sports.
Adventure	Control a character to complete a series of puzzles that are required to achieve a final goal.
Arcade	Games on coin-op arcade machines or games that have similar qualities to classic arcade games. Generally, they are fast paced, action games.
Flight	Plan flights and pilot an aircraft in a realistic, simulated environment.
All other games	Educational, compilations, nonflight simulators, rhythm games, and so on.

34.4.2.2 Casual Games

Casual games is a rapidly growing segment of the video games market, producing an estimated $500 million in online sales in 2005 (IDG 2005). Casual games as a whole are appealing to a broad range of users, can be found on all platforms, and represent several genres. For these reasons, they do not fit into either of the previous categorization schema. Casual games generally meet the following requirements: (1) are easy to start and control; (2) can be enjoyed in small time intervals; (3) do not require an extensive investment in time to enjoy or progress, and therefore usually don't have deep linear storylines; and (4) have discreet goals and rules that are intuitive or easy to learn. Casual games often have a significantly lower development cost, can be distributed digitally (or via physical media), offer trial versions and lower retail prices (or are free), and utilize lower system requirements and storage space. These requirements and attributes make these games well suited for platforms such as PC distributed via the web and mobile devices, where they are most common.

Websites such as Real Arcade, Pogo.com, Yahoo! Games, and MSN Games provide free online casual games, pay-per-play casual games, subscription services, and downloadable games that include a free trial. The downloaded games can be purchased for $5–$20. Mobile phone carriers and a variety of websites provide casual games for mobile devices. Although there are feature rich, 3D noncasual games available for mobile devices, the top selling titles are casual games such as *Tetris, Bejeweled, Bowling*, and *Pac Man* (Hyman 2005).

34.4.3 Recent Trends in Gaming

34.4.3.1 Physical Gaming and New Input Paradigms

New input paradigms are an ongoing area of exploration and innovation in games that will continue into the future. The most recent innovation has been the advent of physically based at-home video gaming as with the highly popular Wii gaming system (Nintendo 2006). Additionally, in recent years there have been several highly successful games that require the user to simulate musical instrument play via rhythm-based gaming like in *Guitar Hero* (Activision 2005) or *Rock Band* (Electronic Arts 2007) using simulated guitar controllers or, in some cases, to closely mimic actual musical play like when using drums in *Rock Band* or singing in *SingStar* (Sony Computer Entertainment 2004). Historically these video game types date back to at least the 1990s. There were arcade games in the mid-to-late 1990s requiring physical movement to play including *Alpine Racer* (Namco 1995) and *Dance Dance Revolution* (Konami 1998). Karaoke-style singing was popularized in Japan in the 1970s, though the idea of turning it into a game with a scoring system did not arise until the aforementioned *SingStar*. Looking into the future, it appears the trend toward at-home physically based video gaming will only continue as the Playstation Move (Sony Computer Entertainment 2010) and Kinect (Microsoft 2010) have each been recently released and both systems rely on improved gesture and physically based control input systems.

New input paradigms create immense complications when considering user-centered game design because we must now account for differing talent levels of the individual players. In the game *SingStar*, to be successful (from the game design's perspective), a player must have some ability to hear and sing at various pitches in order to succeed in the game. In some cases, the game does mimic exactly the real world activity, but instead is based on an approximation of how to do something in the real world. This is the case with most *Rock Band* and *Guitar Hero* gameplay. In these cases, having actual experience and skills with a guitar may impede a player's ability to adapt to the modified guitar-controller interface. Finally, there are other factors to consider. Similar to the talent requirement for singing, in physically based gaming, we must account for the fatigue level, flexibility, and coordination of potential players—even when considering a relatively simple game such as the archery mini-game in *Wii Sports Resort* (Nintendo 2008).

34.4.3.2 Social Network Gaming

Gaming on social network sites, such as Facebook, is the most popular new trend in internet gaming. *FarmVille* launched on Facebook in June 2009 and had bloomed to over 80 million active users as of April 2010 (Gardner 2009; Facebook 2010).

Earlier social successes, such as *Second Life* (2003), innovated on AOL's chat rooms by giving players a "sand box" like virtual world that they could mold and shape to fit their identities and their group connection needs. Inside these spaces, persistent clubs could form to bring people with common interests together across otherwise insurmountable distances. MMO games such as *World of Warcraft* built economies in their game world to necessitate the formation of friendships, allies and guilds out of strangers.

Social network games borrow from these types of games and extend the social equation in a way that has successfully attracted a mainstream audience. Like *World of Warcraft*, social connections are required to succeed. Players must recruit friends as neighbors and connect with them daily through gift-giving in order to advance. This recruiting process serves a viral marketing channel to bring new players into the game. The extension comes primarily from reducing social barriers. Virtual worlds with strong in-group communities require intense time commitment and expert knowledge. Social networking games are free and can be played in 5 minutes a day, asynchronously, to suit busy, varied schedules, and time zones. They use socially normative themes such as farming, pets, restaurants, and cities as their inspiration, title, and language. Then they use familiar shared events such as holidays and seasons to introduce freshness and novelty on a daily basis. They provide social safety by using a trusted social network (Facebook) for authentication and identity and largely eliminate direct interaction. Virtual gifts are free to the giver and the receiver but still valuable for advancing in the game. Through these social lubricants, social networking games have attracted a massive, mainstream audience. The average player is 43 and female. This typical player might have logged thousands of hours on *Solitaire* and *Minesweeper* but wouldn't have called themselves gamers.

34.4.3.3 Cross Platform

Cross-platform convergence is an emerging trend in the games industry that complicates the classification of games by platform. Developers are now creating multiple versions of a game that interact with one another across platforms. For example, Nintendo games such as *Animal Crossing* (Nintendo of America 2002), *The Legend of Zelda: The Wind Waker* (Nintendo of America 2003), *Harvest Moon* (Nintendo of America 2003) allow users to connect a Gameboy portable device to the GameCube console to access additional features and content, or use the Nintendo DS as a touch screen controller. Another example of cross-platform games would be a title where the player may execute specific planning or strategic tasks on a mobile device at any time, then have those actions affect the full game experience the next time it is played on a console or PC. This cross-platform design effect has been referred to as a reciprocation effect (Yuen 2005).

Cross-platform convergence creates new challenges in user centered game design. The act of switching between different platforms means the game must be adapted to multiple interfaces. Users must be informed how and why they should take advantage of the alternate platform. Users must also be made aware of the alternate platform version's existence so they can choose to take advantage of it. For example, in 2010, Microsoft released a Facebook game called *Toy Soldiers: Match Defense* (Microsoft Game Studios 2010) and shortly thereafter released the Xbox 360 game *Toy Soldiers* (Microsoft Game Studios 2010). Several relationships between the games were established. Playing the Facebook version of the game unlocked or awarded certain features in the Xbox version of the game. Meanwhile, the Xbox version of the game included several hints or loading tips, pointing out that there were benefits to playing the Facebook version. Ensuring success at each point in the seams between the games and platforms represents a new and ongoing responsibility for user-centered game design now and into the future.

The next generation of cross-platform experiences may involve matching players for real-time, or asynchronous, competitive and cooperative multiplayer experiences regardless of what platform they are on (portable, PC, console, etc.). As these trends become realized, interesting challenges and opportunities for game developers will mount as games will have to be designed with the limitations of the platform in mind. Indeed, spanning platforms with a single game will not be as simple as porting it. Careful consideration will have to be made with regard to the unique user needs associated with each platform they are interacting with.

34.5 PRINCIPLES AND CHALLENGES OF GAME DESIGN

Having differentiated games from other applications we can look at some of the unique issues in game design and evaluation.

34.5.1 Identifying the Right Kind of Challenges

Games are supposed to be challenging. This requires a clear understanding of the difference between good challenges and frustrating usability problems. Most productivity tools struggle to find a balance between providing a powerful enough tool set for the expert, and a gradual enough learning curve for the novice. However, no designer consciously chooses to make a productivity tool more difficult. After all, doing so would go against the main design goal of making users productive. The ideal tool enables users to experience challenge only in terms of expressing their own creativity. For games, learning the goals, strategies, and tactics to succeed is part of the fun.

Unfortunately, it is not always clear which tasks should be intuitive (i.e., easy to use) and which ones should be challenging. Input from users becomes necessary to distinguish good challenges from incomprehensible design. Take a driving game for example. It's not fun having difficulty making your car move forward or turn. But learning to drive is still a fundamental part of the challenge in the game. While all cars should use the same basic mechanisms, it may be fun to vary the ways that certain cars respond under certain circumstances. It should be challenging to identify the best car to use on an icy, oval track as opposed to a rally racing track in the middle of the desert. The challenge level in a game must gradually increase in order to maintain the interest of the player.

34.5.2 Addressing Different Skill Levels

Unfortunately, all players don't start from the same place in terms of gaming experience or talent. Obviously, frequent failure can be a turn off. Success that comes too easily can also become repetitive. Games must address the problem of meeting all players with the correct level of challenge. Tuning a game to the right challenge level is called "game balancing."

There are many ways to balance the difficulty of the game. The most obvious way is to let players choose the difficulty themselves. Many games offer the choice of an easy, medium or hard difficulty level. While this seems like a simple solution, it is not simple to identify exactly how easy the easiest level should be. Players want to win, but they do not want to be patronized. Too easy is boring and too hard is unfair. Either experience can make a person cease playing.

Another approach to varying skill levels is to provide explicit instruction that helps all users become skilled in the game. You might imagine a tutorial in which a professional golfer starts by explaining how to hit the ball and ends by giving instruction on how to shoot out of a sand trap onto a difficult putting green. Instruction, however, need not be presented in a tutorial. It could be as direct as automatically selecting the appropriate golf club to use in a particular situation with no input from the user, similar to the notion of an adaptive interface, where the interface provides the "right information" at the "right time."

The environments, characters, and objects in a game provide another possibility for self-regulation. Most games will offer the player some choices regarding their identity, their opponents, and their environment. The better games will provide a variety of choices that allow users to regulate the difficulty of their first experiences. With learning in mind, it is not uncommon for the novice player to choose a champion football team to play against a weak opponent. As long as the player can distinguish the good teams from the bad ones, and the teams are balanced appropriately, users will be able to manage their own challenge level.

Some games take it even further by identifying the skill level of the player and regulating the instruction level appropriately. In this situation, instruction can be tuned to the skill level of the player by associating it with key behavioral indicators that signifies that the player is having difficulty. If the game does not detect a problem, it does not have to waste the player's time with those instructions. In *Halo 2* (Microsoft Game Studios 2004) the game detects difficulties that a player may have with certain tasks. For example, to get into a vehicle, the player must press and hold the "X" button on their controller when standing next to the driver's seat of that vehicle. If the player is standing in the right position, but taps the "X" button repeatedly (instead of holding the button down), the game will present a more explicit instruction to press and *hold* the button. This is just one of many dynamic instructions that appear throughout *Halo 2* based on behavioral indicators of player difficulty.

Productivity tools have implemented similar problem-identification features, but often with mixed success due to the open nature of tasks in most productivity applications. Good game tutorials have succeeded by setting clear goals and completely constraining the environment. Doing so focuses the user on the specific skill and simplifies the detection of problematic behavior. Other lessons from game tutorial design will be described in Sections 34.6.2.3, 34.7.2.2.1, and 34.7.4.2.1 of this chapter.

Another in-game approach to autoregulating the difficulty level requires adjusting the actual challenge level of the opponents during the game. Evaluating the success of the player and adjusting the opponent difficulty during the game is often called "dynamic difficulty adjustment" or "rubber-banding." When players perform very skillfully, their performance is moderated by computer-generated bad luck and enhanced opponent attributes. In a football game, the likelihood of fumbling, throwing an interception, or being sacked, may increase as the player increases their lead over their opponent. Even though this may seem like a good solution, there can be a downside. Most people would prefer to play a competitive game (and win) than to constantly trounce a less-skilled opponent. However, overdeveloped rubber-banding can cheat a skilled player out of the crucial feeling of mastery over the game.

A final approach focuses on providing tools that maximize the ability of the trailing player to catch up with the leading player. The key for the game designer is to think of ways to maintain challenge, reward, and progress for the unskilled player without severely hampering the skilled player.

One interesting and explicit example of this is found in *Diddy Kong Racing* (Nintendo of America 1997). In this game, the racer can collect bananas along the roadway. Each banana increases the top speed of your car. The player can also collect missiles to fire forward at the leading cars. Each time you hit a car with a missile it not only slows the car's progress, but it jars loose several bananas that the trailing player can pick up. Thus, trailing players have tools that they can use to catch the leaders even if the leaders are not making any driving mistakes. The chief distinction between this and dynamic difficulty adjustment is that the game is not modifying skills based on success. Instead, the rules of the game provide the trailing player with known advantages over the leader.

34.5.3 Rewarding Players Appropriately

Explicit or slow reinforcement schedules may cause users to lose motivation and quit playing a game. Because playing a game is voluntary, games need to quickly grab the user's attention and keep them motivated to come back again and again. One way to accomplish this is to reward players for continued play. Theories of positive reinforcement suggest behaviors which lead to positive consequences tend to be repeated. Thus, it makes sense that positive reinforcement can be closely tied to one's motivation to continue playing a game. However, it is less clear which types of reinforcement schedules are most effective.

Although it's not necessarily the model that should be used for all games, research suggests that continuous reinforcement schedules can establish desired behaviors in the quickest amount of time (Domjan 2010; Mazur 2006). Unfortunately, once continuous reinforcement is removed, desired behaviors extinguish very quickly. Use of partial reinforcement schedules take longer to extinguish desired behaviors, but may take too long to capture the interest of gamers. Research suggests that variable ratio schedules are the most effective in sustaining desired behaviors (Jablonsky and DeVries 1972). This kind of schedule is a staple of casino gambling games in which a reward is presented after a variable number of desired responses. Overall, there is no clear answer. Creating a game that establishes immediate and continued motivation to continue playing over long periods of time is a very complex issue.

Another facet of reinforcement systems that may impact enjoyment of a game is whether the player attributes the fact that they have been playing a game to extrinsic or intrinsic motivations. Intrinsic explanations for behavior postulate that the motivators to perform the behavior come from the personal needs and desires of the person performing the behavior. Whereas extrinsically motivated behaviors are those that people perform in order to gain a reward from or please other people. In research on children's self-perceptions and motivations, Lepper, Greene, and Nisbett (1973) discovered that children who were given extrinsic rewards for drawing were less likely to continue drawing than those who had only an intrinsic desire to draw. The conclusion that they drew is that children perceived their motivation to draw as coming from extrinsic sources and thus discounted their self-perception that they liked to draw.

The same may be true of reward systems in games (Lepper and Malone 1987; Malone 1981). To a certain degree, all reinforcement systems in games are extrinsic because they are created or enabled by game developers. But, some reward systems are more obviously extrinsic than others. For instance, imagine the following rewards that could be associated with combat in a fantasy role-playing game (RPG). The player who slays a dragon with the perfect combination of spell casting and swordplay may acquire the golden treasure that the dragon was hoarding. In this situation, the personal satisfaction comes from being powerful enough to win and smart enough to choose the correct tactics. The gold is an extrinsic motivator. The satisfaction is intrinsic. By analogy from Lepper, Green, and Nisbett's research, feelings of being powerful and smart (intrinsic motivators) are more likely to keep people playing than extrinsic rewards.

34.5.4 Collecting and Completing

The chief goal of many games is to acquire all of the available items, rewards or knowledge contained in the game. In games such as *Pokemon Crystal* (Nintendo Japan 2000) the central challenge is to acquire as many of the Pokemon characters as you can and learn all of their skills well enough to outsmart your opponent at selecting the right characters for a head-to-head competition. Not coincidentally, the catch phrase for the *Pokemon Crystal* game is "Gotta catch 'em all!"

This game mechanic is also used by numerous games to add depth and repeat play. Though this isn't the primary mechanic in *Madden NFL 06* (Electronic Arts Inc. 2005), the ability to collect electronic player cards and use them strategically in games provides incentive for gamers to experiment with much of the content that they may not experience if playing through a standard season.

34.5.5 Story

Characters and narrative help gamers attach meaning and significance to action sequences. There are those in the games industry that propose that many games neither have nor need a story. It is our contention that the key to understanding narrative in games is to realize that storylines may be both embedded in the game, or they may emerge in the course of playing a game.

When most consumers think about story, they think about embedded storylines (Levine 2001). *Final Fantasy X* (Square Co., Ltd. 2001) tells its story by cutting action sequences with a series of full-motion cut scenes, real-time cut scenes and player-driven character interactions. The embedded story forms a central part of the appeal of the game. But Ken Levine (2001) points out that much of the narrative in a game emerges in the successes and failures experienced by players throughout the course of the game. This is especially true of multiplayer games, in which story is often generated exclusively by the interactions of the participants. As Levine describes it, the story is generated by replaying an abstract narrative structure with a strict set of rules and possibilities within a novel set of circumstances. Sporting events both within and outside of the video game world provide an excellent example of this type of narrative. No author scripted the result of the last World Cup tournament, but each such event has the potential to be an epic narrative for both participants and viewers.

34.5.6 Technological Innovation Drives Design

There is a great deal of pressure on designers to utilize new technologies that may break old interaction models. The desire to experience ever more realistic and imaginative games has pushed game developers into engineering and computer science research domains. Likewise, technology often drives game design in order to showcase new capabilities. The constant demand for novelty can be strong enough incentive for game makers to try untried designs, "spruce up" familiar interfaces and break rules of consistency. For example, the original *NFL2K* series (Sega 1999) sported a new interface model in which users selected interface areas by holding the thumbstick in a direction while pressing a button. It is possible that Sega chose the new design primarily because it was new and different from existing interfaces. It required the somewhat new (at that time) mechanics of the thumbstick on the controller, it minimized movement because one could point directly at any given item in the menu, and it was cleverly shaped like a football (which made more sense for *NFL2K* than for another sport). However, errors due to more error-prone targeting and the hold and click interaction metaphor made the system harder for first-time players to use.

34.5.7 Perceptual-Motor Skill Requirements

The way that functions are mapped onto available input devices can determine the success or failure of a game. A crucial part of the fun in many games comes from performing complex perceptual-motor tasks. While today's arcade-style games include increasingly more sophisticated strategic elements, a core element of many games is providing the ability to perform extremely dexterous, yet satisfying physical behaviors. These behaviors are usually quick and well-timed responses to changes and threats in the environment. If the controls are simple enough to master and the challenges increase at a reasonable difficulty, these mostly physical responses can be extremely satisfying (Csikszentmihalyi 1990).

Problems can arise when games require unfamiliar input devices. This is a common complication in console game usability research because new console systems usually introduce new input device designs unique to that system (see Figure 34.1). Furthermore, game designers often experiment with new methods for mapping the features of their games to the unique technical requirements and opportunities of new input devices. Unfortunately, this does not always result in a better gameplay experience.

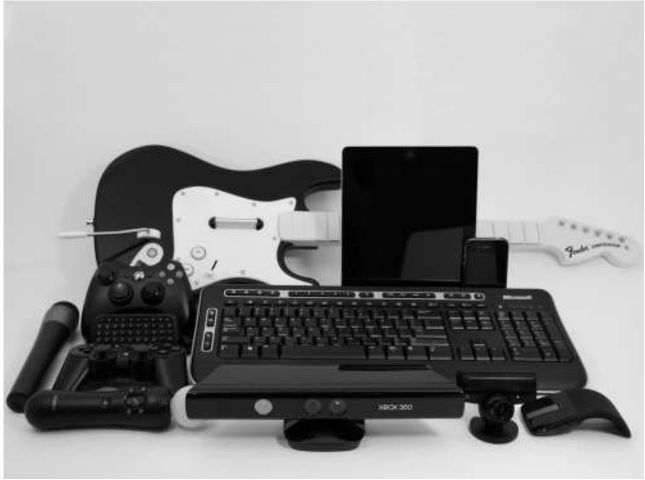

FIGURE 34.1 This is a sample of a variety of input devices used in games from the traditional keyboard and mouse to more advanced input mechanisms.

34.5.8 Balancing Multiplayer Games

As we've seen, different strategies can be used to support a broad range of player skill levels. While this is complicated in single-player games, it becomes even more daunting when players of different skills make up both the opponents and the allies. By far the most common strategy for regulating the challenge level of online multiplayer games is to provide strong matchmaking tools. *Internet Backgammon* (Microsoft Windows XP 2001) automatically matches players from around the world based on their self-reported skill level. Other games use algorithms that count player winning percentages and strength of opponent.

Another strategy seeks to solve skill balance problems outside of the game by offering players a wide array of arenas and/or game types. Rather than actively connecting players of like skill, this approach provides a broad array of places to play and allows players to self-select into game types that suit their style and attract the players with whom they want to associate. A final approach, used frequently by instant messaging clients (e.g., Yahoo IM, Windows Live Messenger), is to make it easy to start a game with friends. Though skill levels of friends may not always match, you are presumably less likely to perceive the match as unfair against people whom you know.

Game designers also employ a variety of in-game strategies to balance out the competition. The most common way to allow less-skilled players to compete effectively with more skilled players is to play team games. Many games allow players to take on a variety of roles. Capture the Flag is a common backyard tag-style game that forms the basis for a game type in many first-person shooters. Some players go on offense to capture the opponent's flag, some stay back to defend their flag. Likewise, some players may take a long-range sniper weapon to frustrate the enemy, while others take weapons that are more effective at close range. The defending and sniping roles can be more comfortable for some novice players because they allow the player to seek protective cover, they require less knowledge of the play field and one-on-one combat can be avoided.

Some first-person shooters also allow the game host to set "handicaps" for successful players and bonuses for less successful players. For example, one version of *Unreal Tournament* increased the size of the player's character with every point that they won, and decreased the size of the character every time that the character died. The size differences made successful players easier targets and unsuccessful players more difficult targets.

34.5.9 Enabling Social Networking

Skill level is not the only dimension of importance. Systems such as the Xbox Live service seek to group players of similar attitudes and behaviors. The goal is to place more antagonistic players with like-minded others who appreciate tough talk, while protecting players who don't want to or shouldn't be exposed to aggressive or offensive language.

This is just one of many tools that games have developed to promote group play and improve communication between online players. Most online games include some form of in-game messaging. Often this messaging is tailored for fast and efficient communication of key functions or timely game events. Most MMORPGs have negotiation systems that help people trade objects safely and efficiently. Most first-person shooters present automatic messages telling you which players have just been killed by whom. Real-time strategy (RTS) games allow gamers to set flares or markers on the map to notify your allies of key positions. Each game genre has a key set of in-game communication tools to support the game play.

More and more frequently game designers are starting to embed cooperative tools into the environment itself. Much of the benefit of vehicles in first-person shooter games comes from their use as cooperative tools. Used in concert these tools can often be extremely effective. From a game design perspective, they provide a great incentive for people to come together, strategize and work cooperatively. These shared successes can be a huge part of the fun in online games.

Massively multiplayer games employ a wide variety of incentives for players to form groups. Success comes from taking on missions that are far too dangerous for any single player to accomplish on their own. Players choose a role and learn to compliment the strengths of the other members of their group in order to overcome fearful enemies and accomplish great quests. Recent massively multiplayer games have invested even more in the creation of large-scale guilds. Most massively multiplayer games intentionally keep large areas of information secret from their players to provide the need and the opportunity for symbiotic relationships between experts and novices. In addition, modern MMO games often provide pyramid-scheme style bonuses in wealth and experience to the leaders and captains of guilds. In return, members receive physical, material, educational, and social protection from their leaders and peers.

34.5.10 Mobile Gaming Environmental Factors

The success of *Tetris* points out several fundamental truths of portable gaming. The most successful portable games fit efficiently and effectively into the user's lifestyle. They don't require prolonged concentration and are robust to environmental distractions, allowing the busy person to pause when needed and resume without difficulty. This is why so many successful portable games are brief, turn-based, or pauseable. They're with you when you have time to play—on the bus to school, or train to work, in the back of a car on the way to practice, or at a friend's house for head-to-head competition. They're challenging, but they don't require special experience or knowledge to be successful at the start of the game. Many portable successes are simple, familiar or particularly resistant to creating failure states.

Many of the same fundamental truths apply to mobile phone games. Mobile games appear poised to break new ground in social gaming due to increased accessibility to communication, connectivity, location, and identity features. The barriers to mobile phone gaming come largely from lack of hardware and software standardization. There are dozens of mobile game development platforms and thousands of hardware form factors. For example, while iPhone has a substantial amount of mind-share in the mobile space, it was estimated that there were a little over 6 million of them in operation in the United States in 2009 (Nielsenwire 2009).

34.6 IMPORTANT FACTORS IN GAME TESTING AND EVALUATION

Most game genres are subtly different in the experiences that they provoke. It may seem obvious that the point of game design is making a fun game. Some games are so fun that people will travel thousands of miles and spend enormous amounts of money to participate in gaming events. However, we would like to propose a potentially controversial assertion: the fundamental appeal of some games lies in their ability to challenge, to teach, to bring people together, or to simply experience unusual phenomena. Likewise, the definition of fun may be different for every person. When you play simulation games, your ultimate reward may be a combination of learning and mastery. When you play something like the *MTV Music Generator* (Codemasters 1999), your ultimate reward is the creation of something new. When you go online to play card games with your uncle in Texas, you get to feel connected. *Flight SimulatorX* (Microsoft Corporation 2006) lets people understand and simulate experiences that they always wished they could have. While these may be subcomponents of fun in many cases, there may be times when using "fun" as a synonym for overall quality will lead to underestimations of the quality of a game. While a fun game is often synonymous with a good game, researchers are warned to wisely consider which measures best suit the evaluation of each game that they evaluate.

34.6.1 Game Designer Intent

As stated earlier, the design goal of a game is to create a pleasurable experience and to help users have fun, and the main user goal is to have fun. Goals in a game are not necessarily derived from external user needs as in productivity applications. In games, goals are defined in accordance with the game designer's vision, which is a novel position because historically, success in productivity application testing has been defined by the accomplishment of user tasks and goals (Pagulayan, Gunn, and Romero 2006). When approaching a game for UCD or testing, it is best to assume the role of facilitating the designer's vision for the game (Pagulayan and Steury 2004; Pagulayan et al. 2003) because many times, it is only the designer who can recognize when the player experience is not being experienced as intended. In traditional usability testing, it is often very recognizable when there is user error, but not so in games.

Davis, Steury, and Pagulayan (2005) discuss a case study in the game *Brute Force* (2003), which revealed that players were not encountering certain gameplay features early enough in their gameplay experience. It was not the case that players were failing, but that players were taking much longer to play through the second mission than intended. By understanding the design vision, the authors were able to work with the designers to provide feedback which resulted in shortening the second mission, and also reordering other missions to match the design intent of the game.

34.6.2 Ease of Use

The ease of use of a game's controls and interface is closely related to fun ratings for that game. Think of this factor as a gatekeeper on the fun of the game. If the user must struggle or cannot adequately translate their intentions into in-game behaviors, they will become frustrated. This frustration can lead the user to perceive the game as being unfair or simply inaccessible (or simply not fun). Thus, it becomes very clear why usability becomes very important in games. Ease of use should be evaluated with both usability and attitude measurement methodologies, which are discussed later in the chapter.

34.6.2.1 Basic Mechanics

The basic mechanics of a game are best imagined by this example. In chess, each player expresses more strategic desires by turn-taking, movement, checking, and capturing. These actions are the core mechanics. Combined with the board and pieces, roles and rules, and strategies and situations, they make up the experience of chess. Of these mechanics, movement is one of the most important; yet, it is simple. Each piece has a role with defined movements, but it also contains the magic of chess. The power of the queen is expressed by the lack of restraint on her movement. Every game, similarly, has a set of core mechanics. Getting the core mechanics right is fundamental to making a great game.

34.6.2.2 Starting a Game

Starting the kind of game that the user wants is an easily definable task with visible criteria for success. This is something one can measure in typical usability laboratories. Though designers often take game shell (the interface used to start the game) design for granted, a difficult or confusing game shell can limit users' discovery of features and impede their progress toward enjoying the game. The most immediate concern for users can be starting the kind of game that they want to play. Games often provide several modes of play. When the game shell is difficult to navigate, users may become frustrated before they have even begun the game. For example, we have found that many users are unable to use one of the common methods that sports console games use to assign a game controller to a particular team. This has resulted in many users mistakenly starting a computer versus computer game. Depending on the feedback in the in-game interface, users may think that they are playing when, in fact, the computer is playing against itself! In these cases users may even press buttons, develop incorrect theories about how to play the game, and become increasingly confused and frustrated with the game controls. The most effective way to avoid these problems is to identify key user tasks and usability test them.

Pagulayan et al. (2003) discuss a case study where they found issues with difficulty settings in the game shell. In early usability testing, participants were having problems with setting the difficulty level of opponents in *Combat Flight Simulator* (Microsoft Corporation 1998). This is a case where the users' gameplay experience would have been quite frustrating because of a usability error in the game shell if it were not addressed.

34.6.2.3 Tutorials or Instructional Gameplay

Tutorials are sometimes necessary to introduce basic skills needed to play the game. In this situation, instructional goals are easily translated into the usability lab with comprehension tasks and error rates.

One of the risks of not testing tutorials or instructional missions is inappropriate pacing, which can often result from an ill-conceived learning curve at the start of the game. Many games simply start out at too difficult a challenge level. This is an easy and predictable trap for designers and development teams to fall into because when designers spend months (or even years) developing a game, they risk losing track of the skill level of the new player. A level that is challenging to the development team is likely to be daunting to the beginner.

Unfortunately, the reverse can also be troubling to the new user. Faced with the task of addressing new players, designers may resort to lengthy explanations. Frequently, developers will not budget time to build a gradually ramping learning process into their game. Instead, they may realize late in the development cycle that they need to provide instruction. If this is done too abruptly, the learning process can end up being mostly explanation, and to be frank, explanation is boring. The last thing that you want to do is to bore your user with a longwinded explanation of what they are supposed to do when they get into your game. It is best to learn in context and at a measured pace or users may just quit the game.

A very positive example is the first level of *Banjo Kazooie* (Nintendo of America 2000). At the start the player is forced to encounter a helpful tutor and listen to a few basic objectives. Then they must complete some very basic objectives that teach some of the basic character abilities. Much of the tutorial dialogue may be skipped, but the skills necessary to continue must be demonstrated. In this way, the game teaches new skills but never requires tedious instruction. The player learns primarily by doing. All of this is done in the shadow of a very visible path onto the rest of the game so the user never loses sight of where they need to go.

34.6.2.4 Camera

The camera perspective (i.e., the view that the player sees into the virtual world) in a game is often treated as an advanced game mechanic. That is, known difficulties in seeing the environment, threats, and opportunities can be exploited to create challenge and tension. When not done effectively, this can result in a poor experience for many users who are powerless to see something that they believe they could see in real life. This can be frustrating, resulting in a loss of immersion in the game world.

A 3D isometric view is a very effective camera perspective for viewing game boards or maps or moving a character through a game world. But there is an important trade-off to consider when thinking about how much distance to have between the camera and the objects of view. The farther away the camera is, the more environment the user can consider in his or her strategy. For this reason, it's generally easier to drive a car, command troops, or play *Monopoly* from a bird's eye view. On the other hand, the user may lose a very important part of the visceral experience by being too far away. Viewing a race from the inside of the car will cut down on the user's awareness of competitor cars and upcoming turns, but it feels a lot faster and more intense. Because of this inherent trade-off and different preferences around it, most racing games allow the user to choose between several viewing distances. The same effect can be seen in a shooting game. *Gears of War* feels extra gritty and dangerous in part due to the intentional placement of the camera lower over the shoulder of the main character than in many shooting games (Microsoft Game Studios 2006).

It's also worth noting that tight spaces can cause havoc for over-the-shoulder cameras. User research can identify problem areas and suggest custom cameras to help users see what they are supposed to see. Because designers know, and professional software testers learn, where to go and what to avoid, UCD can be a necessary way to discover camera blind spots that can be extremely frustrating to the mass of users who only play through an experience once.

At the extreme end, with very good tuning, nontraditional camera perspectives can be part of the fun of a game. Crash Bandicoot successfully kept the game fresh and increased dramatic tension by switching the camera after several levels to look directly into frightened Crash's eyes as he ran from a charging dragon (Universal Interactive Studios 2001). Likewise, *Resident Evil* increased suspense and fear in its games by employing fixed cameras at awkward locations and forcing people to enter areas and fight zombies blindly (Capcom 2005).

34.6.2.5 In-Game Interfaces

In-game interfaces are used primarily to deliver necessary status feedback and to perform less-frequent functions. We measure effectiveness with more traditional lab usability testing techniques and desirability with attitude measurements such as surveys (e.g., see Section 34.6.2.6).

Some PC games make extensive use of in-game interfaces to control the game. For example, simulation and RTS games can be controlled by keyboard and mouse presses on interface elements in the game. Usability improvements in these interfaces can broaden the audience for a game by making controls more intuitive and reducing tedious aspects of managing the game play. In-game tutorial feedback can make the difference between confusion and quick progression in learning the basic mechanisms for playing. In this situation, iterative usability evaluations become a key methodology for identifying problems and testing their effectiveness (e.g., see Section 34.6.2.6).

Many complex PC and console video games make frequent use of in-game feedback and heads-up displays (HUD) to display unit capabilities and status. For example, most flight combat games provide vital feedback about weapons systems and navigation via in-game displays. Without this feedback, it can be difficult to determine distance and progress toward objectives, unit health and attack success. This feedback is crucial for player learning and satisfaction with the game. With increasing game complexity and 3D movement capabilities, these displays have become a crucial part of many game genres. Usability testing is required to establish whether users can detect and correctly identify these feedback systems. See Pagulayan et al. (2003) for detailed example of usability testing the HUD in *MechWarrior 4: Vengeance* (Microsoft Corporation 2000).

34.6.2.6 Mapping Input Devices to Functions

A learnable mapping of buttons, keys or other input mechanisms to functions is crucial for enjoying games. We measure effectiveness with usability techniques and desirability with attitude measurements. Without learnable and intuitive controls, the user will make frequent mistakes translating their desires into onscreen actions. We have seen consistently that these kinds of mistakes are enormously frustrating to users, because learning to communicate one's desires through an eight-button input device is not very fun. The selection of keys, buttons, and other input mechanisms to activate particular features is often called "control-mapping." Players tend to feel that learning the control-mapping is the most basic part of learning the game. It is a stepping stone to getting to the fun tasks of avoiding obstacles, developing strategies, and blowing things up.

By contrast with other ease of use issues, evaluating the control-mapping may involve as much subjective measurement as behavioral observation. Button presses are fast, frequent, and hard to collect automatically in many circumstances. Furthermore, problems with control-mappings may not manifest themselves as visible impediments to progress, performance, or task time. Instead, they may directly influence perceptions of enjoyment, control, confidence, or comfort. Due to differences in experience levels and preferences between participants, there may also be significant variation in attitudes about how to map the controls.

Dissatisfaction with the controller design can also be a central factor that limits enjoyment of all games on a system. For example, the results of one whole set of studies on the games for a particular console game system were heavily influenced by complaints about the system's controller. Grasping the controller firmly was difficult because users' fingers were bunched up and wrists were angled uncomfortably during game play. Ratings of the overall quality of the games were heavily influenced by the controller rather than the quality of the game itself.

Because of these concerns and the importance of optimizing control-mappings, we recommend testing control-mappings with both usability and attitude assessment methodologies.

34.6.3 Challenge

Challenge is distinct from ease of use and is measured almost exclusively with attitude assessment methodologies. This can be a critical factor to the enjoyment of a game, and obviously can be highly individualized and is rightly considered subjective.

Consumers may have difficulties distinguishing the "appropriate" kinds of challenge that result from calculated level and obstacle design from the difficulty that is imposed by inscrutable interface elements or poor communication of objectives. In either case, the result is the same. If not designed properly, the player's experience will be poor. Thus, it is up to the user research professional to make measurement instruments that evaluate the appropriateness of the challenge level independently of usability concerns. In one example, Pagulayan et al. (2003) used attitude assessment methodologies to determine the final design of the career mode in *RalliSport Challenge* (Microsoft Corporation 2002). In this situation, finding a solution to the design problem was not necessarily related to ease of use issues, or other usability-related issues. The final design was based on what was most fun and appropriately challenging for users.

34.6.4 Pace

We define pace as the rate at which players experience new challenges and novel game details. We measure this with attitude measurement methodologies.

Most designers will recognize that appropriate pacing is required to maintain appropriate levels of challenge and tension throughout the game. You might think of this as the sequence of obstacles and rewards that are presented from the start of the game to the end. However, the way a designer will address pace will depend on a variety of issues, including game type, game genre, and their particular vision for the gameplay experience. In a tennis game, pace can be affected by a number of things, including the number of cut scenes in between each point, to the actual player and ball movement speed (Pagulayan and Steury 2004).

One group at Microsoft uses a critical juncture analogy to describe pacing. As a metaphor, they suggest that the designer must attend to keeping the user's attention at 10 seconds, 10 minutes, 10 hours, and 100 hours. The player can always put down the game and play another one, so one must think creatively about giving the user a great experience at these critical junctures. Some games excel at certain points but not others. For example, the massively multiplayer game may have the user's rapt attention at 10 seconds and 10 minutes. And the fact that hundreds of thousands pay $15 per month to continue playing indicates that these games are very rewarding at the 100-hour mark. But anyone who has played one of these games can tell you that they are extremely difficult and not too fun to play at the 10-hour mark. At this point, you are still getting "killed" repeatedly. That is no fun at all. Arcade games obviously take this approach very seriously. Though they may not scale to 100 hours, good arcade games attract you to drop a quarter and keep you playing for long enough to make you want to spend another quarter to continue.

Pacing may also be expressed as a set of interwoven objectives much like the subplots of a movie. Again, *Banjo Kazooie* provides an excellent example of good pacing. Each level in *Banjo Kazooie* contains the tools necessary to complete the major objectives. Finding the tools is an important part of the game. New abilities, objectives, skills, and insights are gradually introduced as the player matures. While progressing toward the ultimate goal (of vanquishing the evil witch and saving the protagonist's sister), the player learns to collect environmental objects that enable them to fly, shoot, become invincible, change shape, gain stamina, add extra lives, and unlock new levels. This interlocking set of objectives keeps the game interesting and rewarding. Even if one is unable to achieve a particular goal, there are always sets of sub goals to work on. Some of which may provide cues about how to achieve the major goal.

34.6.5 Summary

Attitude methodologies are better apt to measure factors such as overall fun, graphics, sound, challenge, and pace. The typical iterative usability is an exploratory exercise designed to uncover problem areas where the designer's intentions don't match the user's expectations, as a result, we typically choose to not use usability testing to assess "fun" or challenge. When attempting to assess attitudinal issues such as "overall fun" and "challenge" we make use of a survey technique that affords testing larger samples. Internally, we have adopted the term Playtest or sometimes Consumer Playtest for this technique. At the same time, we use typical iterative usability methods to determine design elements which contribute to or detract from the experience of fun.

34.7 USER RESEARCH IN GAMES

34.7.1 Introduction to Methods—Principles in Practice

In Sections 34.7.1 to 34.7.7, we propose various methodologies and techniques that attempt to accurately measure and improve game usability and enjoyment. Many of the examples are taken from techniques used and developed by Studios User Research at Microsoft Studios.

Our testing methods can be organized by the type of data being measured. At the most basic level, we categorize our data into two types: *behavioral* and *attitudinal*. *Behavioral* refers to observable data based on performance, or particular actions performed by a participant that one can measure. This is very similar to typical measures taken in usability tests (e.g., time it takes to complete a task, number of attempts it takes to successfully complete a task, and task completion). *Attitudinal* refers to data that represent participant opinions or views, such as subjective ratings from questionnaires or surveys. These are often used to quantify user experiences. Selection of a particular method will depend on what variables are being measured and what questions need to be answered.

Another distinction that is typically made is between *formative* and *summative* evaluations, which we apply to our testing methods as well. *Formative* refers to testing done on our own products in development. *Summative* evaluations are benchmark evaluations, either done on our own products, or on competitor products. It can be a useful tool for defining metrics or measurable attributes in planning usability tests (Nielsen 1993), or to evaluate strengths and weaknesses in competitor products for later comparison (Dumas and Redish 1999).

While these methods are useful, they do not allow us to address issues with extended gameplay, that is, issues that may arise after playing the game for a couple of days or more. This is problematic, because one of the key challenges in game design is longevity. With the competition, the shelf life of a game becomes very limited.

34.7.2 Usability Techniques

Traditional usability techniques can be used to address a portion of the variables identified as important for game design. In addition to measuring performance, we use many standard usability techniques to answer "how" and "why" process-oriented questions. For example, how do users perform an attack, or why are controls so difficult to learn? We use (1) structured usability tests, (2) rapid iterative testing and evaluation (RITE) (Medlock et al. 2002, 2005), and (3) other variations and techniques, including open-ended usability tasks, paper prototypes, and gameplay heuristics. For clarity of presentation, each technique will be discussed separately, followed by a case study. Each case study will only contain information pertinent to a specific technique, thus examples may be taken from a larger usability test.

34.7.2.1 Structured Usability Test

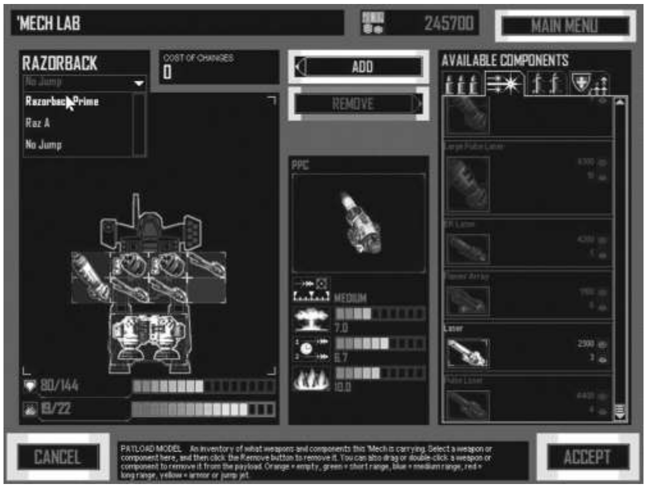
A structured usability test maintains all the characteristics that Dumas and Redish (1999) propose as common to all usability tests: (1) the goal is to improve usability of the product, (2) participants represent real users, (3) participants do real tasks, (4) participant behavior and verbal comments are observed and recorded, and (5) data are analyzed, problems are diagnosed, and changes are recommended. We have found that issues relating to expectancies, efficiency, and performance interaction are well suited for this type of testing. Some common areas of focus for structured usability testing are in game shell screens, or control schemes. The game shell can be defined as the interface in which a gamer can determine and or modify particular elements of the game. This may include main menus and options screens (i.e., audio, graphics, controllers, etc.).

An example which uses this method is in the *MechCommander 2* (*MC2*) (Microsoft Corporation 2001) usability test. Portions of the method and content have been omitted.

34.7.2.1.1 Case Study: MechCommander 2 Usability Test

MC2 is a PC RTS game where the gamer takes control of a unit of *mechs* (i.e., large giant mechanical robots). One area of focus for this test was on the *Mech Lab*, a game shell screen where mechs can be customized (see Figure 34.2). Here the gamer is able to modify weaponry, armor, and other similar features, and are limited by constraints such as heat, money, and available slots.

The first step in approaching this test was to define the higher order goals. Overall, the game shell screens had to be easy to navigate, understand, and manipulate, not only for those familiar with mechs and the mech universe, but also for RTS gamers who are not familiar with the mech universe.



PAYLOAD MODEL. An inventory of what weapons and components this 'Mech is carrying. Select a weapon or component here, and then click the Remove button to remove it. You can also drag or double-click a weapon or component to remove it from the payload. Orange = empty, green = short range, blue = medium range, red = long range, yellow = armor or jump jet.

FIGURE 34.2 Screenshot of the *Mech Lab* in *MechCommander 2*.

Our goal was for gamers to be able to modify/customize mechs in the *Mech Lab*.

As mentioned, one of the most important steps in this procedure is defining the participant profile(s). Getting the appropriate users for testing is vital to the success and validation of the data since games are subject to much scrutiny and criticism from its gamers. To reiterate, playing games is a choice. For *MC2*, we defined two participant profiles which represented all of the variables we wanted to cover. The characteristics of interest included those who were familiar with RTS games (experienced gamers) and those who were not RTS gamers (novice gamers). We also wanted gamers that were familiar with the mech genre, or the mech universe. Overall, we needed a landscape of gamers that had some connection or interest that would make them a potential consumer for this title, whether through RTS experience, or mech knowledge.

Tasks and task scenarios were created to simulate situations that a gamer may encounter when playing the game. Most importantly, tasks were created in order to address the predefined higher order goals. Participants were instructed to talk aloud, and performance metrics were recorded (i.e., task completion, time). The following are examples from the usability task list.

1. Give the **SHOOTIST** jumping capabilities.

   This task allowed us to analyze participant expectations. To succeed in this task, one had to select a "CHANGE WEAPONS" button from a different game shell screen which brought them into the *Mech Lab*. If the task was to change a weapon on a mech, the terminology would probably have been fine. Thus, this task had uncovered two main issues: (1) could they get to the *Mech Lab* where you modify the mech, and (2) were they able to discover the process of modifying the mech. It was accurately predicted that gamers would have difficulties with the button terminology. Thus, that button was changed to "MODIFY MECH."

   To change the components (i.e., add the jump jets), participants could either select the item, and drag it off the mech, or select the item, and press the "REMOVE" button (see Figure 34.2). One unexpected issue that arose was that participants unknowingly removed items because the distance required for removing an item was too small. The critical boundary that was implemented was too strict. In addition, participants had difficulties adding items by dragging and dropping because the distance required for adding an item was too large (i.e., the item would not stay on the mech unless it was placed exactly on top of the appropriate location). Appropriate recommendations were made, and implemented.

2. Replace the **MG Array** with the **Flamer**.

   One of the constraints presented for modifying a mech was heat limit. Each weapon had a particular heat rating. For example, if the heat limit for a mech is 35, and the current heat rating is 32, only weapons with a rating of 3 or fewer could be added. In this task, the "Flamer" had a heat rating much larger than the "MG Array," thus making impossible to accomplish this task without removing more items. The issues here were the usability of the heat indicator, heat icons, and the discoverability of heat limit concept. None of the participants figured this out. Recommendations included changing the functionality of the Heat Limit Meter, and to add better visual cues to weapons that exceed the heat limit. Both of these changes were implemented.

34.7.2.2 Rapid Iterative Testing and Evaluation Method

Medlock et al. (2002, 2005) have documented another common usability method used by Studios User Research at Microsoft Studios, which they refer to as the RITE method. In this method, fewer participants are used before implementing changes, but more cycles of iteration are performed. With RITE, it is possible to run almost two to three times the total sample size of a standard usability test. However, only one to three participants are used per iteration with changes to the prototype immediately implemented before the next iteration (or group of one to three participants).

The goal of the RITE method is to be able to address as many issues and fixes as possible in a short amount of time in hopes of improving the gamer's experience and satisfaction with the product. However, the utility of this method is entirely dependent on achieving a combination of factors (Medlock et al. 2002, 2005). The situation must include (1) a working prototype, (2) the identification of critical success behaviors, important, but not vital behaviors, and less important behaviors, (3) commitment from the development team to attend tests and immediately review results, (4) time and commitment from development team to implement changes before next round, and (5) the ability to schedule and/or run new participants as soon as the product has been iterated. Aside from these unique requirements, planning the usability test is very similar to more traditionally structured usability tests.

It is very helpful to categorize potential usability issues into four categories: (1) clear solution, quick implementation, (2) clear solution, slow implementation, (3) no clear solution, and (4) minor issues. Each category has implications for how to address each issue. In the first category, fixes should be implemented immediately, and should be ready for the next iteration of testing. In the second category, fixes should be started, in hopes that it can be tested by later rounds of testing. For the third and fourth category, more data should be collected.

The advantage of using the RITE method is that it allows for immediate evaluation and feedback of recommended fixes that were implemented. Changes are agreed upon, and made directly to the product. If done correctly, the RITE method affords more fixes in a shorter period of time. In addition, by running multiple iterations over time we are potentially able to watch the number of usability issues decrease. It provides a nice, easily understandable, and accessible measure. In general, the more iterations of testing, the better. However,

TABLE 34.2

Age of Empires **Example Concepts and Behaviors Categorized into Three Concepts Using the Rapid Iterative Testing and Evaluation Method**

Essential Concepts/Behaviors	Important Concepts/Behaviors	Concepts/Behaviors of Lesser Interest
• Movement	• Queuing up units	• Using hotkeys
• Multiselection of units	• Setting gathering points	• Using mini-map modes
• “Fog of war”	• Garrisoning units	• Using trading
• Scrolling main screen via mouse	• Upgrading units through technology	• Understanding sound effects

Source: Medlock, M. C., D. Wixon, M. Terrano, and R. Romero. 2002. *Using the RITE Method to Improve Products: A Definition and a Case Study*. Orlando, FL: Usability Professionals Association. With permission.

this method is not without its disadvantages. In this situation, we lose the ability to uncover unmet user needs or work practices, we are unable to develop a deep understanding of gamer behaviors, and we are unable to produce a thorough understanding of user behavior in the context of a given system (Medlock et al. 2002, 2005).

The following example demonstrates how the RITE method was used in designing the *Age of Empires II: The Age of Kings* (Microsoft Corporation 1999) tutorial. Again, portions of the method and content have been omitted. See Medlock et al. (2002) for more details.

34.7.2.2.1 Case Study: Age of Empires II: The Age of Kings Tutorial

Age of Empires II: The Age of Kings (*AoE2*) is an RTS game for the PC where the gamer takes control of a civilization spanning over a thousand years from the Dark Ages through the late medieval period. In this case study, a working prototype of the tutorial was available, and critical concepts and behaviors were defined. Also, the development team was committed to attending each of the sessions. And, they were committed to quickly implementing agreed upon changes. Finally, the resources for scheduling were available. The key element in this situation for success was the commitment from the development team to work in conjunction with us.

In the *AoE2* tutorial, there were four main sections: (1) marching and fighting (movement, actions, unit selection, the “fog of war”),* (2) feeding the army (resources, how to gather, where to find), (3) training the troops (use of mini-map, advancing through ages, build and repair buildings, relationship between housing and population, unit creation logic), and (4) research and technology (upgrading through technologies, queuing units, advancing through ages). Each of these sections dealt with particular skills necessary for playing the game. In essence, the tutorial had the full task list built in. In the previous case study, this was not the case.

At a more abstract level, the goals of the tutorial had to be collectively defined (with the development team). In more concrete terms, specific behaviors and concepts that a gamer should be able to perform after using the tutorial were identified, then categorized into the three levels of importance: (1) essential behaviors that users must be able to perform without exception, (2) behaviors that are important, but not vital to product success, and (3) behaviors that were of lesser interest. Table 34.2 lists some examples of concepts and behaviors from each of the three categories. This is an important step because it indirectly sets up a structure for decision rules to be used when deciding what issues should be addressed immediately, and what issues can wait.

The general procedure for each participant was similar to other usability tests we often perform.

If participants did not go to the tutorial on their own, they were instructed to do so by the specialist.

During the session, errors and failures were recorded. In this situation, an error was defined as anything that caused confusion. A failure was considered an obstacle that prevented participants from being able to continue. After each session, a discussion ensued among the specialist and the development team to determine what issues (if any) warranted an immediate change at that time.

In order to do this successfully, certain things had to be considered. For example, how can one gauge how serious an issue is? In typical usability tests, the proportion of participants experiencing the error is a way to estimate its severity. Since changes are made rapidly here, the criteria must change to the intuitively estimated likelihood that users will continue to experience the error. Another thing to consider is clarity of the issue, which was assessed by determining if there is a clear solution. We have often found that if issues do not have an obvious solution then the problem is not fully understood. And finally, what errors or failures were essential, important, or of lesser interest. Efforts of the development team should be focused on issues related to the essential category when possible.

At this point we broke down the issues into three groups. The first group included issues with a solution that could be quickly implemented. Every issue in this group was indeed quickly implemented before the next participant was run. The second group consisted of issues with a solution that could not be quickly implemented. The development team began working on these in hopes it could be implemented for later

* The *fog of war* refers to the black covering on a mini-map or radar that has not been explored yet by the gamer. The fog of war “lifts” once that area has been explored. Use of the fog of war is most commonly seen in RTS games.

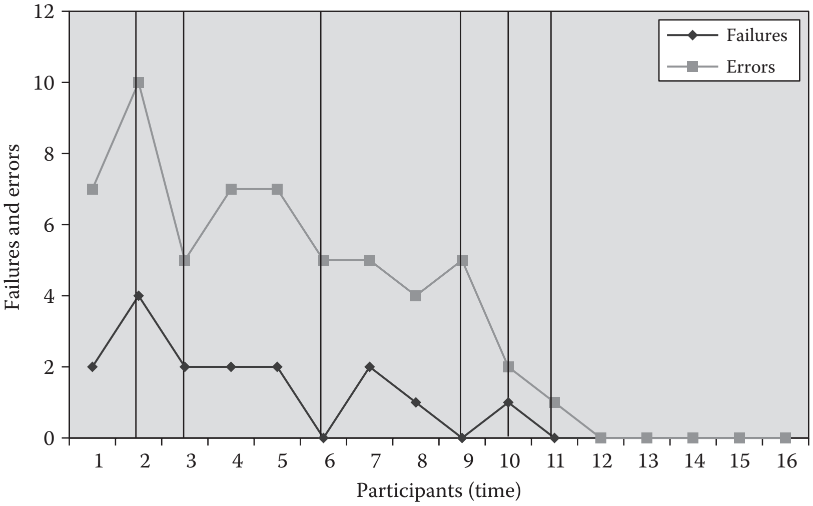


FIGURE 34.3 A record of failures and errors over time for the *Age of Empires* Tutorial when using the rapid iterative testing and evaluation method. (From Medlock, M. C., D. Wixon, M. Terrano, and R. Romero. 2002. *Using the RITE Method to Improve Products: A Definition and a Case Study*. Orlando, FL: Usability Professionals Association. With permission.)

iterations of the test. Finally, there were issues with no clear solutions. These issues were left untouched because more data were needed to assess the problem at a deeper level (i.e. more participants needed to be run). Any fixes implemented in the builds were kept as each participant was brought in. Thus, it was possible that many of the participants experienced a different version of the tutorial over the duration of testing.

Overall, seven different iterations were used across 16 participants. Figure 34.3 represents the number of errors and failures recorded over time. The number of errors and failures gradually decreased across participants as new iterations of the build were introduced. By the seventh and final iteration of the build, the errors and failures reliably were reduced to zero.

Although we feel that the *AoE2* tutorial was an enormous success, largely due to the utilization of the RITE method, the method does have its disadvantages and should be used with caution. Making changes when issues and/or solutions are unclear may result in not solving the problem at all, while creating newer usability problems in the interface. We experienced this phenomena a couple of times in the *AoE2* study.

Also, making too many changes at once may introduce too many sources of variability and create new problems for users. Deducing specifically the source of the new problem becomes very difficult. A related issue is not following up changes with enough participants to assess whether or not the solution really addressed the problem. Without this follow-up, there is little evidence supporting that the implementations made were appropriate (which is a problem with traditional usability methods as well). The last thing to consider is that other important usability issues that may surface less frequently are likely to be missed. Using such small samples between iterations allows for the possibility that those less occurring issues may not be detected.

34.7.2.3 Variations on Usability Methods

Now that we have presented two general types of usability testing, it is worth mentioning some variations on these methods: (1) open-ended tasks, (2) paper prototyping, and (3) gameplay heuristics.

In general, it is often recommended that tasks in usability tests be small, with a specified outcome (e.g., Nielsen 1993). However, we have found situations where the inclusion of an open-ended task yields important data as well. In many usability studies, we often include an open-ended task where participants are not instructed to perform or achieve anything in particular. In other words, there is no specified outcome to the participant. These tasks can be used to analyze how gamers prioritize certain tasks or goals in a nonlinear environment. These tasks are also useful in situations where structured tasks may confound the participant experience or situations where we are interested in elements of discovery. An example of an open-ended task is as follows:

> Play the game as if you were at home. The moderator will tell you when to stop.

This example was taken from a usability test on *Halo: Combat Evolved* (Microsoft Corporation 2001) (Pagulayan et al. 2003). Participants were presented with a mission with no instruction other than playing as if they were at home. Traditional usability metrics were not tracked or used. Instead, the focus was watching players and the tactics and strategies they employed while playing through the game. Results demonstrated that novice players would start firing at enemies as soon as they were visible, which was not how the designers intended combat to occur. The design intent was for combat to occur at closer ranges.

By allowing participants to play through the mission with no structured task, designers were able to detect the strategies players would employ. As a result, several changes were made to the gameplay to encourage players to engage in much closer combat. See Pagulayan et al. (2003) for more details.

Prototyping, heuristic evaluations, and empirical guideline documents are other techniques we often use when more time-consuming testing cannot be done. In practice, these techniques do not differ when used on games. Nielsen (1993) categorizes prototyping and heuristic evaluations as "discount usability engineering," and we would agree. We also tend to view empirical guideline documents in a similar manner. Empirical guideline documents are essentially lists of usability principles for particular content areas based on our collective experience doing user research. Examples of some of these content areas include console game shell design, PC game shell design, PC tutorial design principles, movement, aiming, and camera issues in first- or third-person shooter games, and online multiplayer interfaces. Desurvire, Caplan, and Toth (2004) have developed a list of heuristics targeted at computer and video games. These have been broken down into four general categories: game play, game story, game mechanics, and game usability. For the full list of gameplay heuristics, see Desurvire, Caplan, and Toth (2004).

34.7.3 Survey Techniques

The use of surveys has been explored in great depth (e.g., Bradburn and Sudman 1988; Couper 2000; Labaw 1981; Payne 1979; Root and Draper 1983; Sudman, Bradburn, and Schwarz 1996) and is considered a valid approach for creating an attitudinal data set as long as you ask questions that users are truly capable of answering (see Root and Draper [1983]). We conduct surveys in the lab and online in order to collect attitudinal data regarding gameplay experiences, self-reported play behaviors, preferences, styles, and motivations.

34.7.3.1 Formative Playtest Surveys

We combine hands-on play with surveys to create a formative lab method called "playtest." In nearly all instances, questioning follows the pattern of a forced choice question (sometimes a set of forced-choice questions) followed by a more open-ended question encouraging the participants to state the reasons behind their response. The goal of a playtest is to obtain specific information about how consumers perceive critical aspects of a game and provide actionable feedback to game designers (Davis, Steury, and Pagulayan, 2005; Amaya et al. 2008). The basic playtest method is used formatively to compare a product at time one and time two during its development. While a modified version of the basic method is used summatively to compare a summative evaluation to other, relevant games.

Playtests have several advantages and characteristics that differentiate them from usability studies and online survey research. For one, they focus mainly on perceptions. A larger sample size is required for statistical power and generalization of the results to the target audience. In most cases, 25–35 participants are used as a pragmatic trade-off between confidence and resource constraints. Specialized studies may require more. Statistical representations of the attitudinal measures are used to identify potential strengths and weaknesses that need to further be explored, provide information about the extent or severity of an attitude, or to describe trends of interest that come to light.

Conducting the studies in the lab, as opposed to online, allows us to test in-progress games during early development. It also allows us to take more control of the testing situations and monitor a limited amount of play behaviors that can be paired with the attitudinal data.

On the other hand, there are a few notable disadvantages. First, structured lab studies limit the amount of gameplay that can be tested in a single study. An artificial lab scenario or timeline may prevent the engineer from collecting critical information about the game experience. This is a classic validity trade-off present in most lab studies. Second, the amount of preparation that is required to design a playtest questionnaire takes some time. The study plan cannot be adjusted during the course of the study. The engineer must be intimately aware of the development team's questions to include all of the relevant questions in the survey. This requires domain knowledge in games and experience in survey design.

Second, the data can sometimes be difficult to interpret if the problem isn't major, or if the game facet is novel. Sometimes the data doesn't provide specific causes for the problem, making it difficult to nail down the best solution. Follow-up studies, (playtest or usability) are often recommended (or necessary) to parse out these issues. Finally, the approachable nature of the data is ripe for misinterpretation by team members who may not be familiar with the current state of the game, design details, or the methods used in playtest. It has been rightfully asserted that usability tests do not necessarily require a formal report upon completion (Nielsen 1993). We believe that may be less true for using this kind of technique. Careful and consistent presentation formats are required. Instructions and contextual information that will help with interpretation should be included, along with some form of qualitative data (e.g., open-ended comments). Metrics from games that are in development should focus on problem detection and often cannot be used for predictive purposes.

34.7.3.2 Development of the Playtest Surveys

Several steps have been taken to increase the effectiveness and efficiency of playtest. First, core questions for each genre, play style, and core game feature have been developed, using a multistep iteration and evaluation process. This process included construct development, survey item development, formative evaluation with subject matter experts, and formative evaluation of question validity using Cognitive Interviewing techniques and statistical validation. While many survey items have been validated, most playtests require new items to be created in order to meet the specific needs of that particular game and study goal. Therefore, a repository of previously used customized questions has been created, along with guidelines for writing new survey items.

34.7.4 Type of Formative Studies

There are essentially three types of formative studies that are conducted during development: (1) the critical facet test,

(2) the initial experience test, and (3) the extended playtest. We also run tests that do not easily fit into any of these categories, including subtle variations on the above, a few cases of large sample observationally based studies, and studies that focus on games from a more conceptual level.

As in Section 34.7.2, for clarity of presentation, each technique will be discussed separately, followed by a case study. Each case study will only contain information pertinent to a specific technique, thus examples may be taken from a larger playtest.

34.7.4.1 Critical Facet Playtest

Games often take the form of repeating a core experience within an array of different context and constraints. A driving game is always about aiming an object that is hurtling through space. The critical facet playtest focuses directly on that core experience and making sure that it is fun. While the core experience can often be assessed in usability testing, playtesting is necessary to assess attitudes and perceptions about the core experience.

The following example demonstrates how a critical facet test was applied to the critical facets of *Oddworld: Munch's Oddysee* (Microsoft Corporation 2001), an Xbox game. *Munch's Oddysee* is a platform/adventure game that allows you to switch back and forth between two main characters as they proceed through the increasingly difficult dangers of Oddworld on a quest to save Munch's species from extinction. The core gameplay is exploring the realm by running, jumping, and swimming through the environment. In this case, there were concerns about the user's visual perspective—which we typically call the camera. Does the camera support exploration of the environment?

34.7.4.1.1 Case Study: Munch's Oddysee, Camera

Previous usability testing with the *Munch's Oddysee* had determined that while some users indicated dissatisfaction with the behavior of the camera, other participants chose not to mention it at all while engaged in the open-ended usability tasks. The camera's behavior was programmed so as to create maximal cinematic effects (i.e., sometimes zooming out to show the size of an area) and also attempt to enhance gameplay. The camera would often show a specific view with the intent of showing you what was behind "the next door" or on the other side of the wall while still keeping the main character in view. While many users liked the look, style, and behavior of the camera, users often wanted more control over the behavior of the camera. Indeed some participants would actively say things such as, "That looks really cool right now [after the camera had done something visually interesting] but I want the camera back pointing this way now." Because feedback from the usability lab contained both positive and negative feedback, the development team didn't see the usability data as conclusive. Further, changing the camera would be a major cost to the game in terms of redesign and redevelopment time.

After having played the game for an hour, 25 participants were asked for general perceptions of the game. More specific questions followed. Questions related to the camera were asked in the latter portion of the questionnaire because previous experience in the usability lab had shown that merely mentioning the camera as part of a task would often cause participants previously silent on the subject to vociferously criticize aspects of the camera's behavior. With the knowledge that we wanted to factor out any priming-related effects, two analyses were conducted.

The first analysis was based on the response to the questions related to the behavior of the camera itself. Nearly half of the participants (46%) indicated that the camera did not give them "enough flexibility" of control.

The second analysis went back through individual responses to determine the attitudes of those participants who mentioned the camera before the survey first broached the subject. Forty-three percent of the participants were found to have mentioned the camera in a negative fashion prior to being asked specifically about the camera questions.

Based on this data and other anecdotal evidence, the development team chose to give the players more flexibility of camera control. The result was more frequent use of a camera behavior we termed a "3rd-person follow camera." The behavior of this camera had the double advantage of being more easily controlled by users and of conforming to a set of behaviors more often expected by users. It maintained focus on the main character without major adjustments to point of view (i.e., to "look over a wall" or "behind a door"). Other camera behaviors (i.e., still camera behaviors that pan with the character) are still a part of the game but have been localized to areas where these alternative camera behaviors can only create an advantage for the user.

34.7.4.2 Initial Experience Playtest

As with many things, first impressions are a key component of overall satisfaction with a game. Given that many games are a linear experience/narrative there is a lot of value in obtaining attitudinal data related to the first portions of gameplay. Lessons learned at first are often applied throughout the game. Obviously, the later portions of the game will never be experienced unless the first portions of the game are enjoyed.

The following example explains how a set of formative initial experience tests were run for *MC2*, the RTS game described earlier in the chapter. The earlier usability test focused on the choices that users could make prior to starting a mission, whereas this test focused on in-game components, such as the user's ability to take control of their squad and lead them through battles, while experiencing satisfaction and motivation to continue playing.

34.7.4.2.1 Case Study: MechCommander 2, Initial Missions

Twenty-five participants who were representative of the target market were brought onsite and were asked to begin playing from the first mission of the game. After each mission, participants were asked to stop playing and report their impressions of the "fun," the "excitement," and the "clarity" of objectives. Participants also indicated their "comfort level" with the basics of controlling the game. The participants were able to play through as many as three missions before the session ended. For purposes of brevity, this case study will focus on the results related to the first mission.

Although the first mission had been designed to offer tutorial elements in a brief and fun way, the experience was generally not satisfying to participants. Approximately a third of the participants had a poor initial impression of the game. They felt that the "challenge" was "too easy" and that the mission was "not exciting." Furthermore there were some problems related to clarity of goals. By combining the survey results with opportunistic observation, it was noted that some participants moved their units into an area where they were not intended to go. This disrupted their experience and limited their ability to proceed quickly. Responses to more open-ended questions indicated that some of the core gameplay components and unique features did not come across to users. Some users complained about the "standard" (predictable or commonplace) nature of the game. Finally several participants complained about the fact that they were "being taught" everything and wanted to "turn the tutorial off."

A number of actions were selected from team insight and user testing recommendations. First, the team decided to separate the tutorial missions from the required course of the game in order to save experienced players from the requirement of completing the tutorial. Second, the scope of the first mission was expanded so that users would have more time in their initial experience with the game. Third, the clarity of objectives was improved via minor interface changes. Fourth, addressing the same issue, the design of the "map" on which the mission took place was revamped to require a more linear approach to the first mission that limited the likelihood of users becoming "lost." Fifth, the amount and challenge of combat was increased. Finally, one of the unique components of the game was introduced. The new mission included the ability to "call in support" from off-map facilities. Despite all these changes, the mission was still targeted to be completed within approximately 10–15 minutes.

A follow-up playtest was intended to verify the efficacy of the changes. Twenty-five new participants were included in the study. Results from this test indicated that the design changes had created a number of payoffs. Far fewer participants felt the mission was "too easy" (13% vs. 33%), only 3% indicated that the mission was "not exciting," measures of "clarity of objectives" improved and, surprisingly, there was no drop-off on ratings of "comfort" with basic controls as a result of the tutorial aspects being improved. Results were not a total success, as some participants were now rating the mission as "too hard" while others in response to open-ended questions complained about the "overly linear" nature of the mission (i.e., there was only one way to proceed and few interesting decision related to how to proceed through the mission). In response to these results the development team decided to "re-tune" the first mission to make it a little easier, but not to address the comments related to the linearity of the mission. The second mission of the game was far less linear and so it was hoped that, with the major constraints to enjoyment removed, most participants would proceed to the second mission and find the mission goals to be more engaging. The data from mission 2 was rated far more "fun" than mission 1, validating their assumption.

34.7.4.3 Extended Playtests

While the initial experience with a game is very important, the success or failure of a game often depends on the entire experience. In an attempt to provide game developers with user-centered feedback beyond the first hour of game play, we conduct extended playtests that test several hours of consecutive gameplay. This is done by conducting playtest studies that run for more than 2 hours, or by having participants participate in more than one study. Attitudinal data is taken at significant time or experience intervals (i.e. after a mission). Participants can also provide self-directed feedback about a specific point in the game at anytime during the session. Basic behaviors and progress (e.g., completed level 4 at 12:51 PM) can be recorded by playtest moderators and used in conjunction with the attitudinal data.

34.7.4.4 Focus Groups

In addition to usability and survey techniques, we sometimes employ other UCD methods which are qualitative in nature. Focus groups provide an additional source of user-centered feedback for members of the project team. Our playtest facilities offer us the opportunity to precede a candid user discussion with hands-on play or game demonstration. In this setting, participants can elaborate on their experience with the product, provide feedback about the user testing process, speculate about the finished version of the product, generate imaginative feature or content ideas or find group consensus on issues in a way that models certain forms of real-world shared judgments.

For example, a focus group discussion regarding a sports game revealed that users had varying opinions about what it meant for a game to be a "simulation" versus an "arcade-style" game. Additionally, they had many different ideas as to what game features made up each style of game. From this conversation, we learned a few of the playtest survey questions were not reliable and needed revision.

Besides the general limitations inherent in all focus group studies (Greenbaum 1988; Krueger 1994), the focus groups described here typically include practical limitations that deviate from validated focus group methods. Generally, focus group studies comprise of a series of four to twelve focus groups (Greenbaum 1988; Krueger 1994), however, we typically run one to three focus groups per topic. This makes the focus group more of a generative research tool rather than a confident method for identifying "real" trends and topics in the target population. Fewer group interviews make the study more vulnerable to idiosyncrasies of individual groups.

34.7.5 Testing Physical Games

When testing physically-oriented games such as with Kinect, the Wii, or the Move, the basic concept of how to test is very similar to what we have noted previously. In a usability scenario we will use a mixture of open-ended and directed tasks and in a playtest scenario we will still ask users to play and then fill out brief surveys about the experience. The key considerations mostly focus on how the details of a test design will interact with the physical nature of the test. These differences touch on every aspect of research design.

34.7.5.1 Participants

When considering who to include in the study, some thought should be given to the preexisting skill level that you would prefer to see from your study participants. In the case of a singing game, the level of skill a participant brings may be a subject of interest prior to the test. And for a physically-oriented game, testing with people of different physical capabilities may be a matter of some importance.

You have to ensure that the participant is ready for and physically capable of participating in the study. Prior to the study, the participants might be asked to show up wearing clothes and shoes they can comfortably move around in. Liability issues may require you to modify any pretest agreements to cover potential physical issues that can occur.

A separate but related point is that the act of using a talent or physical capability, even in a private enclosed venue such as a research laboratory, may touch on feelings of anxiety and an individual's discomfort with their own ability to perform an action. While considerations like this are a factor in most research, the fact that a person is actually performing the action or skill-based task removes an abstraction layer that is more commonly a part of testing with standard game controller-based games. For example, if a player struggles with a game that requires expert use of a game controller then the player has a few strategies to manage self-esteem and express frustration. She has the option of choosing from statements such as "I cannot do that" or "the game is too hard" or "I am no good with this controller." Meanwhile in the context of a physical or talent-based game, while the same options are still available the "I cannot …" and "I am no good …" statements can point out deficits that are more personal in nature, are uncomfortable to discuss, and perhaps not pertinent to the needs of the test. Standard participant management techniques are called for to reduce anxiety and discomfort.

Finally, some consideration should be given to the idea of recruiting participants in groups. While not always true, it is very common for a physically oriented game to be oriented towards group play. The use of groups can complicate the assessment and that will be touched on in Section 34.7.5.3. But the use of groups also has the pleasant side effect of reducing some of the awkwardness of asking a user to perform a talent-based task and potentially failing in front of strangers.

34.7.5.2 Facilities

A key differentiator for physical-based gaming is that the facilities must support numerous scenarios. Sometimes the games are quite loud, in which case some soundproofing may be a helpful factor in the test setup. At other times the key factor would be providing a sufficient amount of space for two or more people to comfortably play together, while swinging their arms and perhaps moving through the rooms. Additional considerations should go to safety concerns; ensuring the floor surfaces in the testing environment are not and cannot become especially slick and to either move furniture out of the way or to ensure it is adequately padded in case of a fall.

From the perspective of the testing, the facilities should have multiple cameras watching the play experience, preferably from a frontal view, a side view and a top-down view. All views should have as wide an angle as possible available so that the tester can capture a reasonable range of motion without having to adjust the cameras in real time. Getting by without all the views is possible but the tester will miss details about the depth or actual size of a motion if only some of the fields of view are available.

34.7.5.3 Test Methods

For physical gaming, the primary adjustment to the methods occurs in usability testing. Put most simply, the think aloud technique may not be appropriate when the participant may be out of breath. It is more advisable to just concentrate on logging behaviors while a participant is playing and then to follow up with a more interview-oriented approach to understand what they were thinking at various points when they were playing.

Since the testing is of a physical experience, the researcher must divide attention between the game status as presented on screen to the participant and on the participants themselves as they move while playing. This only represents a change in that in physical scenarios there are numerous movements of interest, requiring multiple cameras to detect and study them.

From our experience, groups of participants are commonly treated as a 'single participant set'. So in the standard discussion of how many participants you want for a study (Nielsen and Landauer 1993) the number of individuals must be replaced with the number of groups. The plusses and minuses of using groups as the minimal measure of interest are best detailed within a context devoted to the subject. In our testing, to avoid problems associated with groupthink (Janis 1972) all participants are instructed to be open and honest and are informed that we are not trying to reach a consensus and that it is okay to disagree. These instructions are based on the standard approach to conducting a focus group (Greenbaum 1988; Krueger 1994). When coding the usability test, the behavior of the group and its success, failure and/or time on task is treated in similar fashion to coding the behavior of an individual. So if an 8-year-old child is on the cusp of figuring out an interface element but his mother insists that he is on the wrong track, then the nature of the failure is treated similarly to an individual going through the same process. The interface element is still judged to have failed the task, though the initial attractiveness is noted as well as the reason for group attention moving elsewhere.

34.7.5.4 Data Analysis and Reporting

The analysis of physically based gaming data is not especially different from the typical. Data can be coded and communicated similarly to data from other kinds of game testing. In the reporting, however there will often be a much stronger emphasis on visual analysis and accurately describing a physical motion. Time spent poring over video will likely increase and efficiencies can and must be sought from the use of strong video and data-coding software. Additionally the use of high-powered video editing software will often be required to create strong clear presentations of results.

34.7.6 Tracking Real-Time User Experience Instrumentation

For several years, we have been utilizing an instrumentation technique we call Tracking Real-Time User Experience (TRUE). TRUE instrumentation involves having the game track key user behaviors during gameplay, along with contextual variables, and allowing users to answer survey questions at key points in time. The TRUE method provides broad coverage, detailed recommendations, and quick turnaround of data collection, analysis, and recommendations. Its unique combination of quantitative analysis of behavioral data, collection and analysis of evaluative data (ratings and preferences), and ability to link all of these to qualitative data (video) make it a very powerful tool in a user researcher's arsenal. It combines the best of problem detection with in-depth analysis; the in-depth analysis makes the data actionable by design teams. The advantages of this combination deserve some discussion, and useful and practical recommendations for applying TRUE are discussed elsewhere (Kim et al. 2008; Schuh et al. 2008).

34.7.6.1 Behavior, Evaluation, and Context

To fully understand how effectively a game meets the intent of the designers one needs to know what people are doing at any point in the game (behavior), what conclusions they are drawing about the game (evaluations), and what in the mechanics of the game is leading to these behavioral and evaluative results (context). By collecting both behavior and evaluation and linking those results to indexed video, the development team can quickly identify (detect) problem areas and then zoom down to video to determine what elements of the game are creating those problems. Put another way, the TRUE method captures the primary elements needed to empirically understand and change the mechanics of a game in order to produce improved dynamics (behavior) and aesthetics (evaluation). Other methods (e.g., usability testing) may capture all these elements but they often do so in an informal way (thinking out loud and watching participants). In addition, the labor intensive nature of these data collection and analysis techniques means that, from a practical standpoint, they cannot cover the entirety of a sizable game. This increase in efficiency provided by TRUE does not just make work easier, it opens new possibilities. The scope of the application of TRUE combined with its breadth and depth make it unique.

34.7.6.2 Issue Discovery

Like other user research methods TRUE can be thought of as a "discovery" method. It collects and plots data so that anomalies and patterns can be spotted. Once an anomaly is spotted, for example, more deaths than expected at a given place or time or users not progressing past a given point in a mission or on a map, one can look at more and more detailed elements of the data until the likely cause for the unexpected outcome is discerned. This often involves a progressive drill down into the data, which may lead ultimately to viewing the video showing exactly what players did and in what context they did it. It shows what the team as a whole could not have predicted or at least did not anticipate. This "detection" quality is an essential characteristic of many user research methods (traditional usability test, RITE tests, Heuristic reviews, and others). TRUE is not really intended as a method to compare designs. Other methods like playtest and benchmark testing are better suited to those tasks.

Like other methods TRUE is best applied in some contexts and not at all applicable in some others. However the conditions for success for TRUE are more subtle than those of other methods. Specifically, TRUE is best applied when the development effort is characterized by common framework and shared definitions. For example, TRUE works well when missions are defined in a similar way throughout the game. Specifically, a mission begins when a prior climatic battle is won (e.g., the previous boss is vanquished) and ends when a final climatic battle is won (e.g., the current boss is killed). It also is well applied to games where the player navigates a map facing puzzles to solve and enemies to vanquish or in racing games where there is a clear start and finish of a gameplay segment. Its application is difficult if not impossible to a game where missions are defined in an inconsistent way, for example, sometimes a mission ends when a boss is vanquished and sometimes it ends when a boss is encountered. This kind of consistency needs to exist in all parts of the game. If the player relationship between damage and weapon use is not lawful and uniform, then analyzing the game with automated tools becomes difficult or impossible. The analyst is confronted with anomalies that defy explanation or are explained by lapses in consistency. Needless to say such haphazard elements will also make the game difficult to play and not in the good sense of that term. That is not difficult because the game is challenging but because it is arbitrary. That said, TRUE can detect bugs in a game—an accidently overly powerful enemy for example. Those kinds of bugs will stand out as anomalies just like a level or puzzle that is too challenging.

To be applied, the TRUE method must have a working prototype. Thus, it cannot be applied to an effort that is at the stage of ideation or story boards. It could be applied to any portion of a game that is playable. It could also be applied to a prior version of a game to identify areas for improvement. It can't be applied to other elements that contribute to the success of a game, such as story line or character depth. However, while these elements may play significant roles in a game's success, the game play is what defines a game and differentiates it from other art forms like books or movies.

In summary, TRUE is a powerful and flexible method, but requires a great amount of investment. When done correctly, its application has resulted in hundreds of improvements to dozens of games. It has greatly extended the "reach" of empirical methods into game design and development. It stands as a proven, practical, and effective method that has contributed to the development and commercial and critical success of many games (Thompson 2007). It represents a methodological breakthrough in games research and stands as a yardstick against which new methods can and should be assessed.

34.7.7 A Combined Approach

There are a variety of user research techniques we use in game development and evaluation—each suited for answering a particular type of question the development team has. As can be seen in this chapter, there are clear differences between the techniques but the end goal is the same: improve the user experience in our games. The important thing to realize is that no one method exists independent of other methods. The following is a brief case study on a PC game called *Rise of Nations: Rise of Legends* (Microsoft Game Studios 2006) that demonstrates how some of these techniques can be used in tandem.

34.7.7.1 Case Study: *Rise of Nations: Rise of Legends*

Rise of Nations: Rise of Legends is an RTS game in which the player must acquire resources, build up their armies and cities, and defeat/overtake any enemies in an effort to take control of the map. Our initial concern was the core controls—users must be able to successfully gather resources, build units and buildings, and engage in combat. A secondary concern was related to the Conquer the World Campaign and the mission progression throughout it.

The first issues addressed were the core controls and gameplay. We wanted to know if users could successfully build, resource, and engage in combat, so we decided to run a RITE usability test on the core gameplay and controls. This RITE testing was only possible because we had the development team from Big Huge Games on site with the ability to make quick iterative changes to the game between participants.

For the initial building controls, in order to place a building, the user had to determine where they wanted it, and then *right click* the mouse button to place the building on the map in that location. During our initial RITE study, we observed several participants attempting to place buildings using a *left click*. Moreover, they continued to make this error even after they discovered how to properly execute this action (right click). We attempted to fix this issue by adding a visual prompt when placing buildings (i.e., a visual icon of a mouse with the right button highlighted green) and tested this fix with four subsequent participants. All four understood the prompt; however, all continued to sporadically make left-click errors. We decided then to modify the controls to eliminate this usability issue and the game was changed to allow either left- *or* right-click building placement. No user following the change had difficulty placing buildings.

In addition to building, we were also interested in finding out if users could successfully resource. We noticed early on in the study that some participants did not explore the map at all. This type of behavior has repercussions for resourcing in that in order to find resources, one must explore the map. The designer intent for the game was that users would explore the map early on in order to find resources and plan strategies. It became clear that one of the barriers to exploration was that users needed to create scout units to help them explore. Yet, in order to create a scout unit, one had to first build a barracks. Both the time and sequence required for these events meant that users did not always create scout units and if they did, it was usually after a bit of time playing. The team decided to give users a “free scout unit” at the start of the game. The scout unit was placed conspicuously right in front of the player’s home city. As a result, fourteen of the next fifteen users explored the map and resourcing performance was greatly improved.

During this RITE study, we also discovered some small usability issues related to combat. These issues were addressed during the course of the study, changes were made to the game, and these changes were validated. Thus, by the end of the study, we were able to improve the usability of the core controls and gameplay and have those improvements implemented into the game.

After this initial RITE study, we began concentrating on the single-player Conquer the World Campaign. The Conquer the World Campaign involves the player progressing through 47 separate missions “scenarios” with the end goal of conquering the world map. The team wanted to apply the RITE techniques to each scenario in order to get fine-grained user data and determine if there were any problematic areas across the campaign. The design questions we wanted answered were the following: Where are users getting blocked? Where are users not having fun? Is the challenge ramp appropriate? Do users think a particular scenario is too easy or too difficult? What do users like/dislike about the campaign experience after several hours?

Some of these design questions we could not answer via usability techniques alone and RITE testing 47 missions was both time and resource prohibitive. Thus, we combined several research methodologies to help answer the design questions. We decided to get broad coverage of the game, follow it up with a fine-grained analysis of the problem areas, fix the issues, go back and cast the broad net, and follow that up by more focused fine-grained testing. To begin, we started running extended playtests over the weekends with TRUE instrumentation. The TRUE instrumentation gave us a mapping of user behavior over time as well as attitudinal data to couple with it. The Monday following the weekend test, we utilized the TRUE data to determine problematic areas to focus our RITE testing on during the week. During the week, we would RITE test those scenarios, all along fixing the builds, and the following weekend, run extended playtests with TRUE instrumentation on the updated game. Over the course of several weeks, we were able to get complete coverage of the entire Conquer the World Campaign and answer most of the design questions we set out to answer. By combining RITE testing, which allowed us to discover and fix many instances of user behavior not matching designer intent, and TRUE instrumentation, which allowed us to discover patterns in user behavior over the course of extended gameplay as well as giving us rich qualitative information and attitudinal data, we were able to help better match the user experience to the design vision across the entire game.

34.8 CONCLUSION

The need for the continued development of UCD methods in video games has indeed arrived. Games drive new technologies, generate enormous revenue, and affect millions of people. In addition, games represent a rich space for research areas involving technology, communication, attention, perceptual-motor skills, social behaviors, and virtual environments, just to name a few. It is our position that video games will eventually develop an intellectual and critical discipline, like films, which would result in continually evolving theories and methodologies of game design. The result will be an increasing influence on interface design and evaluation. This relationship between theories of game design and traditional human–computer interaction evaluation methods has yet to be defined, but definitely yields an exciting future.

UCD methods are beginning to find their way into the video games industry. Commercial game companies such as Ubisoft Entertainment and Electronic Arts, Inc., in addition to Microsoft, employ some level of user-centered methodologies to their game development process. Games share as many similarities as differences to other computer fields that have already benefited from current UCD methods. Thus, it makes sense to utilize these methods when applicable but also to adapt methods to the unique requirements that we have identified in video games.

In this chapter, we emphasized the difference between games and productivity applications in order to illustrate the similarities and differences between these two types of software applications. We also chose to reference many different video games in hopes that these examples would resonate with a number of different readers. Case studies were included to demonstrate, in practice, how we tackle some of the issues and challenges mentioned earlier in the chapter. It is our intention that practitioners in industry, as well as researchers in academia, should be able to take portions of this chapter and adapt them to their particular needs when appropriate, similar to what we have done in creating the actual methods mentioned in this chapter. That said, we are upfront that most, if not all, of our user research methods are not completely novel. Our user research methods have been structured and refined based on a combination of our applied industry experience, backgrounds in experimental research, and of course, a passion for video games. This allows us to elicit and utilize the types of information needed for one simple goal: to make the best video games that we can, for as many people as possible.

ACKNOWLEDGMENTS

We would like to thank Studios User Research at Microsoft Studios. In addition, we would like to express our gratitude to Paolo Malabuyo, Michael Medlock, and Bill Fulton for their insights and input on the creation of this chapter, and Kathleen Farrell and Rally Pagulayan for their editing assistance and reviewing early drafts. The views and opinions contained in this chapter are those of the authors and do not necessarily represent any official views of Microsoft Corporation.

Designing for Diversity

35 Older Adults and Information Technology

Opportunities and Challenges

Sara J. Czaja and Chin Chin Lee

CONTENTS

35.1 INTRODUCTION

The expanding power and proliferation of information technologies such as the Internet and mobile devices have made possible for large numbers of people to have direct access to an increasingly wide array of information sources and services. Network usage is exploding, and new interfaces, search engines, and features are becoming available at an unprecedented rate. In 2010, about 79% of adults in the United States reported that they were Internet users and 66% have broadband access at home (Figures 35.1 and 35.2). In addition, 82% of Americans own a cell phone or some other device such as a Blackberry that is also used as a cell phone (Smith, 2010).

Use of technology is pervasive among all aspects of life and has become an integral component of work, education, communication, and entertainment. Technology is also being increasingly used within the health care arena for service delivery, in-home monitoring, interactive communication (e.g., between patient and physician), transfer of health information, and peer support. Use of automatic teller machines, interactive telephone-based menu systems, and digital entertainment equipment is also quite common. Furthermore, communication devices are becoming more integrated with computer network resources providing faster and more powerful interactive services. In essence, to function independently and successfully engage in routine activities, people of all ages will increasingly need to interact with some form of technology.

Coupled with the "technology explosion" is the aging of the population. In 2004, persons 65 years or older represented 12.4% of the U.S. population, and it is estimated that people in this age group will represent 20.6% of the population by 2050 (Figure 35.3). In addition, the older population itself is getting older. Currently, there are about 44.5 million people over the age of 75 years, and by the year 2050, there will be almost 50 million people 75+ years old and about 19 million people aged 85 and older (National Center for Health Statistics 2005; Federal Interagency Forum on Aging-Related Statistics 2010) (Figure 35.3).

Given that older people represent an increasing large proportion of the population and will need to be active users of technology, issues surrounding aging and information technologies are of critical importance within the domain of human–computer interaction (HCI). To ensure that older adults are able to adapt to the new information environment, we need to understand the following: (1) the implications of age-related changes in functional abilities for the design and implementation of technology systems; (2) the needs and preferences of older people with respect to the design

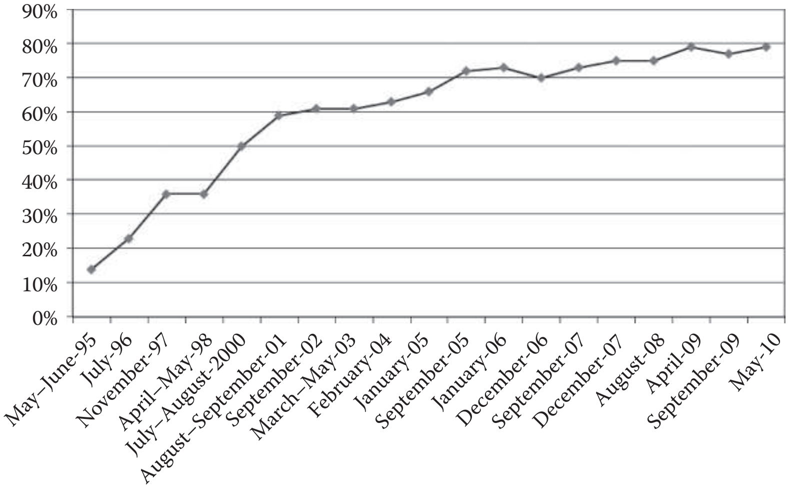

FIGURE 35.1 Percentage of adults online. (From Pew Research Center's Internet & American Life Project. http://www.pewinternet.org/Static-Pages/Trend-Data/Internet-Adoption.aspx. With permission.)

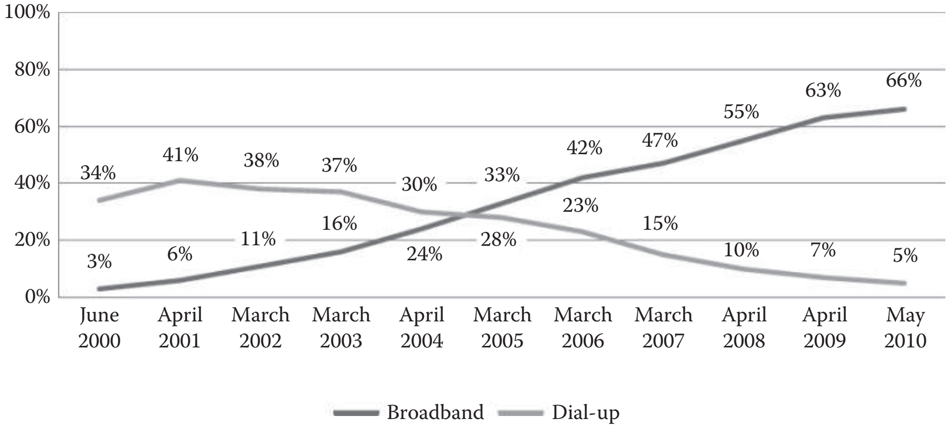

FIGURE 35.2 Percentage of adults who access Internet via broadband or dial-up. (From Smith, A. *Home Broadband 2010*. Pew Internet & American Life Project Surveys, 2010. http://pewinternet.org/Reports/2010/Home-Broadband-2010.aspx. With permission.)

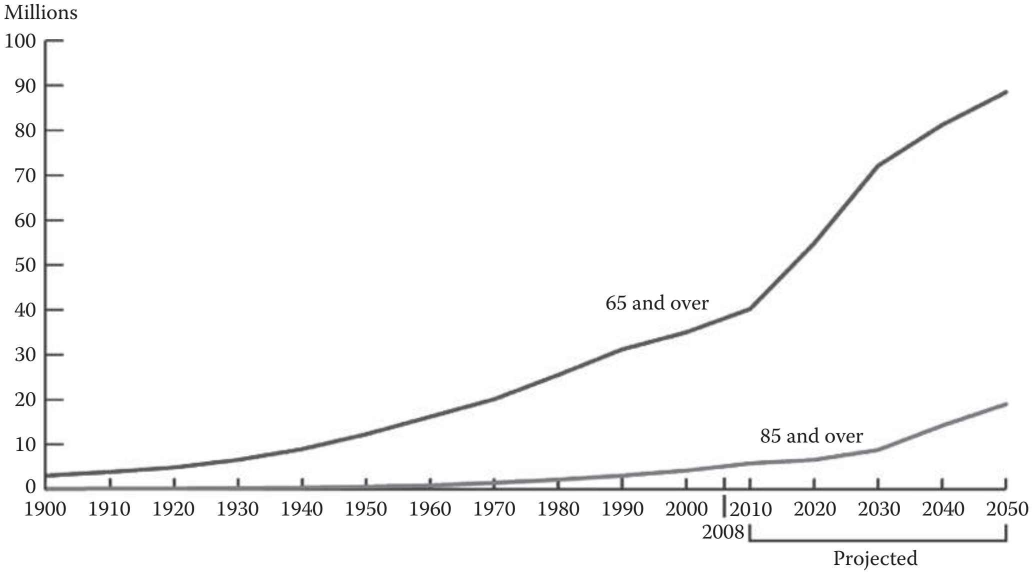

FIGURE 35.3 Percentage of U.S. population aged 65 and over. (From Federal Interagency Forum on Aging-Related Statistics. *Older Americans 2010: Key Indicators of Well-being*. Washington, DC: U.S. Government Printing Office, 2010. http://www.agingstats.gov/agingstatsdotnet/Main_Site/Data/2010_Documents/Slides/OA_2010.ppt.)

of technology interfaces and applications; (3) applications of technology that are useful to and usable by older adults; (4) the reasons for technology nonadoption among seniors; and (5) the problems and challenges that older adults confront when adopting new technologies.

The intent of this chapter is to summarize the current state of knowledge regarding information technologies and older adults. A particular focus will be on web-based technology applications. Topics that will be discussed include the following: adoption and use of information technologies by older adults, training, interface design issues, and other topics such as acceptance of by older adults, privacy, and trust in technology. A detailed discussion of the aging process will not be provided. There are many excellent sources of this material (e.g., Fisk et al. [2009]; Schulz et al. [2006]; Birren and Schaie [2001]). Instead, a brief review of age-related changes in abilities that have relevance to the design of technology systems will be presented. In addition, for the most part, material presented in the previous edition of this book (Czaja and Lee 2007) will not be reiterated. It is hoped that this chapter will serve to motivate researchers and system designers to continue to consider older adults as an important population within the HCI community.

35.2 USE OF TECHNOLOGY BY OLDER ADULTS

35.2.1 Usage Patterns and Trends

As noted, there are numerous settings where older people are likely to encounter technology including the workplace, the home, the health care arena, service, and entertainment settings. However, despite increased use of technology among older people, use of technology is still lower among older people compared with younger people. As shown in Figure 35.4, although use of the Internet among older people is increasing, it is still lower than that among younger age groups. In 2010, about 42% of people aged 65+ were Internet users compared with 78% of people aged 50–64 and 87% of those 30–49 years old. Among those 65 years and older, only about 25% of those 75–84 years of age and 5% of those 85+ years are computer or Internet users (Charness, Fox, and Mitchum 2010). Furthermore, people aged 65+ are much less likely than younger people to have a high-speed Internet connection. In 2010, 31% of adults aged 65+ in the United States had broadband access at home compared with 75% of those aged 30–49 years and 61% of those aged 50–64 years (Figure 35.5). In addition, seniors who do have Internet access and high-speed access tend to be white, highly educated, and living in households with higher incomes (Pew Internet & American Life Project 2004, 2010). Recent data (Czaja et al. 2006; Fox 2010) also indicate that older adults are less likely than younger adults to use other forms of technology such as cell phones, automatic teller machines, or DVRs. For example, data from the Pew Internet and American Life survey found that, although 82% of adults in the United States have a cell phone, only 57% of people aged 65+ years report cell phone ownership. Use of technology also tends to be lower among people with chronic conditions. According to recent data from the Pew Internet and American Life Project (Fox and Purcell 2010), living with a chronic disease has an independent negative effect on someone's likelihood to have Internet access, especially if they have more than one chronic condition. The majority of older adults have at least one chronic condition such as arthritis or hypertension and many have multiple conditions. In addition, many older people report difficulty seeing, hearing, and ambulating (Administration on Aging 2009). All these limitations can have an impact on one's ability to successfully use technology.

This age-related digital divide puts older adults, especially those in the older cohorts, at definite disadvantage in terms of their ability to live and function independently in today's technology-oriented society. It can hamper their ability to access needed information and services; compete successfully in today's labor market; engage in health care management activities; and perform routine task such as shopping, money management, and bill paying. Furthermore, the full benefits of technology may not be realized by older populations.

Technology holds great potential for improving the quality of life for older people. For example, the Internet can facilitate linkages between older adults and health care providers and communication with family members and friends, especially those who are at long distant. It is quite common within the United States for family members to

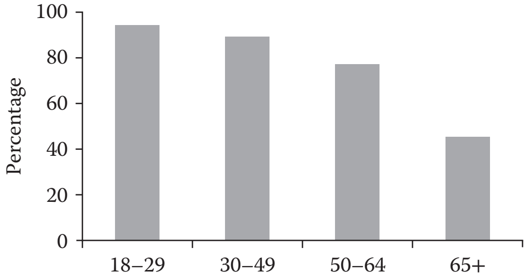

FIGURE 35.4 Percent of Internet users by age group. (From Smith, A. *Home Broadband 2010*. Pew Internet & American Life Project Surveys, 2010. http://pewinternet.org/Reports/2010/Home-Broadband-2010.aspx. With permission.)

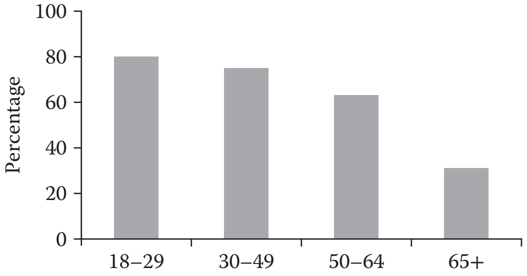

FIGURE 35.5 Percent of broadband users by age group. (Adapted from Smith, A. *Home Broadband 2010*. Pew Internet & American Life Project Surveys, 2010. http://pewinternet.org/Reports/2010/Home-Broadband-2010.aspx; U.S. Census Bureau, Current Population Survey, October 2003.)

be dispersed among different geographic regions. In fact, nearly 7 million Americans are long-distance caregivers for older relatives (Family Caregiver Alliance 2010). Clearly, network linkages can make it easier for family members to communicate with distant relatives, especially those who live in different time zones. Current technologies can also facilitate the ability of caregivers to monitor older relatives who are in need of care and support. Monitoring technologies may be especially beneficial for caregivers who are employed and must juggle work and caregiving responsibilities. A significant portion of workers are also providing care to elder family members. Recent estimates indicate that about 35% of all workers report that they are currently providing, or have recently provided, care to someone aged 65+ (Family Caregiver Alliance 2010).

The Internet may also be used to help older people communicate with health care providers. For example, telemedicine applications allow direct communication between health care providers and patients. The number of e-health applications has also grown markedly in the past several years. There are millions of websites that provide information related to health and health care activities. The Internet is also increasingly being used to access peer support among those who have a chronic condition or disease or providing care to someone who is ill. Electronic medical records (EMRs) are also becoming a fundamental component of health care. Many EMR systems include a patient portal that enables people to engage in health care management tasks, such as monitoring of laboratory/test results, medication management, appointment scheduling, and communicating with physicians and other providers.

The Internet also provides many opportunities for education. There are numerous online courses available on a myriad of topics. These opportunities will continue to expand and be more enhanced with future developments in multimedia and videoconferencing technologies. The Internet can also help older people access information about community services and resources and facilitate the performance of routine tasks such as financial management or shopping. Access to these resources and services may be particularly beneficial for older people who have mobility restrictions or lack of transportation. Finally, many government services such as Medicare and Social Security have online information and are moving toward "online" application processes. Clearly, technology is becoming an integral component of our everyday lives. The following section (35.2.2) will present a more detailed discussion of the potential use of technology by older adults. This will be followed by a discussion of the implications of aging for system design.

35.2.2 Technology Usage in Everyday Domains

35.2.2.1 Work Environments

Technology is ubiquitous within the work domain and a fundamental component of most jobs. Most workers, across all occupational sectors, need to interact with some form of technology on a daily basis. The introduction of technology into the workplace has dramatically changed work processes and the content of jobs. Workers are continually confronted with the need to adapt to new technologies, interface modifications to existing technology applications (e.g., new versions of a software application), and new ways of performing work. For many workers, existing job skills and knowledge are becoming obsolete and new knowledge and skills are required to meet the demands of today's jobs, creating enormous needs for worker training and retraining. Issues of skill obsolescence and training are especially significant for older workers as they are less likely to have had exposure to technologies such as the Internet (Czaja et al. 2006; The Pew Internet & American Life Study 2010). In addition, there is data to suggest that employers invest less in training older workers than younger workers (Barth, McNaught, and Rizzi 1993). Data from a recent focus group study that examined issues regarding barriers confronting older adults seeking employment found that the most common perceived obstacles to employment included age, insufficient qualifications, and lack of technical/computer skills. The sample included community-dwelling adults ranging in age from 51 to 76 years (Lee, Czaja, and Sharit 2009). It is important to point out that numerous studies have shown (e.g., Czaja et al. [2001]; Sharit et al. [2004]) that older adults are willing and able to learn technology-based work tasks. However, they must be provided with access to training, and training programs must be designed to accommodate the learning needs and training preferences of older learners. As will be discussed later in this chapter, much research is needed regarding the optimal training formats for older workers.

In this regard, technology is also changing the way worker training is being delivered. Technology-mediated learning or "e-learning" is quickly emerging as a preferred method for training employees. Use of e-learning tools may present special challenges for older learners who have limited technical skills or limited access to technology or broadband access. Other potential disadvantages of e-learning include the lack of face-to-face interaction with instructors or peers (Czaja and Sharit 2009). To date, there has only been limited research examining where mature learners can effectively use e-learning programs.

Technology is also influencing where work is being performed. The number of people engaging in telework is rapidly increasing. Telework encompasses a number of work arrangements, including home-based work, satellite office, and neighborhood telework centers. It can also be done on a full- or part-time basis. In 2001, about 29 million workers in the United States engaged in some form of telecommuting, and it is estimated that there could be slightly more than 40 million telecommuters by 2010 (Potter 2003). Telecommuting may be particularly appropriate for older adults, as they are more likely than younger people to be "mobility impaired" or engaged in some form of caregiving. Telecommuting also allows for more flexible work schedules and autonomy and is more amenable to part-time work. These job characteristics are generally preferred by older people. Sharit et al. (2004) found that older people are interested in pursuing this type of work as it provides them with an opportunity to remain productive and engaged in work activities at a more flexible schedule. However, more recent data (Sharit et al. 2009) from a study that examined managers' attitudes toward telework and the importance of various worker attributes they consider important to telework. Overall, the managers' attitudes were mixed with respect to potential employment of older workers as teleworkers. For example, the managers indicated that trust, maturity, time management ability, and the ability to work independently were important attributes of teleworkers. They also rated older workers high on these attributes compared with younger workers. However, the managers also perceived older workers as being inflexible, not being able to adjust to teamwork, and having less ability to keep up with changes in technology. Telework also typically involves the use of computers and the Internet, which may be problematic for older people as they are less likely to have computer skills. The prevalence of telecommuting also raises other interesting issues such as strategies to keep workers updated on changes in job demands and that can be used to provide teleworkers with technical support.

Technology will have a continuing major impact on the future structure of the labor force. Most of the job growth in the next decade will come from three occupational groups: (1) computer and mathematical occupations, (2) health care practitioners and technical occupations, and (3) education, training, and library occupations. Other occupations that will experience growth include management and financial occupations; sales and related occupations; office and administrative support operations; and installation, maintenance, and repair occupations, especially within the telecommunications industry (U.S. Bureau of Labor Statistics 2010). Internet and communication technologies will be an integral component of most of these occupations. In addition, new technology applications for job-related tasks are continually being developed.

Overall, these employment trends have significant implications for older adults. Current labor projects indicate that by 2025 the number of workers aged 55+ will be about 33 million (U.S. General Accounting Office 2003). There will also be an increase in the number of workers aged 65+. To insure that older adults are able to compete successfully in today's labor market and adapt to new workplace technologies, it is important that older adults are provided with access to retraining programs and incentives to invest in learning new skills. Greater attention also needs to be given to the design of training and instructional materials for older learners, and it is important that the abilities and characteristics of older workers are accounted for in the design of technical systems. The role of adaptive technologies in helping to make work more viable for older people especially those with some type of chronic condition or disability also needs further exploration. For example, there are a number of technologies available that can aid people with blindness or low vision such as portable Braille computers, speech synthesizers, optical character recognition, screen enlargement software, or video magnifiers. Similarly, personal amplifying devices and amplified telephone receivers can be used to aid persons with hearing loss, and voice recognition software may be beneficial for persons who have limited ability to use traditional input devices such as a mouse or keyboard because of hand or finger limitations. Clearly, there are a number of technologies that can improve the ability of older adults to function in work environments; however, the availability of these technologies does not guarantee their success. The degree to which these technologies improve the work life of older persons depends on the usability of these technologies, the availability of these technologies within organizations, the manner in which these technologies are implemented (e.g., training), and the willingness of older people to use these devices.

35.2.2.2 Home Environments

There are a number of ways older people can use computers at home to enhance their independence and quality of life. The Internet can provide access to information and services and can be used to facilitate the performance of tasks such as banking and grocery shopping. Many older people have problems performing these tasks because of functional limitations, restricted mobility, lack of transportation, and fear of crime (Nair 1989). For example, about 42% of older people report that they have functional limitations and many report that they are unable to perform tasks such as walking 2 or 3 blocks, lifting, shopping, managing money, or managing medications (Administration on Aging 2009; Federal Interagency Forum on Aging-Related Statistics 2010). Recently, a relatively large focus group study was conducted that examined use and attitudes about technology in the context of their home, work, and health care. The sample included 113 older adults, males and females, ranging in age from 65 to 85 years. The findings indicated that one of the reasons they liked technology was that use of some technologies could provide support for activities. Within home, these activities included communication (e.g., e-mail), cooking (e.g., microwaves), leisure and hobby activities, and finding information (Mitzner et al. 2010).

Several studies (e.g., Czaja et al. [1993]; Mitzner et al. [2010]; Madden [2010]) have shown that older adults are receptive to using e-mail as a form of communication and that e-mail is effective in increasing social interaction among the elderly. In fact, recent data from the Pew Internet and American Life Study (Madden 2010) indicate that among those older adults who have Internet access, 92% of those aged 50–64 and 89% of those aged 65+ use e-mail on a daily basis. Interestingly, social networking has also become prevalent among older adults with Internet access; 20% of people aged 50–64 and about 13% of those 65+ report using social networking sites on a typical day. Use of social networking sites is more prevalent among older people with high-speed Internet access.

Increased social connectivity can be beneficial for older people, especially those who are isolated or live alone. Currently, about 30.5% (11.2 million) of all non-institutionalized older persons live alone and the proportion living alone increases with advanced age. Among women aged 75 and over, for example, about 50% live alone (Administration on Aging 2009). Cody et al. (1999) found that older adults who learned to use the Internet had more positive attitudes toward aging, higher levels of perceived social support, and higher levels of connectivity with friends and relatives. A more recent study (Guilleard, Hyde, and Higgs 2007) found that use of communication technologies such as cell phones and the Internet enabled older adults to increase indirect access to family and friends living outside their neighborhood. Substantial evidence indicates that social relationships and the extent to which individuals are integrated into the community have an impact on the health of the individual (Berkman 1995). Social isolation is associated with poorer quality of life, life satisfaction, well-being, poorer health status, and distress and mental illness (Cantor and Sanderson 1999; Cobb 1976; Dykstra 1995; Ellaway, Wood, and MacIntrye 1999; Ellis and Hickie 2001).

The Internet can also be used by older people for continuing education and cognitive engagement. There are websites and software programs available on a wide variety of topics. As noted, e-learning is becoming one of the most popular forms of training within industry and in the education industry for lifelong learners (Willis 2004). There are also formal online degree programs and opportunities to be linked via videoconferencing and networking facilities to actual classrooms. The American Association for Retired Persons offers several online courses as does SeniorNet. In fact, both organizations offer several online courses and tutorials related to computer skills and use of the Internet. Currently, SeniorNet has over 40,000 members and over 240 learning centers throughout the United States (www.seniornet.com. 2005).

These learning opportunities can enable older adults to remain intellectually engaged and active, especially those who have difficulty accessing more traditional classroom-based adult education programs. Research (e.g., Baltes and Smith [1999]) clearly shows that cognitive engagement and stimulation are important for successful aging. In fact, a recent study found that the simple act of reading was associated with reduced mortality among a visually and cognitively intact sample of men (Jacobs et al. 2006). Lifelong learning is a growing interest among older people. Currently, in the United States, more than 33 million adults aged 45+ are engaged in some form of continuing education (Adler 2002).

The Internet can also be used to create "online learning communities" that bring social interaction to learning and support the learning process. An online community refers to an aggregation of people who have a shared goal, interest, need, or activity and have repeated interactions and share resources (Preece and Maloney-Krichmar 2003). The imminent availability of the next-generation Internet and interactive multimedia programming will further expand the education experiences that are available to individuals and enable information to be tailored to the specific needs and characteristics of users. This may be particularly beneficial to older adults who often learn at a slower pace than younger people and need more instructional support. A recent pilot study (Stoltz-Loike, Morrell, and Loike 2005) found that e-learning can be an effective tool for teaching older adults technology- and business-related skills. The e-learning tool evaluated in the study was customized for older adults. However, as noted by the authors, the results were based on a small sample and the e-learning methods were not compared with other traditional training methods. They also point that many of the e-learning materials that are available on the market assume a relatively sophisticated knowledge of technology and familiarity with e-learning environments. This may be disadvantageous to older people who have less knowledge of technology and less experience with computers.

As noted, currently, there is little empirical data to guide the development of these applications. In addition, almost no research has been done with older adults. This issue is especially compelling given that multimedia applications place demands on cognitive processes such as visual search, working memory, and selective attention, which are known to decline with age.

Technology may also be used to augment the memory of older people. There are many software-based applications such as e-mail calendar functions, which are intended to support memory abilities such as the ability to remember dates or appointments. Recent research (e.g., Günther et al. [2003]; Edwards et al. [2002]; Klusmann et al. [2010]) indicates that computerized cognitive training programs can be used in older people to achieve long-term improvements in important aspects of cognition. Quite recently, Tun and Lachman (2010) examined the relationship between the computer use and cognition among people aged 32–84 years. Overall, they found that frequent computer activity is associated with good cognitive function, especially executive function across adulthood. Damianakis et al. (2010) found that the use of digital video technology to produce personalized multimedia biographies helped stimulate positive social interactions between family members and individuals with Alzheimer's disease and mild cognitive impairments. However, findings regarding the beneficial use of computers and the Internet on the cognitive functions of older adults are not conclusive. Current research (e.g., Charness and Boot [2009]; McKay and Maki [2010]) is investigating the use of video-game-based training to augment the cognitive abilities of older adults.

Slegers, von Boxtel, and Jolles (2009) found that learning to use a computer and the Internet did not benefit the cognitive functioning of independent older adults. The authors discuss the fact that the differences in findings between their study and that of others may be because the participants in their study were community-dwelling elders who had less to gain from the computer intervention and because the intervention may not have sufficiently challenged the cognitive capacity of the participants. Finally, they suggest that access and use of the Internet among older adults may have an impact on other outcomes such as indices of functional limitations.

Technology also offers numerous possibilities for enhancing the safety and security of older people living at home. As noted, a large proportion of older adults, especially older women, live at home alone. Systems can be programmed to monitor home appliances, electrical, and ventilation systems, and can be linked to emergency services.

35.2.2.3 Health Care

Technology also holds the promise of improving access to health care for older people and empowering them to take an active role in health self-management. Electronic links can be established between health care professionals and older clients, providing health care providers with easy access to their patients and allowing them to conduct daily status checks or to remind patients of home health care regimes. In addition, with the rapid introduction of EMRs, many of which have patient portals, patients will also be able to communicate with health care providers via e-mail messages. There are also health websites available that allow patients and consumers to ask health care providers health-related questions. Technology may also be used to facilitate health assessment and patient monitoring. Ellis, Joo, and Gross (1991) demonstrated that older people could successfully use a computer-based health-risk assessment. There are also telemedicine applications that are being used to monitor a patient's physical functioning, such as measuring blood pressure, pulse rate, temperature, and so on. These applications offer the potential of allowing many people who are at risk for institutionalization to remain at home. The application of technology in health care delivery and services will continue as current trends in health care are toward health self-management. Individuals and their families are expected to perform a range of health care tasks and interact with a vast array of medical devices and technologies within home settings.

In this regard, the Internet is shaping and having a pronounced impact on personal health behavior. Interactive health communication or "e-health" generally refers to the interaction of an individual with an electronic device or communication technology (such as the Internet) to access or transmit health information or to receive or provide guidance and support on a health-related issue (Robinson, Eng, and Gustafson 1998). The scope of e-health applications is fairly broad but mostly encompasses searching for health information, participating in support groups, and consulting with health care professionals. Most Internet users (83%) have searched the Internet for health information (Pew Internet & American Life 2010). The majority of consumers search for information on a specific disease or medical problem, medical treatments or procedures, medications, alternative treatments or medicine, or information on providers or hospitals. Reasons for the growth of online health information seeking includes easier access by a more diverse group of users to more powerful technologies, the development of participative health care models, the growth of health information that makes it difficult for any one physician to keep pace, cost containment efforts that reduce physicians time with patients, and raising concerns about self-care and prevention (Cline and Hayes 2001). In addition, many people with health conditions or who care for someone with a health condition use social media tools to receive help from people with similar issues. In this regard, recent data from the Pew Internet and American Life Project (Fox and Purcell 2010) indicate that, although people with one or more chronic diseases are less likely to have Internet access than healthy adults, those who are Internet users are more likely to participant in online discussion groups or forums that help people with health problems.

Many consumers say that the Internet has had a significant impact on their health care behavior in terms of the way they care for themselves or for others. A recent study (Taha, Sharit, and Czaja 2009) examined health information needs among older adults and differences in perceptions and use of health information between Internet users and nonusers. The findings indicated that older people use a variety of sources to find information. Many of those who used the Internet to search for health information reported that they found empowered when they were able to bring information obtained from the Internet to their doctors and that their conversations with their physicians improved as a result of having this information. The data also indicated that there were no significant reported differences between users and nonusers in difficulty finding health information or satisfaction with the information found. However, many of the nonusers indicated that they would be willing to try using the Internet if they had some training.

However, the fact that consumers have access to e-health applications has significant implications for both patients and providers. On the positive side, access to health information can empower patients to take a more active role in the health care process. Patient empowerment can result in better informed decision making, better and more tailored treatment decisions, stronger patient–provider relationships, increased patient compliance, and better medical outcomes. On the negative side, access to this wide array of health information can overload both patient and physicians, disrupt existing relationships, and lead to poor decision making on the part of consumers. For example, one major concern within the "e-health arena" is the lack of quality control mechanisms for health information on the Internet. Currently, consumers can access information from credible scientific and institutional sources (e.g., Medline Plus) and unreviewed sources of unknown quality. Inaccurate health information could result in inappropriate treatment or cause delays in seeking health care. In fact, data indicate (El-Attar et al. 2005; Czaja, Sharit, and Nair 2008) that older adults trust health information on the Internet and generally find the Internet to be a valuable source of health information. However, data also indicated that health websites can be challenging for older adults to use (Czaja, Sharit, and Nair 2008; Taha, Sharit, and Czaja 2009). Other concerns related to the ability of nonspecialists to integrate and interpret the wealth of information that is available and the ability of health care providers to keep "pace" with their patients. Physicians increasingly report that patients come to office visits armed with information on their illness or condition and treatment options (Ferguson 1998). Results from a recent Internet user survey (Pew Internet & American Life Project 2000) also indicate that access to Internet health information has an influence on consumer decisions about seeking care, treatment choices, and their interactions with physicians. Finally, some consumers may find health information difficult to access because of design features that result in usability problems, lack of training, or limited access to technology.

The Internet may also be beneficial for family caregivers who are providing care for an older person with a chronic illness or disease such as dementia. Generally, the prevalence of chronic conditions or illnesses such as dementia, diabetes, heart disease, or stroke increases with age, and consequently, older adults (especially the "oldest old") are more likely to need some form of care or assistance. Family members are the primary and preferred source of help for elders. Currently, at least 52 million Americans are providing care for an adult who is ill or disabled (Family Caregiver Alliance 2010).

Current information technologies offer the potential of providing support and delivering services to caregivers and other family members. Networks can link caregivers to each other, health care professionals, community service, and educational programs. Information technology can also enhance a caregiver's ability to access health-related information or information regarding community resources. The Pew Internet and American Life Project (Fox 2010) queried caregivers, who said they had found the Internet to be crucial or important during a loved one's recent health crisis, about the Internet's specific role during that time. The findings indicated that the Internet helped the caregivers find advice or support from other people (36%), helped them find professional or expert services (34%), and helped them find information or compare options (26%). Recent findings from an interview study of approximately 1500 caregivers indicated that 53% of the caregivers reported that they use the Internet as a source of information about caregiving (National Alliance for Caregiving and AARP 2009).

Several studies have also shown that the computer networks (e.g., Czaja and Rubert [2002]; Gallienne, Moore, and Brennan [1993]) can increase social support for caregivers. Technology can also aid caregivers' ability to manage their own health care needs and those of the patient by giving them access information about medical problems, treatments, and prevention strategies. Software is available on several health-related topics such as stress management, caregiving strategies, and nutrition. There are also several websites available that provide information for caregivers, such as that of the Alzheimer's Association (www.alzheimers.com), National Alliance for Caregiving, and Family Caregiver Alliance. The Senior Health Website of the National Institutes of Health also contains caregiving information (http://nihseniorhealth.gov/).

Clearly, technology holds the promise of improving the quality of life for older adults and their families. However, for the full potential of technology to be realized for these populations, the needs and abilities of older adults must be considered in system design. As will be demonstrated in this chapter, older adults generally find technologies such as computers to be valuable and are receptive to using this type of technology. However, available data (e.g., Mead et al. [1997]; Czaja et al. [2001]; Sharit et al. [2003], [2009]; Czaja, Sharit, and Nair [2008]) also indicate that, although older people are generally willing and able to use technology, they typically have more problems learning to use and operate technology systems than younger adults. They also have less knowledge about potential uses of and how to access computers and other forms of technology. Morrell, Mayhorn, and Bennett (2000) found that the two primary predictors for not using the Internet among people aged 60+ years were lack of access to a computer and lack of knowledge about the Internet. Other barriers to computer and Internet access include cost, lack of technical support, usability problems, and creeping functionality (Morrell, Mayhorn, and Echt 2004; Adams, Stubbs, and Woods 2005). Older adults also tend to report lower confidence than younger people in their ability to learn to use computers (AARP 2002; Czaja et al. 2006). Before the full benefits of computer technology can be realized for older people, it is important to maximize the usefulness and usability of these technologies for this population. The following section will review characteristics of older adults that have relevance to the design of computer-based systems.

35.3 WHO ARE TODAY'S OLDER ADULTS?

In general, older Americans today are healthier, more diverse, and better educated than previous generations. Between 1970 and 2008, the percentage of older persons who had completed high school rose from 28% to 77.4% and about 20.5% had a bachelor's degree or higher. However, the percentage of minority older adults who had completed high school and obtained higher degrees was lower than white older adults (Administration on Aging 2009). As noted, higher levels of education are typically associated with technology adoption, and people who are better educated are more likely to use computers and the Internet.

On some indices, today's older adults are healthier than previous generations. The number of people aged 65+ reporting very good health and experiencing good physical functioning, such as ability to walk a mile or climb stairs, has increased in recent years. Disability rates among older people are also declining (Federal Interagency Forum on Aging-Related Statistics 2010). However, the likelihood of developing a disability increases with age, and many older people have at least one chronic condition such as arthritis or hearing and vision impairments (Figure 35.6).

As discussed in Section 35.2.1, disability among older adults has important implications for system design. People with disabilities, especially disabled elders and minorities with disabilities, are less likely to use technology such as the Internet (Fox and Purcell 2010).

Consistent with demographic changes in the U.S. population as a whole, the older population is becoming more ethnically diverse. The greatest growth will be seen among Hispanic persons, followed by non-Hispanic blacks. Currently, individuals from ethnic minority groups are less likely to own or use technologies such as computers. This

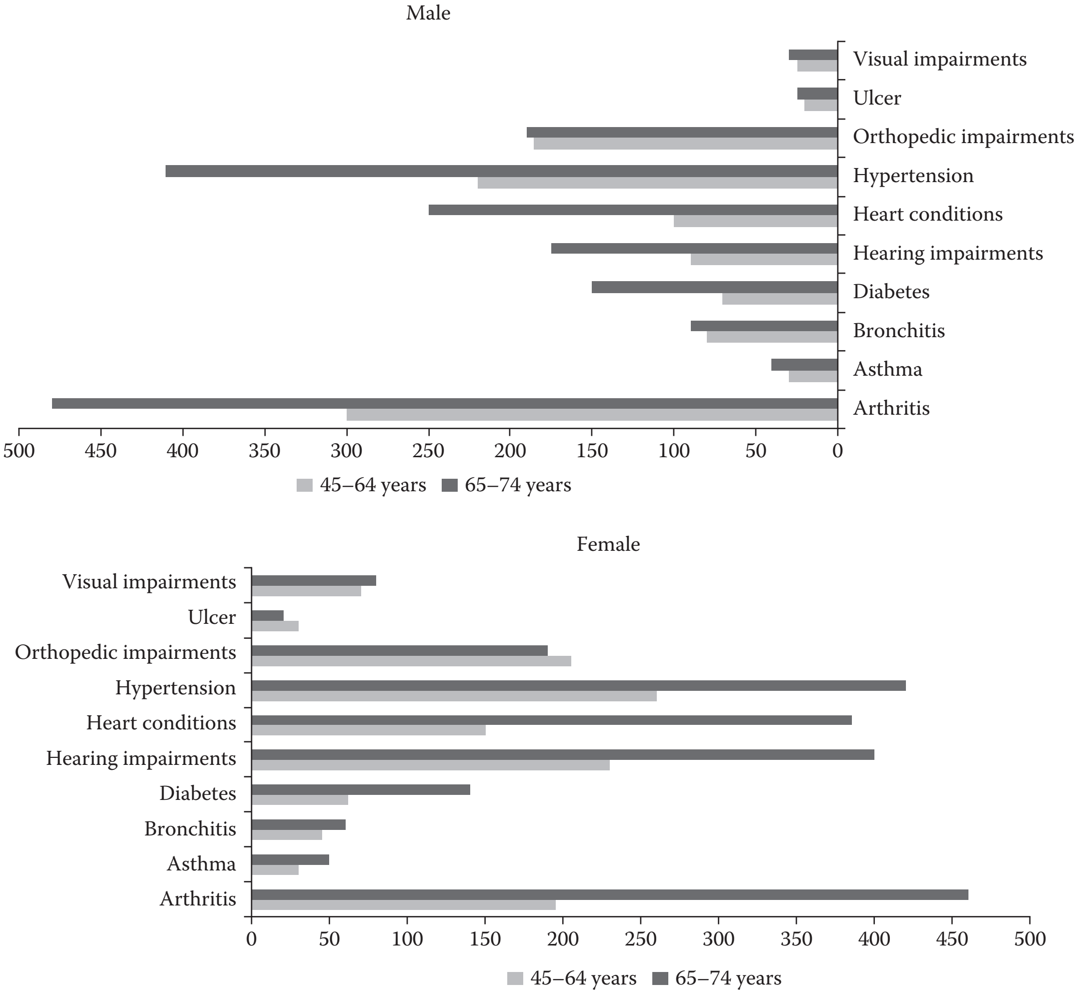

FIGURE 35.6 Chronic illness and older adults. (From Clinical Geriatrics. *Clin Geriatrics* 7(8):77. 1999. With permisson.)

implies that technology access and training programs need to be targeted for older minority populations. Also, there are gender differences in the older adult population, older women outnumber older men. In summary, health status, race, gender, educational background, cultural traditions, and economic circumstances may all influence the adoption and use of computer-based technologies. Thus, system designers need to understand the heterogeneity of the older adult population and ensure that usability testing is done with representative user groups.

35.3.1 Aging and Abilities

There are several age-related changes in functional abilities that have relevance to the design of technology systems. These include changes in sensory/perceptual processes, motor abilities, response speed, and cognitive processes. A brief review of these age-related changes in abilities is provided as a framework for understanding the potential implications of the aging process for system design. It is, however, important to recognize that there are substantial individual differences in rate and degree of functional change. Within any age group, young or old, there is significant variability in range of abilities and rate of age-related change in abilities, and this variability tends to increase with age.

35.3.2 Sensory Processes

There are a number of changes in visual abilities that have relevance to the design of computer systems. Currently, about 14 million people in the United States suffer from some type of visual impairment, and as shown in Figure 35.6, the incidence of visual impairment increases with age. Although most older people will not experience severe visual impairments, they may experience declines in eyesight sufficient to make it more difficult to perceive and comprehend visual information. This has vast implications for the design of technology systems given that many technology interfaces are primarily based on visually presented text. Visual decrements may make it more difficult for older people to perceive small icons on toolbars, read e-mail, or locate information on complex screens or websites (e.g., Charness and Holley [2001]). Age-related changes in vision also have implications for the design of instruction manuals (Fisk et al. 2009).

Aging is also associated with declines in auditory acuity. Many older adults experience some decline in auditory function such as a loss of sensitivity for high-frequency tones; difficulty understanding speech, especially if the speech is distorted; problems localizing sounds; problems in binaural listening; and increased sensitivity to loudness (Schieber et al. 1991). These changes in audition are also relevant to design of technology systems. Older people may also find it difficult to understand synthetic speech as this type of speech is typically characterized by some degree of distortion. Multimedia systems with voice output may also be problematic for older adults. High-frequency alerting sounds associated with alarm or emergency systems may also be difficult for older adults to detect.

35.3.3 Motor Skills

Aging is also associated with changes in motor skills, including slower response times, declines in ability to maintain continuous movements, disruptions in coordination, loss of flexibility, and greater variability in movement (Fisk et al. 2009). The incidence of chronic conditions such as arthritis also increases with age (Figure 35.6). These changes in motor skills have direct relevance to the ability of older people to use current input devices such as a mouse or a keyboard. For example, various aspects of mouse control such as moving, clicking, fine-positioning, and dragging are likely to be difficult for older people (Smith et al. 1999; Riviere and Thakor 1996; Walker, Millians, and Worden 1996; Charness, Bosman, and Elliott 1995).

Findings from these studies suggest that alternative input devices might be beneficial for older people (Charness and Holley 2001; Fisk et al. 2009). Murata and Iwase (2005) compared target pointing times among younger, middle-aged, and older adults using a mouse and a touch panel. They found that pointing time was longer for the older age group when using a mouse but that there were no significant age-related differences in pointing time with the touch panel. On the basis of these results, they recommend that for pointing tasks, a touch-panel interface should be used for middle-aged and older adults and provide design guidelines for touch-panel interfaces. General guidelines for the design of input devices for older adults are available (Fisk et al. 2009).

35.3.4 Cognitive Abilities

Age-related changes in cognition have important implications for the performance of technology-based tasks. It is well established that many cognitive abilities include attentional processes, working memory, discourse comprehension, problem solving and reasoning, inference formation and interpretation, and encoding and retrieval in memory decline with age. (Park 1992; Fisk et al. 2009). Aging is also associated with declines in information processing speed. Older people tend to take longer to process incoming information and typically require a longer time to respond.

35.4 WILLINGNESS AND ABILITY OF OLDER ADULTS TO ADOPT INFORMATION TECHNOLOGIES

One issue that warrants discussion when considering age and information technology is the degree to which older people are willing to interact with these types of systems and the factors that influence technology adoption. A commonly held belief is that older people are resistant to change and unwilling to interact with "high tech" products. However, the available data largely dispute this stereotype. The majority of studies that have examined the attitudes of older people toward computer technology indicate that older people are receptive to using computers. However, older people do report more computer anxiety, less computer self-efficacy, and less comfort using computers than younger adults (Nair, Lee, and Czaja 2005; Czaja et al. 2006). Furthermore, computer anxiety and computer self-efficacy are important predictors of technology adoption (Ellis and Allaire 1999; Czaja et al. 2006). However, the data also indicate that attitudes toward technology and comfort using technology are influenced by experience and the nature of interactions with computer systems and system design (e.g., Jay and Willis [1992]; Charness, Schumann, and Boritz [1992]; Dyck and Smither [1994]; Czaja and Sharit [2003]; Adams, Stubbs, and Woods [2005]). Not surprisingly, the data indicate that older adults who have a positive perception of factors such as usability, ease of use, and usefulness of technology applications and a positive interaction with technology have more positive attitudes and greater technology efficacy and are more likely to use technology applications such as the Internet.

Numerous studies (e.g., Elias et al. [1987]; Gist, Rosen, and Schwoerer [1988]; Zandri and Charness [1989]; Czaja et al. [1986]; Czaja, Hammond, and Joyce [1989]; Charness, Schuman, and Boritz [1992]; Morrell et al. [1995]; Mead et al. [1997]; White et al. [2002]) have examined if the older adults can learn to use technology such as computers and the Internet. These studies encompass a variety of technology applications and also vary with respect to training strategies. The influence of other variables, such as attitude toward computers and computer anxiety, on learning has also been examined.

Overall, the results of these studies indicate that older adults are, in fact, able to use technology such as computers and the Internet for a variety of tasks. However, they are typically slower to acquire new skills than younger adults and generally require more help and "hands-on" practice. Also, compared with younger adults on performance measures, older adults often achieve lower levels of performance. However, the literature also indicates that training interventions can be successful in terms of improving performance and it points to the importance of matching training strategies with the characteristics of the learner (Charness, Czaja, and Sharit 2007). It is also important to provide older people with training on the potential use of the technical system (e.g., what the Internet can be used for) and training on basic procedural operations (e.g., use of the mouse). As one would expect, the "usability" of the system from both a hardware and software perspective is also important (Fisk et al. 2009).

Mayhorn and colleagues (Mayhorn et al. 2004; Fisk et al. 2009) provide suggestions for development of effective computer training for older adults. Generally, these guidelines stress the importance of considering the goals, abilities, and experience levels of older adults in the design and evaluation of instructional programs and materials. Also, given the important role of anxiety and self-efficacy in technology adoption (Czaja et al. 2006), it is important that training environments are relaxed and strategies that reduce anxiety and increase self-efficacy are incorporated into training programs.

Similarly, studies have examined the ability of older people to perform technology-based tasks such as computer-based tasks that are common in work settings. For example, Czaja and colleague (1993, 1998, 1998a, 1998b, 2001; Sharit et al. 2009) conducted a series of studies examining age performance differences on a variety of simulated computer-based tasks (e.g., data entry, inventory management, customer service, and telework). Overall, the results of these studies indicate that older adults are willing and able to perform these types of tasks. However, generally the younger adults performed at higher levels than the older people. Importantly, the data also indicated that there was considerable variability in performance among the older people, and that with task experience, those in their middle years (40–59 years) performed at roughly the same levels as the young adults. In fact, task experience resulted in performance improvements for people of all ages. The results also indicated that interventions such as redesigning the screen, providing on-screen aids, and reconfiguring the timing of the computer mouse improved the performance of all participants.

Other investigators have examined age as a potential factor impacting the ability to use the Internet for information search and retrieval (e.g., Sharit et al. [2008]; Czaja, Sharit, and Nair [2008]; Czaja et al. [2010]). This is an important area of investigation given that this is one of the most common reasons people use technology such as computers. For example, this type of activity is central to use of the Internet. Also, in many work settings such as department stores, airlines, hotels, utility and health insurance companies, and educational institutions, workers are required to search through computer databases and access information to respond to customer requests. Generally, the findings from these studies indicate that while older adults are capable of performing these types of tasks, there are age-related differences in performance. Furthermore, these differences appear to be related to age differences in cognitive abilities.

For example, they examined the relationship between spatial ability, spatial memory, vocabulary skills, and age and the ability to retrieve information from a computer database that varied according to how the database was structured (e.g., hierarchical vs. linear). In general, they found that the older subjects were slower in retrieving the information than the younger adults, but there were no age-related differences in accuracy. The learning rates also differed for the two groups such that the older people were slower than the younger people. They found that the slower response on the part of the older adults was dependent on general processing speed (e.g., Westerman et al. [1995]; Freudenthal [1997]; Mead et al. [1996]; Sharit et al. [2008]; Pak et al. [2008]; Czaja et al. [2010]).

Information seeking is a complex process and places demands on cognitive abilities such as working memory, spatial memory, reasoning, and problem solving. Information seeking within electronic environment also requires special skills such as knowledge related to the search system. Given that older adults typically experience declines in cognitive abilities, such as working memory, and are less likely than younger people to have knowledge of the structure and organization of search systems, a relevant question is the degree to which they will experience difficulty searching for information in electronic environments. Generally, the available literature suggests that older adults are able to search and retrieve information within "electronic environments." However, they appear to have more difficulty than do younger adults and tend to use less efficient navigation strategies. They also appear to have problems remembering where and what they searched. To maximize the ability of older people to successfully interact with electronic information systems such as the Internet and have access to the "information highway," we need to have an understanding of the source of age-related difficulties. This type of information will allow us to develop interface design and training strategies to accommodate individual differences in performance. Currently, there is very little information on problems experienced by older people when attempting to learn and navigate the Internet, especially in real-world contexts.

35.5 DESIGNING TECHNOLOGY SYSTEMS TO ACCOMMODATE OLDER ADULTS

As discussed in Section 35.1, there are age-related changes in functioning that have implications for the design of technology systems. For example, careful attention needs to be paid to the design of display screens, placement, size, shape, and labeling of controls and design and layout of instructional materials and manuals. Design features such as character size and contrast are especially important for older computer users. Generally, larger characters and high-contrast displays are beneficial for older people. This may not be a major problem with most computers used in the home or the workplace, as it is relatively easy to enlarge screen characters. However, it may be an issue for computers in public places such as information kiosks and ATM machines. In addition to character size and contrast, it is also important to minimize the presence of screen glare (Fisk et al. 2009).

The organization and amount of information on a screen is also important as there are declines in visual search skills and selective attention with age. Only necessary information should be presented on a screen and important information should be highlighted. Further principles of perceptual organization, such as grouping, should be applied. Caution must also be exercised with respect to the use of color coding as there are declines in color discrimination abilities with age. Finally, as far as possible, information should be in a consistent location and important information should stand out and be in central locations. A flaw with many existing web pages is that advertising information has more prominence than the site information, for example, pharmaceutical advertisements on health websites.

Designing and labeling of controls and input devices also need special consideration. Although there is a growing body of research examining the relative merits and disadvantages of various input devices, there are only a few studies that have examined age effects. Generally, the existing data suggest that commonly used input devices such as keyboards and the mouse may be problematic for older people. More research needs to be directed toward identifying the efficacy of alternative input devices for older people, such as speech interfaces, especially for those who have restrictions in hand function.

Given that there are age-related changes in cognitive processes, such as working memory and selective attention, it is the interface style and usability of the interface that will have a significant influence on the performance of older adults. For example, systems should place minimal demands on cognitive abilities such as working memory, selective attention, and spatial abilities. On-screen aids such as maps and history markers may also prove to be beneficial for older people. We found, for example, that a simple graphical aid that depicted the structure of the menu system helped older adults use interactive telephone menu systems (Sharit et al. 2003).

Clearly, there are a number of interface issues that need to be investigated. At the present time, there are guidelines with respect to designing interfaces to accommodate the needs of older users (Fisk et al. 2009). The National Institute on Aging and National Library of Medicine also published guidelines for web design for older adults. In addition, the World Wide Web Consortium provides guidelines for web pages and software for persons with disabilities (http://www.w3.org/TR/WAI-WEBCONTENT/). However, as discussed by Hanson and Crayne (2005), guidelines or standards do not guarantee a good experience for all users. Usability testing with representative user groups is the cornerstone of good design. There is also an abundance of research that needs to be carried out within this area to inform the design of future systems.

In addition to general guidelines for the design of training programs and interface parameters, there are other issues that need to be considered to ensure that the benefits of technology are maximized for older people. As noted, the older adult population is very heterogeneous in terms of culture/ethnicity, health, education, and experience with technology, so it is important to take into account the wide range of abilities, needs, and desires of older users to ensure that technology can adapt to their individual differences. For example, it is important to consider different designs (e.g., languages) and approaches (e.g., advertisements) for different cultural/ethnic groups. It is also important to consider how to customize or adjust interfaces and response devices to accommodate those with varying abilities. Privacy issues are also an important concern as the use of technologies become more widespread for health and financial and service applications. For example, Demiris et al. (2004) found that privacy concerns are important to older adults with respect to the acceptance of smart home technology. Recently, Beach et al. (2009) conducted a large-scale, national survey regarding attitudes about the acceptability of using quality of life technology to gather and share information about performance of everyday activities. The sample included baby boomers and older adults with and without disabilities. Overall, the findings indicated that individuals reporting disability in the form of activity limitations had consistently more positive attitudes toward sharing information than those without disabilities. However, attitudes varied somewhat according to the nature of the information being shared, such that sharing information about activities such as toileting was less acceptable. In addition, the respondents were less positive about sharing information with the government and insurance companies than family members.

The issue of trust also needs consideration. Trust and ultimately acceptance of technology may be weakened by unreliability or excessive complexity. There are also potential problems with "over-trust," which can be serious if technology fails or if the information provided by the technology has low credibility. As noted, this is a current concern with health websites. Issues of safety and maintainability must also be addressed. Finally, the cost of systems needs to be considered not only in terms of finances but also in terms of effort required on the part of the user with respect to technology access and learning and maintenance requirements.

35.6 CONCLUSIONS

There are many areas where older people are likely to interact with technology including the workplace, the home, service, and health care settings. Current data indicate that older adults are generally receptive to using technology but often have more difficulty than younger people acquiring the skills needed to use current technology systems. They generally report more anxiety about using technologies such as computers and express less confidence in their ability to learn to interact with these systems than do younger adults. This presents a challenge for the HCI community.

For many older people, especially those who are frail, isolated, or have some type of mobility restrictions, access to technologies such as the Internet hold promise of enhancing independence and quality of life by providing linkages to goods and resources, facilitating communication, and enhancing opportunities for work and lifelong learning. Technology can also enhance the delivery of health services to older adults and help them access information on health-related topics. However, before the potential of technology is realized for older adults, the needs, preferences, skills, and abilities of older people need to be understood by system designers. As discussed by Dickinson and Gregor (2006) and Slegers, van Boxtel, and Jolles (2009), there is currently little systematic evidence to support the notion that use of computers and the Internet in and of themselves have a positive effect on the well-being of older adults. Many of the studies that have examined this issue have been plagued by methodological shortcomings. As such, there is a need for more rigorous research in this area. For example, Slegers and colleagues suggest that it is important to identify older populations who would benefit from Internet-based interventions.

Although research in this area has grown, there are many unanswered questions. For example, there are still many issues regarding design of input devices and interface design such as how to best design speech recognition systems, menus, and help systems to accommodate older people. We also know little about the efficacy of design aids and support tools for older adults. In addition, we need more information on how to best train older adults to learn to use new technologies, and there are many questions regarding the design of online training programs and multimedia formats. Issues regarding privacy and trust in technology also represent critical areas of needed research. There are also many questions related to the Internet, which remain unanswered, such as how does access to Internet information impact health care behavior and how do we best train seniors to identify and integrate the enormous amount of information that is available on the Internet? We also need to examine how technology in the workplace impacts employment opportunities and the work performance of older people. The issue of telecommuting has received little attention. In addition, we need more information on factors influencing technology adoption, especially for minority elderly or those of lower education or economic status. There are also many questions related to quality of life and socialization that need to be addressed.

Many needs of older people would be amenable to technological solutions. However, what is lacking is a systematic effort to understand these needs and incorporate them into design solutions and the marketplace (National Research Council 2004). In essence, in order to design information systems so that they are useful and usable for older people, it is important to understand the following: (1) why technology is difficult to use, when it is; (2) how to design technology for easier and effective use; and (3) how to effectively teach people to use and take advantage of technologies that are available. Answers to these questions will not only serve to benefit older adults but all potential users of technology systems.

36 Human–Computer Interaction for Kids

Amy Bruckman, Alisa Bandlow, Jill Dimond, and Andrea Forte

CONTENTS

36.1 DESIGNING FOR AND WITH CHILDREN

How is designing computer software and hardware for kids different from designing for adults? Many researchers have addressed questions about the impact of technology on children; less has been said about the impact children can have on the design of technology. Methods for designing with and for children are only recently becoming widespread features of the design literature (see Jensen and Skov [2005]).

In designing for children, people tend to assume that kids are creative, intelligent, and capable of great things if they are given good tools and support. If children cannot or do not care to use technologies we have designed, it is our failure as designers. These assumptions are constructive, because users generally rise to designers' expectations. In fact, the same assumptions are useful in designing for adults. Designers of software for children start out at an advantage, because they tend to believe in their users. However, they may also be at a disadvantage, because they no longer remember the physical and cognitive differences of being a child.

In this chapter, we will

- Describe how children's abilities change with age, as it relates to human–computer interaction (HCI);
- Discuss how children differ from adults cognitively and physically, for those characteristics most relevant for HCI
- Discuss children as participants in the design process
- Review recommendations for usability testing with kids
- Review genres of computer technology for kids and design recommendations for each genre

36.2 HOW ARE CHILDREN DIFFERENT?

As people develop from infants to adults, their physical and cognitive abilities increase over time (Kail 1991; Miller and Vernon 1997; Thomas 1980). The Swiss psychologist Jean Piaget was a leading figure in analyzing how children's cognition evolves (Piaget 1970, pp. 29–33). Piaget showed that children do not just lack knowledge and experience, but also fundamentally experience and understand the world differently than adults. He divided children's development into a series of stages, as follows:

- Sensori-motor (birth—2 years)
- Pre-operational (ages 2–7)
- Concrete operational (ages 7–11)
- Formal operational (ages 11 and up)

Contemporary research recognizes that all children develop differently, and individuals may differ substantially from this typical picture (Schneider 1996). However, this general characterization remains useful.

In the sensorimotor stage, children's cognition is heavily dependent on what their senses immediately perceive. Software for children this young is difficult to design. Little interaction can be expected from the child. Obviously, all instruction must be given in audio, video, or animation, since babies cannot read. Furthermore, babies generally cannot be expected to use standard input devices like a mouse effectively, even with large targets.

In order to address this issue, AlphaBaby, is open-source software that allows infants and toddlers to play with the computer without inflicting harm to software. Every time a key or mouse is clicked, letters and shapes appear while sounds play (AlphaBaby 2009). Another example, "Reader Rabbit Toddler" by The Learning Company is targeted at children ages one to three. To eliminate the need for mouse clicking, the cursor is transformed into a big yellow star with room for five small stars inside it. As the mouse is held over a target, the small stars appear one at a time. When the fifth star appears, this counts as clicking on that target. If the child does click, the process simply moves faster. The only downside is the occasional unintended click on the "go back to the main menu" icon.

In most activities in Reader Rabbit Toddler, nearly random mouse movement will successfully complete the activity. For example, in the "bubble castle" activity, the child needs to rescue animals trapped in soap bubbles that are bouncing around the screen. Random mouse movements will catch the animals relatively quickly. Yet the parent or teacher watching a child's use of the software over time will typically begin to detect patterns in that mouse movement that become more and more obviously intentional—the mouse moves more and more directly toward the bubbles with animals in them. This is a particularly well-thought-out interface, because it mimics how young children learn language. A baby's first attempts at sounds are greeted with great enthusiasm—the child says an unrecognizable phoneme and the parents smile and say "You said Dada! This is Dada!" Over time, the utterance begins to really sound like the child said "Dada." An initial positive reinforcement for even the most remote attempt at the target behavior puts the child on a good learning trajectory to acquiring that behavior (Holdaway 1979).

Many examples of software and other cultural artifacts for young children are designed in accordance with adult expectations of what a child should like. There are a few noteworthy exceptions—for example, the television show Teletubbies is out of harmony with those stereotypes. Many adults find the television show bizarre and grating, but it is wildly popular with toddlers. The designers of the original BBC television series, Anne Wood and Andy Davenport, used detailed observations of young children's play and speech in their design. Wood comments, "Our ideas always come from children. If you make something for children, the first question you must ask yourself is, 'What does the world look like to children?' Their perception of the world is very different to that of grown-ups. We spend a lot of time watching very around them; what they say" (Davenport and Wood 1997). Focus groups also played an important role (BBC 1997). Young children are so radically different from adults that innovative design requires careful fieldwork.

While toddlers' interaction with software on a standard desktop computer affords limited possibilities, specialized hardware can expand the richness and complexity of interactions. For example, "Music Blocks" by Neurosmith is recommended for ages 2 and above (Figure 36.1). Five blocks fit in slots in the top of a device rather like a "boom box" portable music player. Each block represents a phrase of music. Each side of the block is a different instrumentation of that musical phrase. Rearranging the blocks changes the music (http://www.neurosmith.com). Interaction of this complexity would be impossible for 2-year olds using a screen-based interface but is quite easy with specialized hardware. Research on alternative computer interfaces such as tangible technologies (Ishii and Ullmer 1997; Dourish 2001) holds great promise for novel children's interface designs (Price et al. 2003; Rogers et al. 2004).

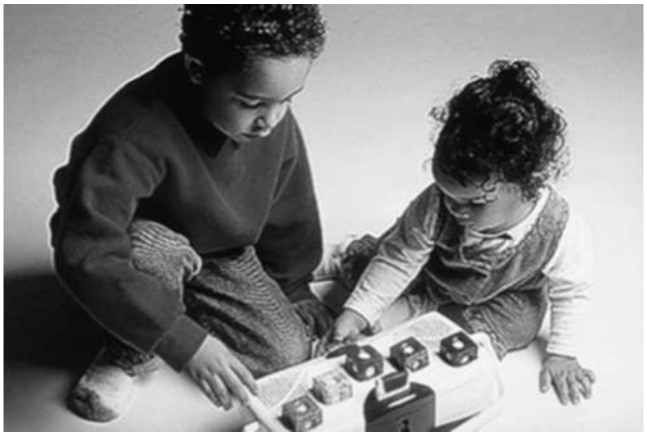

FIGURE 36.1 Children playing with Music Blocks.

In the preoperational stage (ages 2–7), children's attention span is brief. They can only hold one thing in memory at a time. They have difficulty with abstractions. They cannot understand situations from another person's point of view, which may present difficulties in partnering with other children to design technologies. While some children may begin to read at a young age, designs for this age group generally assume the children are still preliterate. It is reasonable to expect children at this age can click on specific mouse targets, but they must be relatively large. Use of the keyboard is still generally avoided by most designers (except "hit any key" approaches).

In the concrete operational stage (ages 7–11), "we see children maturing on the brink of adult cognitive abilities. Though they cannot formulate hypothesis, and though abstract concepts such as ranges of numbers are often still difficult, they are able to group like items and categorize" (Schneider 1996). Concrete operational children are old enough to use relatively sophisticated software, but young enough to still appreciate a playful approach. It is reasonable to expect simple keyboard use. Children's ability to learn to type grows throughout this age group. It is reasonable to expect relatively fine control of the mouse.

Finally, by the time a child reaches the formal operational stage (ages 12 and above), designers can assume the child's thinking is generally similar to that of adults. Their interests and tastes, of course, remain different. Designing for this age group is much less challenging, because adult designers can at least partially rely on their own intuitions.

Using age as a guide can be useful; however, designers should be aware that designing "too young" can be just as problematic as designing "too old." Children are acutely aware of their own abilities; being asked to interact with technology designed for younger children can be perceived as an affront or boring (Halgren, Fernandes, and Thomas 1995; Gilutz and Nielsen 2002). In addition to considering the implications of cognitive development on children's ability to use technologies, it is important to remember that different age groups differ culturally too. Understanding what is fun or interesting for a particular age group involves understanding both developmental ability and children's culturally dependent esthetic sensibilities. Oosterholt, Kusano, and Vries (1996) suggest that designers should avoid trying to be fashionable—what is "cool" changes quickly—and should target a limited age range because children's abilities and sensibilities change quickly as well.

In Sections 36.2.1 to 36.2.5, we will focus on several characteristics of children that are relevant for HCI research, such as the following:

- Dexterity
- Speech
- Reading
- Background knowledge
- Interaction style

36.2.1 Dexterity

Young children's fine motor control is not equal to that of adults (Thomas 1980) and they are physically smaller. Devices designed for adults may be difficult for children to use. Joiner et al. (1998) note that "the limited amount of research on children has mainly assessed the performance of children at different ages and with different input devices."

Numerous studies confirm that children's performance with mice and other input devices increases with age (Joiner et al. 1998; Hourcade 2002). Compared to adults, children have difficulty holding down the mouse button for extended periods and have difficulty performing a dragging motion (Strommen 1994). This means that many standard desktop interface features pose problems for young users. For example, kids have difficulty with marquee selection. Marquee selection is a technique for selecting several objects at once using a dynamic selection shape. In traditional marquee selection, the first click on the screen is the initial, static corner of the selection shape (typically a rectangle). Dragging the mouse controls the diagonally opposite corner of the shape, allowing you to change the dimensions of the selected area to encapsulate the necessary objects. Dragging the mouse away from the initial static corner increases the size of the selection rectangle, while dragging the mouse toward the initial static corner decreases the size of the selection rectangle. A badly placed initial corner can make it difficult and sometimes impossible to select/encapsulate all of the objects.

Berkovitz (1994) experimented with a new encirclement technique: the initial area of selection is specified with an encircling gesture and moving the mouse outside of the area enlarges it. Hourcade developed PointAssist (Hourcade, Perry, and Sharma 2008), which uses sub movements around targets to trigger a precision pointing mechanism. This software enabled 4-year olds to achieve accuracy rates similar to 18- to 22-year olds.

Kids may have trouble double-clicking, and their small hands may have trouble using a three-button mouse (Bederson et al. 1996). As with adults, point-and-click interfaces are easier to use than drag-and-drop (Inkpen 2001; Joiner et al. 1998). Inkpen (2001) notes that "Despite this knowledge, children's software is often implemented to utilize a drag-and-drop interaction style. Bringing solid research and strong results […] to the forefront may help make designers of children's software think more about the implications of their design choices."

Strommen (1998) notes that since young children cannot reliably tell their left from their right, interfaces for kids should not rely on that distinction. In his Actimates interactive plush toy designs, the toys' left and right legs, hands, and eyes always perform identical functions. More recent interactive soft toys like "Learning Baby Tad" by Leapfrog (http://www.leapfrog.com) relies on clear visual markings on left and right paws to indicate their distinct functions.

Surprisingly, there is little work that evaluates direct pointing technologies such as styluses and touch screens with children. One exception looks at designing mobile phone applications for children. Mobile phone interaction presents some challenges—moving from large screens and mouse-based interactions to small screens and touch-based interactions. Revelle and Reardon evaluate kid's interactions on a touch mobile phone application (Revelle and Reardon 2009). They recommend making the touch screen hot spots bigger and tilting features should be at a higher threshold as kids unintentionally tilt the phones more than adults.

Tangible devices also hold some promise in comparison to pointing devices for direct manipulation tasks. Antle et al. evaluated a mouse-based versus tangible-based input for a jigsaw puzzle with 132 children. They found that children were faster and more successful with the tangible-based approach (Antle, Droumeva, and Ha 2009).

36.2.2 Speech

Speech recognition has intriguing potential for a wide-variety of applications for children. O'Hare and McTear (1999) studied use of a dictation program by 12-year olds and found that they could generate text more quickly and accurately than by typing. They note that dictation automatically avoids some of the errors children would otherwise make, because the recognizer generates correct spelling and capitalization. This is desirable in applications where generating correct text is the goal. If instead the goal is to teach children to write correctly (and, for example, to capitalize their sentences), then dictation software may be counter-productive.

While O'Hare and McTear (1999) were able to use a standard dictation program with 12-year olds, Nix, Fairweather, and Adams (1998) note that speech recognition developed for adults will not work with very young children. In their research on a reading tutor for children 5 to 7 years old, they first tried a speech recognizer designed for adults. The recognition rate was only 75%, resulting in a frustrating experience for their subjects. Creating a new acoustic model from the speech of children in the target age range, they were able to achieve an error rate of less than 5%. Further gains were possible by explicitly accounting for common mispronunciations and children's tendency to respond to questions with multiple words where adults would typically provide a one-word answer. Even with the improved acoustic model, the recognizer still made mistakes. To avoid frustrating the children with incorrect feedback, they chose to have the system never tell the child they were wrong. When the system detects what it believes to be a wrong answer, it simply gives the child an easier problem to attempt.

36.2.3 Reading

The written word is a central vehicle for communicating information to humans in human–computer interfaces. Consequently, designing computer technology for children with developing reading skills presents a challenge. Words must be chosen that are at an appropriate reading level for the target population. Larger font sizes are generally preferred. Bernard et al. (2001) found that kids 9 to 11 years old prefer 14-point fonts over 12-point. Surprisingly, very little empirical work has been done in this area. Most designers follow the rule of thumb that the younger the child, the larger the font should be.

Designing for pre-literate children presents a special challenge. Audio, graphics, and animation must substitute for all functions that would otherwise be communicated in writing. The higher production values required can add significantly to development time and cost.

36.2.4 Background Knowledge

Many user interfaces are based on metaphors (Erickson 1990) from the adult world. Jones (1992) notes that children are less likely to be familiar with office concepts like file folders and in-out boxes. In designing an animation system for kids, Halgren, Fernandes, and Thomas (1995) found many kids to be unfamiliar with the metaphor of a frame-based film strip. It is helpful to choose metaphors that are familiar to kids, though kids often have success in learning interfaces based on unfamiliar metaphors if they are clear and consistent (Schneider 1996).

36.2.5 Interaction Style

Children's patterns of attention and interaction are quite different from those of adults. Traditional task-oriented analyses of activity may fail to capture the playful, spontaneous nature of children's interactions with technology. For example, when adults are the intended users, designers take great pains to create error messages that are informative and understandable based on the assumption that users want to *avoid* generating the message again. Hanna, Risden, and Alexander (1997) used a funny noise as an error message and found that the children repeatedly generated the error to hear the noise.

Halgren and colleagues (1995) found that children would click on any readily visible feature just to see what would happen, and they might click on it repeatedly if it generated sound or motion in feedback. This behavior was causing young users to get trapped in advanced modes they did not understand. The designers chose to hide advanced functionality in drawers—a metaphor that is familiar to children. "By hiding the advanced tools, the novice users would not stumble onto them and get lost in their functionality. Rather, only the advanced users who might want the advanced tools would go looking for more options. This redesign allows the product to be engaging and usable by a wider range of ages and abilities" (Halgren, Fernandes, and Thomas 1995). Resnick and Silverman go even further in their design principle: "make it as simple as possible—and maybe even simpler" (Resnick and Silverman 2005). They warn against "functionality creep" and suggest removing advanced functionality altogether if it is not clearly required to support children's creative efforts.

Children are more likely than adults to work with more than one person at a single computer. They enjoy doing so to play games (Inkpen 1997) and may be forced to do so because of limited resources in school (Stewart et al. 1998). Teachers may also create a shared-computer setup to promote collaborative learning. When multiple children work at one machine simultaneously, they need to negotiate sharing control of input devices. Giving students multiple input devices increases their productivity and their satisfaction (Inkpen 1997; Inkpen et al. 1995; Stewart et al. 1998). For use in developing countries where resources may be scarcer, Amershi et al. developed a text entry mechanism for multiple mice (Amershi et al. 2010).

Children also bring unique interaction styles to online environments; they respond to information they encounter while browsing the web in markedly different ways than adults. In a study of 55 first through fifth graders, the Nielsen Norman Group found that kids were often unable to distinguish between site content and advertisements. Moreover, they rarely scrolled down to find content; instead they chose to interact with site elements that were immediately visible. When examining a new site, children were willing to hunt for links in the content by "scrubbing the screen" with the mouse instead of relying solely on visual cues (Gilutz and Nielsen 2002). Using search on the web presents some unique challenges for children. Druin et al. found that children did not look at the screen while typing their search query, missing out on auto complete features that could help correct spelling or lead them to search results (Druin et al. 2009). Children also had difficulty constructing queries that required more than one search step.

36.3 CHILDREN WITH SPECIAL NEEDS

Recent research developments have begun to develop technology interactions for children with special needs. Disabled people represent 10% of the worlds' population (United Nations 2006) and in the United States, 14% of all children enrolled in public secondary education have special needs (National Center for Education Statistics 2011). The work in this area is mainly composed of technologies that foster children's development and education, and certainly there is a need for such focus. Some children with special needs are more likely to be behind in cognitive development than other children due to a lack of appropriate learning resources (Mayberry 2007). For example, more than 90% of deaf children are born to parents of hearing who do not know how to sign; yet language acquisition is crucial for early cognitive development (Moeller 2000). The philosophy that governs most designers in this area is one that focuses on designing for children's abilities rather than one that designs around their disabilities. There has also been a push to consider the abilities of children with special needs and examine how they can be included in the design process (Guha, Druin, and Fails 2008). In this section, we will discuss different technologies that have been developed for children with special needs, specifically for visual impairments, hearing and speech impairments, autistic children, motor and learning impairments, as well as the methods that have been employed for each.

36.3.1 Visually Impaired Children

Sánchez and Sáenz, who represent the majority of work in educational technologies for visually impaired and blind children, developed audio-based learning environments that focus on mathematics and memory (Sánchez and Sáenz 2005). Sánchez and Sáenz also built a mobile haptic and sound device for learning orientation and mobility skills (Sánchez, Sáenz, and Ripoll 2009). Looking to design for abilities, McElligott and van Leeuwan partnered with blind children and designed toys with both tactile and audio interactions, taking advantage of multiple stimuli (McElligott and van Leeuwen 2004). Similarly, Patomaki et al. used haptic feedback from an off-the-shelf game pad to develop a game for visually impaired children to assist in memory tasks (Patomäki et al. 2004). Catering toward more informal learning environments, Bruce and Walker assigned music and sounds to the dynamic position of fish in the Georgia Aquarium, allowing visually impaired visitors to be able to experience the aquarium in a different way (Walker et al. 2006).

36.3.2 Speech and Hearing Impairments

For children with speech impairments some technologies have assisted in speech development. Fell et al. built a system visiBabble which visualizes infant vocalizations in real time (Fell et al. 2004). The system reinforces the production of syllabic noises which has been associated with later language and cognitive development. Similarly, for children, Balter developed a speech training technology designed for children in speech therapy which helped detect the inaccuracies in mispronunciation. (Bälter et al. 2005).

For deaf children, some technologies have focused on learning sign language. Brashear and Henderson designed a game, CopyCat, which teaches deaf children to learn American Sign Language (Brashear et al. 2006; Henderson et al. 2005). The game uses gesture recognition technology to help young deaf children practice sign language skills. Focusing on comprehension of verbal language, Gennari and Mich developed an intelligent web system to teach temporal reasoning, a skill that is difficult for deaf children (Gennari and Mich 2008). Other novel interaction techniques that push the boundaries of technical innovation have been developed for deaf children. Iversen et al. developed a program called Stepstone, which uses body motion and group collaboration in order for children with cochlear implants to close the gap between linguistics and body movement (Iversen et al. 2007).

In designing for both speech and hearing impairments, the Wizard of Oz technique has been proven to be effective to evaluate these technologies. In this technique, children think that they are interacting with a computer, but instead of a computer, an adult interprets and provides feedback to the computer. This technique is helpful for gesture or voice recognition which may have a high error rate in early stages of development which may be frustrating for children who are testing the system. Both Balter and Brashear used this technique in the design of their systems (Bälter et al. 2005; Brashear et al. 2006).

36.3.3 Autistic Children

Autism is a neurodevelopment disorder that exhibits itself in abnormal social interaction, communication ability, and patterns of interests and behaviors. When presented with many choices, children with autism have difficulty in deciding which event is important and easily become overwhelmed. However, computers can also provide reliable and consistent rule enforcement which is useful for children who are uncomfortable with unpredictable environments.

There is a burgeoning area of work around using technology to help autistic children learn social skills. Piper et al. developed a cooperative game that runs on tabletop technology, which was found to be an effective tool for group work with teenagers on the autistic spectrum (Piper et al. 2006). De Leo and Leroy developed a mobile application to help autistic kids manage social interactions in situ (Leo and Leroy 2008). Merryman et al. use virtual peers for autistic children to learn social skills (Merryman et al. 2008). Putnam and Chong surveyed autistic children and parents and found that designing for the strengths of autistic children would be worthwhile; this includes abilities in math and reading (for children in the 7–10 age range), good memory, and a desire to be social (Putnam and Chong 2008).

36.3.4 Learning Impairments

In order to detect motor and learning disabilities early on, Westeyn developed different toys with multiple sensors to evaluate five levels of object play (Westeyn et al. 2008). These toys can help parents identify different motor and learning milestones by automatically collecting information about different kinds of play. To evaluate websites for children with learning disabilities, Andersen and Rowland added to a suite of existing accessibility tools to determine the cognitive load of a website (Andersen and Rowland 2007). Websites that have high reading levels, inconsistent navigation, pop-ups, are especially difficult for children with learning disabilities to navigate and understand. This tool helps developers to identify whether their design may cause problems for children with learning disabilities.

Specifically, for children with Down syndrome, Feng et al. surveyed 600 children with Down syndrome to explore technology use and potential design considerations for this population (Feng et al. 2010). They found that the children not only had cognitive difficulties such as reading and navigating, but also physical difficulties with controlling input devices, and security and privacy issues such as downloading viruses and releasing information. These results indicate that further work is needed in designing physical devices, information presentation, and addressing security and privacy issues for this population of users.

There is little work that addresses these needs for children with Down syndrome. One exception is Ortega-Tudela and Gomez-Ariza who built a system to teach basic mathematics using multimedia. In evaluating the system, they found that these tools aided learning better than paper and pencil (Ortega-Tudela and Gomez-Ariza 2006).

36.3.5 Motor Impairments

For children with motor impairments, technology offers opportunities to interact with their environment differently. EyeDraw, an eye-tracking application, enables children with severe motor impairments to create drawings using their eyes (Hornof and Cavender 2005). Similarly, VoiceDraw uses variations in vocal tones to generate free-form drawings (Harada, Wobbrock, and Landay 2007). Hornof describes a project in which he works with children that have severe motor impairments as design partners to learn how they wish to communicate (Hornof 2008). To address different input needs, Harada et al. developed a vocal joystick which allows users to control the mouse cursor using a variety of vocal parameters (Harada et al. 2006).

36.3.6 Hospitalized Children

In the sterile environment of hospitals, children are often isolated from their family and have few contacts with people outside of the hospital. At the same time, they undergo stressful and severe treatments. Technologies can provide opportunities to socialize and offer support. Tarrin et al. partnered with hospitalized children to create haptic games to be played with other people (Tarrin, Petit, and Chêne 2006). Others have created robotic companions for hospitalized children to mitigate fear and loneliness (Stiehl et al. 2009). Virtual environments also offer children opportunities to socialize within hospital settings. Bers describes an online environment where children undergoing dialysis are able to explore their identity and socialize online (Bers, Gonzalez-Heydrich, and DeMaso 2001).

Considering the abilities of special needs children not only improves accessibility to more children, but also helps push technological interaction innovation and methods.

36.4 CHILDREN AND THE DESIGN PROCESS

Users play a variety of roles in HCI design processes. Visionary designers such as Alan Kay and Seymour Papert began considering the abilities and sensibilities of children in the design of new technologies as early as the 1970s (Kay 1972; Papert 1972). Today, ethnographic and participatory (Schuler and Namioka 1993) methods are becoming increasingly common features of the human-centered design toolkit as HCI designers attempt to deeply understand the practices and preferences of people who will be using new technologies. When designers enter the world of children, and, conversely, when children enter the laboratory, many of the traditional rules change. As we have seen, children are not just “little adults”; they engage with the world in fundamentally different ways. Naturally, they bring a host of social, emotional, and cognitive elements to the design process that are unfamiliar to designers who are accustomed to working with adults. In this section, we examine new and traditional methods for working with children in a human-centered design process.

36.4.1 Use of Video with Children

Like adults, children may change their behavior when a video camera is present. Druin (1999) and her design team found in their early work that children tended to "freeze" or "perform" when they saw a video camera in the room (1999). In subsequent work, Druin's team observed that the problems associated with videotaping had more to do with power relationships than with the video cameras themselves. When the children are in control of the cameras, their discomfort decreases (Alborzi et al. 2000). In addition to considering the social impact of using a camera with children, there are also technical difficulties to deal with. Her research team found that, even with smaller cameras, it was difficult to capture data in small bedrooms and large public spaces. The sound and speech captured in public spaces was difficult to understand or even inaudible. Finally, it was difficult to know where to place cameras because they did not know where children would sit, stand or move in the environment. Druin recommends using multiple data sources to capture "messy" design environments with children, including notetakers and participant observers in addition to videotaping. She also encourages her design team to use video cameras (along with journal writing, team discussion, and adult debriefing) as a way to record their brainstorming sessions and other design activities.

Goldman-Segall (1996) explains why video data are an important part of ethnographic interviews and observations. When using video, the researcher does not have to worry about remembering or writing down every detail: "She can concentrate fully on the person and on the subtleties of the conversation." The researcher also has access to "a plethora of visual stimuli which can never be 'translated' into words in text," such as body language, gestures, and facial expressions. It is especially important to be able to review the body language of children as they interact with software. Hanna, Risden, and Alexander (1997) state that children's "behavioral signs are much more reliable than children's responses to questions about whether or not they like something, particularly for younger children. Children are eager to please adults, and may tell you they like your program just to make you happy." MacFarlane, Sim, and Horton (2005) suggest that both signs (behaviors) and symptoms (children's direct responses) should be used together to understand children's enjoyment of and ability to use new technologies. Video is extremely useful in being able to study behavioral signs as the researchers may miss some important signs and gestures during the actual observation or interview.

Instead of using video in its traditional capacity for ethnographic-style observation, some researchers have attempted to capitalize on children's playful treatment of video cameras to elicit articulation about new technologies. In studies using video probes to capture domestic communication patterns, Hutchinson et al. (2003) observe that images are particularly attractive to young people as an entertaining medium for interacting and communicating. During classroom observations of children using math-learning software, Lamberty and Kolodner (2005) encouraged children to engage in "camera talk" with stationary cameras if they wished. Many of the children regularly talked to the camera. This spontaneous behavior revealed both their preferences for using the software and their developing understanding of fractions. Likewise, Iversen (2002) suggests that, by provoking children to verbalize, video cameras provide a communication link between designers and young informants, thereby enriching both the data collected and the design experience.

36.4.2 Methods for Designing and Testing with Kids

In this section, we review a variety of methods for designing with and for children. These methods differ dramatically in the amount of power they grant to children. Some methods encourage us to view children as codesigners with an equal voice in determining design direction, whereas others place children in a more reactive role as evaluators or subjects in laboratory-based usability tests. In practice, designers use methods from different points on this power spectrum depending on the maturity of the project, and often move back and forth between testing with kids and open-ended exploration (Scaife et al. 1997).

Druin unpacks this spectrum of control by describing four different roles that children can play in the design of new technologies: user, tester, informant, and design partner (Druin 2002). The most reactive role she describes for children in design is *user.* As *users*, children interact with existing technologies and have no direct impact on the design of the technology, except in the form of recommendations for future designs. As *testers*, children are asked to provide feedback about technology in development so that it can be refined before it is released; however, the goals of the technology itself are determined much earlier by adult designers. As *informants*, children play an earlier, more active role in determining the goals and features of new technologies. When children play the role of *informant*, they interact directly with designers, but ultimately, the designer decides what the children need or want based on observations, interviews or other data collection methods. Finally, Druin explains that as *design partners*, children are seen as equal stakeholders in the design process. Although they may not be able to contribute to the development of the technology in equivalent ways, their expertise is viewed as equal in importance to that of other contributors to the design process.

The notion of children as design partners will be explored more fully in Section 36.4.2.1. Methods for including children as informants and design partners borrow from the tradition of participatory design that emerged in the Scandinavian workplace. Participatory design is an "approach toward computer systems design in which the people destined to *use* the system play a critical role in *designing* it" (Schuler and Namioka 1993). With children, this idea is even more important: since they are physically and cognitively different from adults, their participation in the design process may offer significant insights. Schuler writes:

> [Participatory Design] assumes that the workers themselves are in the best position to determine how to improve their work and their work life... It views the users' perceptions of technology as being at least as important to success as fact, and their feelings about technology as at least as important as what they can do with it. (Schuler and Namioka 1993, p. xi)

Empowering children in this way and including them in the design process can be difficult due to the traditionally unequal power relationships between kids and adults.

On the other end of the spectrum, methods for including children as users and testers often borrows from the traditional practices of experimental psychology. Usability testing generally takes place in a controlled setting. Sometimes a single design is tested with the goal of improving it; at other times, different design ideas might be compared to establish which ones generate more positive feedback or better enable task completion. Data collection methods like verbal protocol analysis (Ericsson and Simon 1993) are commonly used and will be further discussed in the Section 36.4.2.2.

36.4.2.1 Cooperative Inquiry

Druin (1999) has developed a systematic approach to developing new technologies for children with children; she has created new research methods that include children in various stages of the design process. This approach, called *cooperative inquiry*, is a combination of participatory design, contextual inquiry, and technology immersion. Children and adults work together on a team as research and design partners. She reiterates the idea that "Each team member has experiences and skills that are unique and important, no matter what the age or discipline" (Alborzi et al. 2000).

In this model, the research team frequently observes children interacting with software, prototypes, or other devices to gain insight into how child users will interact with and use these tools. When doing these observations, adult and child researchers both observe, take notes, and interact with the child users. During these observations, there are always at least two notetakers and one interactor, and these roles can be filled by either an adult or child team member. The interactor is the researcher who initiates discussion with the child user and asks questions concerning the activity. If there is no interactor or if the interactor takes notes, the child being observed may feel uncomfortable, like being "on stage" (Druin 1999). Other researchers have also found that the role of interactor can be useful for members of the design team. Scaife and Rogers (1999) successfully involved children as informants in the development of ECOi, a program that teaches children about ecology. They wanted the kids to help them codesign some animations in ECOi. Rather than just having the software designer observe the children as they played with and made comments about the ECOi prototypes, the software designer took on the role of interactor to elicit suggestions directly. Through these on-the-fly, high-tech prototyping sessions, they learned that "it was possible to get the software designer to work more closely with the kids and to take on board some of their more imaginative and kid-appealing ideas" (Scaife and Rogers 1999).

When working as design partners, children are included from the beginning. The adults do not develop all the initial ideas and then later see how the children react to them. The children participate from the start in brainstorming and developing the initial ideas. The adult team members need to learn to be flexible and learn to break away from carefully following their session plans, which is too much like school. Children can perform well in this more improvisational design setting, but the extent to which the child can participate as a design partner depends on his/her age. Children younger than 7 years may have difficulty in expressing themselves verbally and being self-reflective. These younger children also have difficulty in working with adults to develop new design ideas. Children older than 10 are typically beginning to become preoccupied with pre-conceived ideas of the way "things are supposed to be." In general, it has been found that children of age 7–10 years are the most effective prototyping partners. They are "verbal and self-reflective enough to discuss what they are thinking," and understand the abstract idea that their low-tech prototypes and designs are going to be turned into technology in the future. They also do not get bogged down with the notion that their designs must be similar to preexisting designs and products.

Through her work with children as design partners, Druin (1999) and Druin et al. (2001) has discovered that there are stumbling blocks on the way to integrating children into the design process and to helping adults and children work together as equals. One set of problems deals with the ability of children to express their ideas and thoughts. When the adult and children researchers are doing observations, it is best to allow each group to develop its own style of note-taking. Adults tend to take detailed notes, and children tend to prefer to draw cartoons with short, explanatory notes. It is often difficult to create one style of note-taking that will suit both groups. Since children may have a difficult time communicating their thoughts to adults, low-tech prototyping is an easy and concrete way for them to create and discuss their ideas. Art supplies such as paper, crayons, clay, and string allow adults and children to work on an equal footing. A problem that arises in practice is that since these tools are child-like, adults may believe that only the child needs to do such prototyping. It is important to encourage adults to participate in these low-tech prototyping sessions.

The second set of problems emerges from the traditionally unequal power relationships between adults and children. In what sense can children be treated as peers? When adults and children are discussing ideas, making decisions, or conducting research, traditional power structures may emerge. In conducting a usability study, the adult researcher might lead the child user through the experiment rather than allowing the child to explore freely on his/her own. In a team discussion, the children may act as if they are in a school setting by raising their hands to speak. Adults may even inadvertently take control of discussions. Is it sensible to set up design teams where children are given equal responsibilities to those of adult designers? Getting adults and children to work together as a team of equals is often the most difficult part of the design process. It is to be expected that it may take a while for a group to become comfortable and efficient when working together. It can take up to 6 months for an "intergenerational design team to truly develop the ability to build upon each other's ideas" (Druin et al. 2001). To help diffuse such traditional adult-child relationships, adults are encouraged to dress casually, and there always should be more than one adult and more than one child on a team. A single child may feel outnumbered by the adults, and a single adult might create the feeling of a school environment where the adult takes on the role of teacher. Alborzi et al. (2000) starts each design session with 15 minutes of snack time, where adults and children can informally discuss anything. This helps both adults and children to get to know each other better as "people with lives outside of the lab" (Alborzi et al. 2000) and to improve communication within the group.

Scaife et al. (1997) identified aspects of working with children in the role of informant that require special attention. They found that, when working in pairs, children feel less inhibited about telling strange adults what they were thinking. Other researchers have also found that pairing children, especially with friends, can help ease discomfort (Dindler et al. 2005; Als, Jensen, and Skov 2005). Scaife et al. (1997) caution that adults, too, need to become comfortable in the role of facilitator and should take care not to intervene too quickly if children's discussions wander.

In addition to the social challenges associated with mixing adults and children as equal design partners, kids do not always know how to collaborate well with one another in the first place. Because collaborating on a design project is often a novel experience for children, organizing the activities (without imposing too rigid a structure) can help create productive sessions. For example, Guha et al. (2005) describe a technique to support collaboration among kids and adults during cooperative inquiry sessions called "mixing ideas." First, kids generate ideas in a one-on-one session with an adult facilitator, then work in small groups to integrate these ideas, then in larger groups until the whole group is finally working together.

Although there have been many successes in having children participate as design and research partners in the development of software, there are still many questions to be answered about the effectiveness of this approach. Scaife and Rogers (1999) attempt to address many of the questions and problems faced when working with children in their work on informant design. The first question deals with the multitude of ideas and suggestions produced by children. Children say outrageous things. How do you decide which ideas are worthwhile? When do you stop listening? The problem of selection is difficult since in the end it is the adult who will decide which ideas to use and which ideas to ignore. Scaife and Rogers suggest creating a set of criteria to "determine what to accept and what not to accept with respect to the goals of the system… You need to ask what the trade-offs will be if an idea or set of ideas are implemented in terms of critical 'kid' learning factors: that is, how do fun and motivation interact with better understanding?" (Scaife and Rogers 1999)

In addition to deciding which of the children's ideas to use, there is also the problem of understanding the meaning behind what the child is trying to say. Adults tend to assume that they can understand what kids are getting at, but kid talk is not adult talk. It is important to remember that children have "a different conceptual framework and terminology than adults" (Scaife and Rogers 1999).

Another problem with involving children, particularly with the design of educational software, is that "children can't discuss learning goals that they have not yet reached themselves" (Scaife and Rogers 1999). Can children make effective contributions about the content and the way they should be taught, something which adults have always been responsible for? Adults have assumptions about what is an effective way to teach children. Kids tend to focus on the fun aspects of the software rather than the educational agenda. There may exist a mismatch of expectations if kids are using components of the software in unanticipated ways. Involving children in the design and evaluation process may help detect where these mismatches occur in the software.

36.4.2.2 Adapting Usability Evaluation Methods

HCI practices have evolved to address usefulness, enjoyability, and other measures of design success; however, usability remains a fundamental concern for HCI designers. Although efficiency and task completion are often not central to kids' goals in using technology, usability problems can create barriers to achieving other goals. For example, much research done to date has focused on designing educational software, and evaluation is primarily of learning outcomes, not usability. However, usability is a prerequisite for learning. In student projects in Georgia Tech's graduate class "Educational Technology: Design and Evaluation," many student designers never are able to show whether the educational design of their software is successful. What they find instead is that usability problems intervene, and they are unable to even begin to explore pedagogical efficacy. If children cannot use educational technology effectively, they certainly will not learn through the process of using it. MacFarlane, Sim, and Horton (2005) found that measurements of usability and "fun" were significantly correlated in studies of educational software for science. Usability is similarly important for entertainment, communications, and other applications. Many researchers have explored the effectiveness of traditional usability methods with children. However there is little work that adapts usability methods for tangible and mobile devices. We anticipate this area to grow with the increasing popularity of these devices. In this section, we examine comparative assessments of usability methods and review findings and recommendations.

36.4.2.2.1 Traditional Usability Testing

Several guidelines developed for work with adults become more important when applied to children. For example, when children are asked to work as testers, it is important to emphasize that it is the software that is being tested, not the participant (Rubin 1994). Children might become anxious at the thought of taking a test, and test taking may conjure up thoughts of school. The researcher can emphasize that even though the child is participating in a test, the child is the tester, not the one being tested (Hanna, Risden, and Alexander 1997). Rubin recommends that you show the participant where video cameras are located, let them know what is behind the one-way mirror, and whether people will be watching. With children, showing them behind the one-way mirrors and around the lab gives them "a better sense of control and trust in you" (Hanna, Risden, and Alexander 1997).

Markopoulos and Bekker (2002) describe the following characteristics of kids that can impact the process and outcome of usability testing:

- Children's capacity to verbalize thoughts is still developing.
- Personality may impact both kid's willingness to speak up to adults and their motivation to please authority figures.
- The capacity to concentrate is variable among kids.
- Young children are still developing the capacity for abstract and logical thinking; they may differ in cognitive ability such as remembering several items at once.
- The ability to monitor goal-directed performance develops throughout childhood and adolescence.
- Gender differences may be more pronounced at some ages than others.
- With small children, basic motor skills ability may be a barrier to effective evaluation if kids cannot use prototypes with standard input devices.

Hanna, Risden, and Alexander (1997) developed the following set of guidelines for laboratory-based usability testing with children:

- The lab should be made a little more child-friendly by adding some colorful posters, but avoid going overboard as too many extra decorations may become distracting to the child.
- Try to arrange furniture so that children are not directly facing the video camera and one-way mirror, as the children may choose to interact with the camera and mirror rather than doing the task at hand.
- Children should be scheduled for an hour of lab time. Preschoolers will generally only be able to work for 30 minutes but will need extra time to play and explore. Older children will become tired after an hour of concentrated computer use, so if the test will last longer than 45 minutes, children should be asked if they would like to take a short break at some point during the session.
- Hanna and colleagues suggest that you "explain confidentiality agreements by telling children that designs are 'top-secret'." Parents should also sign the agreements, since they will inevitably also see and hear about the designs.
- Children up to 7 or 8 years will need a tester in the room with them for reassurance and encouragement. They may become agitated from being alone or following directions from a loudspeaker. If a parent will be present in the room with the child, it is important to explain to the parent that he/she should interact with the child as little as possible during the test. Older siblings should stay in the observation area or a separate room during the test as they may eventually be unable to contain themselves and start to shout out directions.
- Hanna suggests that you should "not ask children if they want to play the game or do a task—that gives them the option to say no. Instead use phrases such as 'Now I need you to …' or 'Let's do this …' or 'It's time to …'."

36.4.2.2.2 Think/Talk Aloud

An important method for collecting usability data with adults is think-aloud protocols. Think aloud protocols in HCI research are related to verbal protocol analysis methods in psychology, in which subjects are asked to describe what they are thinking about and paying attention to while they complete some set of tasks (Ericsson and Simon 1993). In usability tests, think aloud methods are generally used in concert with direct observation (Nielsen 1993). Researchers who have used this method with children have observed that children may make very few comments during testing (Donker and Reitsma 2004). In some cases, they seem to have difficulty with concurrent verbalization—verbalizing thoughts while they complete tasks. The cognitive load associated with learning and executing task itself might interfere with kids' abilities to talk about it (Hoysniemi, Hamalainen, and Turkki 2003).

Despite potential obstacles, it has been demonstrated that verbal comments from children can play an important role in identifying usability problems. Donker and Reitsma (2004) reported that, although children produced fewer comments, those few comments provided important information about the severity of usability problems that were identified by direct observation. Other work likewise suggests that, although using think aloud with kids may result in fewer utterances than other approaches, it can be used to generate useful usability data with both older kids aged 8–14 (Donker and Markopoulos 2002; Baauw and Markopoulos 2004) and younger children aged 6–7 (van Kesteren et al. 2003).

Active intervention is closely related to think aloud protocols but involves investigators asking planned questions to encourage testers to reflect aloud on actions at specific points while completing a task. In a small comparative study with kids ages 6 and 7, van Kesteren et al. (2003) found that active intervention elicited the most comments when compared to think aloud, posttask/retrospection, codiscovery, peer tutoring, and traditional usability testing. However, the effectiveness of different usability methods depends on the context and environment. When comparing Active Intervention, Peer

Tutoring, and Cross Age Tutoring, Edwards and Benedyk found that peer tutoring was the most effective method within a classroom setting (Edwards and Benedyk 2007); because children were used to working in pairs in the classroom, peer tutoring was a more authentic experience.

36.4.2.2.3 Posttask Interviews

In posttask interviews, testers are asked to describe their experiences after they have finished using a new technology to complete a set of tasks. In some cases, video data are reviewed with the participant to evoke comments. This kind of retrospective verbal protocol emerged from the same tradition as think aloud (Ericsson and Simon 1993). Van Kesteren et al. (2003) raise the question of whether young kids' limited capacity to hold in memory several concepts at once and still-developing ability to engage in abstract thought limit their ability to accurately recall and recount past actions. They found that some kids age 6 and 7 were able to recall past actions and describe the ways in which their understanding changed. They note that keeping things interesting is important; children become bored with reviewing videos unless the tasks themselves are engaging to watch. In studies with kids aged 9–11, Baauw and Markopoulos (2004) determined that posttask interviews alone revealed fewer usability problems than think aloud; however, when combined with data from observations, which is standard practice, there was no significant difference between the problems that the two methods revealed.

36.4.2.2.4 Codiscovery

Codiscovery exploration is a usability method that is used to understand users' experiences and perceptions of new product designs, especially those that may be unfamiliar. In codiscovery sessions, two users who know one another work together to perform a set of tasks using the product. The goal of using two acquainted users is to encourage them to talk about the problems they encounter and their perceptions of the product in the natural course of collaborating on a task instead of relying on a single user's verbal performance for an experimenter (Kemp and van Gelderen 1996). First, the two users are asked to figure out what a product does and compare it to other products they know about. Next, they are asked to collaborate on a set of specific tasks using the product. Finally, a discussion period allows designers to ask about observed problems and behaviors; in addition, participants can ask questions about the design and the intended purpose of the product. Van Kesteren et al. (2003) found that using codiscovery with kids aged 6 and 7 can be difficult because they often attempt to complete tasks individually. Even when seated next to one another, two children may not interact at all, resulting in very few comments about the product being tested. When compared with traditional usability tests, think aloud, posttask interviews, peer tutoring and active intervention, codiscovery was found to elicit the fewest comments from kids (van Kesteren et al. 2003).

36.4.2.2.5 Peer Tutoring

Peer tutoring is a method for usability testing that was developed to capitalize on the ways that children interact with one another in natural, playful settings. When children play together, they regularly teach one another games and invent rules of play. Hoysniemi, Hamalainen and Turkki (2003, p. 209) explain that "one definition of the usability of a children's software application is that a child is able and willing to teach other children how to use it." Instead of relying on task completion in a lab, peer tutoring is an approach to usability testing that allows kids to engage in exploratory and playful interactions in a naturalistic setting. Peer tutoring involves first helping one or more kids to develop expertise using a piece of software and then asking them to teach other kids how to use it. By observing, recording, and analyzing interactions between tutors and tutees, it is possible to identify usability problems in software as the kids attempt to teach it to one another. Hoysniemi, Hamalainen, and Turkki (2003) point out that, although it can be useful, the peer tutoring approach requires time, training, and careful implementation to be effective.

36.5 GENRES OF TECHNOLOGY FOR KIDS

Technology for kids falls into two broad categories: education and entertainment. When game companies try to mix these genres, they may use the term "edutainment." New products for kids increasingly include specialized hardware as well as software.

36.5.1 Entertainment

Designers of games and other entertainment software rarely write about how they accomplish their job. Talks are presented each year at the Game Developer's Conference (http://www.gdconf.com), and some informal reflections are gathered as conference proceedings. Attending the conference is recommended for people who wish to learn more about current issues in game design. The magazine *Game Developer* is the leading publication with reflective articles on the game design process.

Game designers are usually gamers themselves and often end up simply designing games that they themselves would like to play. This simple design technique is easy and requires little if any background research with users. Because most game designers have traditionally been male, this approach allowed them to appeal quite effectively to a core gaming audience: young men and teenage boys. However, female designers are becoming more common on design teams and gaming companies are increasingly recognizing that people outside the typical gamer stereotype represent a large potential market for their products. Designing for teenagers is relatively easy. As we have seen, designing for very young children presents substantial challenges. The younger your target audience, the more they should be tightly connected to every stage of the design process.

Brenda Laurel pioneered the use of careful design methods for non-traditional game audiences in her work with the company Purple Moon in the mid-1990s. Laurel aimed to develop games that appeal to pre-teen girls both to tap this market segment and also to give girls an opportunity to become fluent with technology. Many people believe that use of computer game leads to skills that later give kids advantages at school and work. Through extensive interviews with girls in their target age range, Purple Moon was able to create successful characters and game designs. However, the process was so time consuming and expensive that the company failed to achieve profitability fast enough to please its investors. The company was closed in 1999, and its characters and games were sold to Mattel. Purple Moon perhaps did more research than was strictly necessary, particularly because their area was so new. The broader lesson is that the game industry typically does not budget for needs analysis and iterative design early in the design process. "Play testing" and "quality assurance" typically take place relatively late in the design cycle. Designers contemplating incorporating research early in their design process must consider the financial cost. (For more on game design and evaluation, see Chapter 34.)

Oosterholt, Kusano, and Vries (1996) describe several design constraints that are specific to the design of products for children. First, they suggest that trying to be fashionable can result in products that are quickly perceived by kids as outdated. They also point out that "fun" is just as important to measure as usability, that measurements of fun should be shared with development teams and, moreover, that the product should grow with users over time and continue to be fun long after kids have learned to use it.

Game designer Carolyn Miller highlights the following seven mistakes ("kisses of death") commonly made by people trying to design games for kids:

> *"Death kiss #1: Kids love anything sweet"*
> Miller writes that "sweetness is an adult concept of what kids should enjoy." Only very young children will tolerate it. Humor and good character development are important ingredients. Don't be afraid to use off-color humor, or to make something scary.
>
> *"Death kiss #2: Give 'em what's good for 'em"*
> She advises, "Don't preach, don't lecture, and don't talk down—nothing turns kids off faster."
>
> *"Death kiss #3: You just gotta amuse 'em"*
> "Don't assume that just because they are little, they aren't able to consume serious themes."
>
> *"Death kiss #4: Always play it safe!"*
> Adult games often rely on violence to maintain dramatic tension. Since you probably won't want to include this in your game for kids, you'll need to find other ways to maintain dramatic tension. Don't let your game become bland.
>
> *"Death kiss #5: All kids are created equal"*
> Target a specific age group, and take into consideration humor, vocabulary, skill level, and interests. If you try to design for everyone, your game may appeal to no one.
>
> *"Death kiss #6: Explain everything"*
> In an eagerness to be clear, some people over-explain things to kids. Kids are good at figuring things out. Use as few words as possible, and make sure to use spoken and visual communication as much as possible.
>
> *"Death kiss #7: Be sure your characters are wholesome!"*
> Miller warns that if every character is wholesome, the results are predictable and boring. Characters need flaws to have depth. Miller identifies a number of common pitfalls in assembling groups of characters. It's not a good idea to take a "white bread" approach, in which everyone is white and middle class. On the other end of the spectrum, it's also undesirable to take a "lifesaver approach" with one character for each ethnicity. Finally, you also need to avoid an "off-the-shelf" approach, in which each character represents a stereotype: "You've got your beefy kid with bad teeth; he's the bully. You've got the little kids with glasses; he's the smart one." Create original characters that have depth and have flaws that they can struggle to overcome (Miller, 1998).

36.5.2 Education

To design educational software, we must expand the concept of user-centered design (UCD) to one of learner-centered design (LCD) (Soloway, Guzdial, and Hay 1994). There are several added steps in the process, as follows:

- Needs analysis
    - For learners
    - For teachers
- Select pedagogy
- Select media/technology
- Prototype
    - Core application
    - Supporting curricula
    - Assessment strategies
- Formative evaluation
    - Usability
    - Learning outcomes
- Iterative design
- Summative evaluation
    - Usability
    - Learning outcomes

In our initial needs analysis, for software to be used in a school setting, we need to understand not just learners but also teachers. Teachers have heavy demands on their time and are held accountable for their performance in ways that vary between districts and between election years.

Once we understand our learner and teacher needs, we need to select an appropriate *pedagogy*—an approach to teaching and learning. For example, behaviorism views learning as a process of stimulus and reinforcement (Skinner 1968). Constructivism sees learning as a process of active construction of knowledge through experience. A social-constructivist perspective emphasizes learning as a social process (Newman, Griffin, and Cole 1989). (A full review of approaches to pedagogy is beyond the scope of this chapter.)

Next, we are ready to select the media we will be working with, matching their affordances to our learning objectives and pedagogical approach. Once the prototyping process has begun, we need to develop not just software or hardware, but (for applications to be used in schools) also supporting curricular materials and assessment strategies.

“Assessment” should not be confused with “evaluation.” The goal of assessment is to judge an individual student’s performance. The goal of evaluation is to understand to what extent our learning technology design is successful. An approach to assessing student achievement is an essential component of any school-based learning technology. For both school and free-time use, we need to design feedback mechanisms so that learners can be aware of their own progress. It is also important to note whether learners find the environment motivating. Does it appeal to all learners, or more to specific gender, learning style, or interest groups?

As in any HCI research, educational technology designers use formative evaluation to informally understand what needs improvement in their learning environment, and guide the process of iterative design. Formative evaluation must pay attention first to usability, and second to learning outcomes. If students cannot use the learning hardware or software, they certainly will not learn through its use. Once it is clear that usability has met a minimum threshold, designers then need to evaluate whether learning outcomes are being met. After formative evaluation and iterative design are complete, a final summative evaluation serves to document the effectiveness of the design and justify its use by learners and teachers. Summative evaluation must similarly pay attention to both usability and learning outcomes.

A variety of quantitative and qualitative techniques are commonly used for evaluation of learning outcomes (Gay and Airasian 2000). Most researchers use a complementary set of both quantitative and qualitative approaches. Demonstrating educational value is challenging, and research methods are an ongoing subject of research.

This represents an idealized LCD process. Just as many software design projects do not in reality follow a comprehensive UCD process, many educational technology projects do not follow a full learner-centered design process. Learner-centered design is generally substantially more time consuming than UCD. While it may in some cases be possible to collect valid usability data in a single session, learning typically takes place over longer periods of time. To get meaningful data, most classroom trials take place over weeks or months. Furthermore, classroom research needs to fit into the school year at the proper time. If you are using Biologica (Hickey et al. 2000) to teach about genetics, you need to wait until it is time to cover genetics that school year. You may have only one or two chances per year to test your educational technology. It frequently takes many years to complete the learner-centered design process. In the research community, one team may study and evolve one piece of educational technology over many years. In a commercial setting, educational products need to get to market rapidly, and this formal design process is rarely used.

36.5.3 Genres of Educational Technology

In 1980, Taylor divided educational technology into three genres:

Computer as tutor
Computer as tool
Computer as tutee

Suppose that we are learning about acid rain. If the computer is serving as *tutor*, it might present information about acid rain and ask the child questions to verify the material was understood. If the computer is a *tool*, the child might collect data about local acid rain and input that data into an ecological model to analyze its significance. If the computer is a *tutee*, the child might program his or her own ecological model of acid rain.

With the advent of the Internet, we must add a fourth genre:

Computer-supported collaborative learning (CSCL)

In a CSCL study of acid rain, kids from around the country might collect local acid rain data, enter it into a shared database, analyze the aggregate data, and talk online with adult scientists who study acid rain. This is in fact the case in the Acid Rain Project (Tinker 1993). See Table 36.1 for an overview of genres of children’s software.

36.5.3.1 Computer as Tutor

In most off-the-shelf educational products, the computer acts as tutor. Children are presented with information and then quizzed on their knowledge. This approach to education is grounded in behaviorism (Skinner 1968). It is often referred to as “drill and practice” or “computer-aided instruction” (CAI). The computer tracks student progress and repeats exercises as necessary.

Researchers with a background in artificial intelligence have extended the drill and practice approach to create “intelligent tutoring systems.” Such systems try to model what the user knows and tailor the problems presented to an individual’s needs. Many systems explicitly look for typical mistakes and provide specially-prepared corrective feedback. For example, suppose a child adds 17 and 18 and gets an answer of 25 instead of 35. The system might infer that the child needs help learning to carry from the ones to the tens column and present a lesson on that topic. One challenge in the design of intelligent tutors is in accurately modeling what the student knows and what their errors might mean.

Byrne et al. (1999) has experimented with using eye tracking to improve the performance of intelligent tutors. Using an eye tracker, the system can tell whether the student has paid attention to all elements necessary to solve the problem. In early trials with the eye tracker, he found that some of the helpful hints the system was providing to the user were never actually read by most students. This helped

TABLE 36.1
Genres of Children's Software

Genre	Description
Entertainment	Games created solely for fun and pleasure.
Educational	Software created to help children learn about a topic using some type of pedagogy—an approach to teaching and learning.
Computer as tutor	Often referred to as "drill and practice" or "computer-aided instruction" (CAI), this approach is grounded in behaviorism. Children are presented with information and then quizzed on their knowledge.
Computer as tool	The learner directs the learning process, rather than being directed by the computer. This approach is grounded in constructivism, which sees learning as an active process of constructing knowledge through experience.
Computer as tutee	Typically, the learner uses construction kits to help reflect upon what he or she learned through the process of creation. This approach is grounded in constructivism and constructionism.
Computer-supported collaborative learning (CSCL)	Children use the Internet to learn from and communicate with knowledgeable members of the adult community. Children can also become involved in educational online communities with children from different geographical regions. This approach is grounded in social constructivism.
Edutainment	A mix of the entertainment and educational genres.

guide their design process. They were previously focusing on how to improve the quality of hints provided; however, that is irrelevant if the hints are not even being read (Byrne et al. 1999).

An interesting variation on the traditional "computer as tutor" paradigm for very young children is the Actimates line interactive plush toys. Actimates Barney and other characters lead children in simple games with educational value, like counting exercises. The "tutor" is animated and anthropomorphized. The embodied form lets young children use the skills they have in interacting with people to learn to interact with the system, enhancing both motivation and ease of use (Strommen 1998; Strommen and Alexander 1999).

36.5.3.1.1 Computer as Tool

When the computer is used as a tool, agency shifts from the computer to the learner. The learner is directing the process, rather than being directed. This approach is preferred by constructivist pedagogy, which sees learning as an active process of constructing knowledge through experience. The popular drawing program Kid Pix is an excellent example of a tool customized for kids' interests and needs. Winograd comments that Kid Pix's designer Craig Hickman "made a fundamental shift when he recognized that the essential functionality of the program lay not in the drawings that it produced, but in the experience for the children as they used it" (Winograd 1996). For example, Kid Pix provides several different ways to erase the screen—including having your drawing explode, or being sucked down a drain.

Simulation programs let learners try out different possibilities that would be difficult or impossible in real life. For example, Biologica (an early version was called "Genscope") allows students to learn about genetics by experimenting with breeding cartoon dragons with different inherited characteristics like whether they breathe fire or have horns (Hickey et al. 2000). Model-It lets students try out different hypotheses about water pollution and other environmental factors in a simulated ecosystem (Soloway et al. 1996).

The goal of such programs is to engage students in scientific thinking. The challenge in their design is how to get students to think systematically, and not simply try out options at random. Programs like Model-It provide the student with "scaffolding." Initially, students are given lots of support and guidance. As their knowledge evolves, the scaffolding is "faded," allowing the learner to work more independently (Guzdial 1994; Soloway, Guzdial, and Hay 1994).

36.5.3.1.2 Computer as Tutee

Seymour Papert comments that much CAI is "using the computer to program the child" (Papert 1992, p. 163). Instead, he argues that the child should learn to program the computer and through this process gain access to new ways of thinking and understanding the world. Early research argued that programming would improve children's general cognitive skills, but empirical trials produced mixed results (Clements 1986; Clements and Gullo 1984; Pea 1984). Some researchers argue that the methods of these studies are fundamentally flawed, because the complexity of human experience cannot be reduced to pre and post tests (Papert 1987). The counter-argument is that researchers arguing that technology has a transformative power need to back up their claims with evidence of some form, whether quantitative or qualitative

FIGURE 36.2 Penguins created using Hypergami.

(Pea 1987; Walker 1987). More recently, the debate has shifted to the topic of technological fluency. As technology increasingly surrounds our everyday lives, the ability to use it effectively as a tool becomes important for children's success in school and later in the workplace (Resnick and Rusk 1996).

In the late 1960s, Feurzeig and colleagues (Feurzeig, personal communication, 1996) at BBN invented Logo, the first programming language for kids. Papert extended Logo to include "turtle graphics," in which kids learn geometric concepts by moving a "turtle" around the screen (Papert 1980). A variety of programming languages for kids have been developed over subsequent years, including Starlogo (Resnick 1994), Boxer (diSessa and Abelson 1986), Stagecast (Cypher and Smith 1995), Agentsheets (Repenning and Fahlen 1993), MOOSE (Bruckman 1997), Squeak (Guzdial and Rose 2001), Alice (Cooper, Dann, and Pausch 2000), and Scratch (Resnick et al. 2009).

Additionally, several programming environments bridge the gap between physical constructions and representations. Lego Mindstorms (originally "Lego/Logo") is a programmable construction kit with physical as well as software components (Martin and Resnick 1993). PicoCrickets, a craft-based robotic construction kit, offers a different pathway into robotics by leveraging interests in craft (Rusk et al. 2008). Similarly, LilyPad Arduino allows microcontrollers and sensors to be sewn into fabric to create e-textiles (Buechley et al. 2008).

Finally, Hypergami, a computer-aided design tool for origami allows students to learn about both geometry and art (Figure 36.2) (Eisenberg, Nishioka, and Schreiner 1997).

In most design tools, the goal is to facilitate the creation of a product. In educational construction kits, the goal instead is what is learned through the process of creation. So what makes a good construction kit? In a 1996 *Interactions* article titled "Pianos, Not Stereos: Creating Computational Construction Kits," Resnick, Bruckman, and Martin discuss the art of designing construction kits for learning ("constructional design"):

> The concept of learning-by-doing has been around for a long time. But the literature on the subject tends to describe specific activities and gives little attention to the general principles governing what kinds of "doing" are most conducive to learning. From our experiences, we have developed two general principles to guide the design of new construction kits and activities. These constructional-design principles involve two different types of "connections":
>
> - *Personal connections.* Construction kits and activities should connect to users' interests, passions, and experiences. The point is not simply to make the activities more "motivating" (though that, of course, is important). When activities involve objects and actions that are familiar, users can leverage their previous knowledge, connecting new ideas to their pre-existing intuitions.
> - *Epistemological connections.* Construction kits and activities should connect to important domains of knowledge—more significantly, encourage new ways of thinking (and even new ways of thinking about thinking). A well-designed construction kit makes certain ideas and ways of thinking particularly salient, so that users are likely to connect with those ideas in a very natural way, in the process of designing and creating (Resnick, Bruckman, and Martin 1996).
>
> Bruckman adds a third design principle:
>
> - *Situated support.* Support for learning should be from a source (either human or computational) with whom the learner has a positive personal relationship, ubiquitously available, richly connected to other sources of support, and richly connected to everyday activities (Bruckman 2000).

Resnick and Silverman (2005) have suggested several more design principles for creating construction kits for kids. Some, such as "iterate, iterate—then iterate again," are familiar mantras for HCI designers. Others may be less familiar, as follows:

- Low Floor and Wide Walls
  If a technology has a low floor, it means that it is easy for novices to begin using it. Wide walls suggest a wide range of possible areas of design and exploration. Construction kits define "a place to explore, not a collection of specific activities."
- Make Powerful Ideas Salient—Not Forced
  When designing toward specific learning goals, construction kits should make these ideas visible and useful in design activities rather than imposing the ideas on students as a pre-determined solution.
- Support Many Paths, Many Styles
  Kids approach problems in different ways; it is important to support a variety of design approaches in a construction kit.
- Make It as Simple as Possible—and Maybe Even Simpler
  Constraints can be the designer's best friend. Limited functionality sometimes wins out over more sophisticated designs because simplicity allows kids to find creative new ways to use a product.

- Choose Black Boxes Carefully
  This principle is related to the previous one; deciding when to reveal complexity and when to conceal it is a difficult question. Resnick and Silverman again suggest that the simplest choice is often the best one.
- A Little Bit of Programming Goes a Long Way
  Because programming is the fundamental mode of construction with computers, designers of construction kits for kids often include some programming functionality. Focusing on powerful, simple commands that kids can do well is often the best way to support a diverse range of activities.
- Give People What They Want—Not What They Ask For
  Observations of kids can often tell designers more than their direct answers to questions. Kids may ask for unrealistic features or may not know themselves why they are having difficulty completing a task.
- Invent Things That You Would Want to Use Yourself
  Although they caution against overgeneralizing one's own personal likes and dislikes, Resnick and Silverman propose that the most respectful approach to designing for kids is to create something that the designer herself finds enjoyable.

36.5.3.2 Computer-Supported Collaborative Learning

Most tools for learning have traditionally been designed for one child working at the computer alone. However, learning is generally recognized to be a social process (Newman, Griffin, and Cole 1989). With the advent of the Internet come new opportunities for children to learn from one another and from knowledgeable members of the adult community. This field is called "CSCL" (Koschmann 1996).

CSCL research can be divided into four categories:

1. Distance education
   Attempts to use online environments in ways that emulate a traditional classroom.
2. Information retrieval
   Research projects in which students use the Internet to find information.
3. Information sharing
4. Technological samba schools

Students debate issues with one another. One of the first such tools was the Computer-Supported Intentional Learning Environment, a networked discussion tool designed to help students engage in thoughtful debate as a community of scientists does (Scardamalia and Bereiter 1994). They may also collect scientific data and share it with others online. In the "One Sky, Many Voices" project, students learn about extreme weather phenomena by sharing meteorological data they collect with other kids from around the world, and also by talking online with adult meteorologists (Songer 1996). In the Palaver Tree Online project, kids learn about history by talking online with older adults who lived through that period of history (Ellis and Bruckman 2001).

A key challenge in the design of information sharing environments is how to promote serious reflection on the part of students (Guzdial 1994; Kolodner and Guzdial 1996).

In *Mindstorms*, Seymour Papert has a vision of a "technological samba school." At samba schools in Brazil, a community of people of all ages gather together to prepare a presentation for carnival. "Members of the school range in age from children to grandparents and in ability from novice to professional. But they dance together and as they dance everyone is learning and teaching as well as dancing. Even the stars are there to learn their difficult parts" (Papert 1980). People go to samba schools not just to work on their presentations, but also to socialize and be with one another. Learning is spontaneous, self-motivated, and richly connected to popular culture. Papert imagines a kind of technological samba school where people of all ages gather together to work on creative projects using computers. The Computer Clubhouse is an example of such a school in a face-to-face setting (Resnick and Rusk 1996). MOOSE Crossing is an Internet-based example (Bruckman 1998). A key challenge in the design of such environments is how to grapple with the problem of uneven achievement among participants. When kids are allowed to work or not work in a self-motivated fashion, typically some excel while others do little. (Elliott et al. 2000).

36.5.4 Safety Issues

One challenge in the design of Internet-based environments for kids is the question of safety. The Internet does contain inappropriate content such as information that is sexually explicit, violent, and racist. Typically, such information does not appear unless one is looking for it; however, it is unusual but possible to stumble across it accidentally. Filtering software blocks access to useful information as well as harmful (Schneider 1997). Furthermore, companies that make filtering software often fail to adequately describe how they determine what to block, and they may have unacknowledged political agendas that not all parents will agree with. Resolving this issue requires a delicate balance of the rights of parents, teachers, school districts, and children (Electronic Privacy Information Center 2001).

36.5.4.1 Cyberbullying

Cyberbullying, or the use of information communication technologies to bully others, has been on the rise with the advent of social networking sites, blogs, mobile phones, online games, and other communication technologies (Lenhart 2007). Unlike physical bullying, bullies can be anonymous and harmful information or comments can be persistent, searchable, and have the potential to be read by a large audience. Cyberbullying tends to be the most common in middle and high school ages (Lenhart 2007). In a survey study of 177 seventh grade students, over a quarter of students reported that they had been cyberbullied and one out of six students had cyberbullied others (Li 2006). The victims were also 60% female, while a slim majority of males are cyberbullies; this study, along with others, point that females prefer to use digital mediums to bully others.

Research on cyberbullying victims show that there are indeed serious consequences. Victims have lower self-esteem, an increased risk of depression and suicide, and may become cyberbullies themselves (Li 2007).

36.5.4.2 Predators

Another danger for kids online is the presence of sexual predators and others who wish to harm children. While such incidents are rare, it is important to teach kids not to give out personal information online such as their last name, address, or phone number. Kids who wish to meet an online friend face to face should do so by each bringing a parent and meeting in a well-populated public place like a fast-food restaurant. A useful practical guide "Child Safety on the Information Superhighway" is available from the Center for Missing and Exploited Children (http://www.missingkids.com). Educating kids, parents, and teachers about online safety issues is an important part of the design of any online software for kids.

36.6 CONCLUSION

To design for kids, we must have a model of what kids are and what we would like them to become. Adults were once kids. Many are parents. Some are teachers. We tend to think that we know kids—who they are, what they are interested in, what they like. However, we do not have as much access to our former selves as many would like to believe. Furthermore, it is worth noting that our fundamental notions of childhood are in fact culturally constructed and change over time. Karin Calvert writes about the changing notion of childhood in America, and the impact it has had on artifacts designed for children and child-rearing:

> In the two centuries following European settlement, the common perception in America of children changed profoundly, having first held to an exaggerated fear of their inborn deficiencies, then expecting considerable self-sufficiency, and then, after 1830, endowing young people with an almost celestial goodness. In each era, children's artifacts mediated between social expectations concerning the nature of childhood and the realities of child-rearing: before 1730, they pushed children rapidly beyond the perceived perils of infancy, and by the nineteenth century they protected and prolonged the perceived joys and innocence of childhood. (Calvert 1992, p. 8)

While Calvert was reflecting on the design of swaddling clothes and walking stools, the same role is played by new technologies for kids like programmable Legos and drill and practice arithmetic programs: these artifacts mediate between our social expectations of children and the reality of their lives. If you believe that children are unruly and benefit from strong discipline, then you are likely to design CAI. If you believe that children are creative and should not be stifled by adult discipline, then you might design an open-ended construction kit like Logo or Squeak. In designing for kids, it is crucial to become aware of one's own assumptions about the nature of childhood. Designers should be able to articulate their assumptions, and be ready to revise them based on empirical evidence.

37 Information Technology for Communication and Cognitive Support

Alan F. Newell, Alex Carmichael, Peter Gregor, Norman Alm, Annalu Waller, Vicki L. Hanson, Graham Pullin, and Jesse Hoey

CONTENTS

37.1 SUMMARY

Well-designed communication and information technology systems can substantially enhance the quality of life and independence for those with cognitive dysfunction, including elderly people. They can do the following:

- Allow people to retain a high level of independence and control over their lives
- Provide appropriate levels of monitoring and supervision of at-risk people, without violating privacy
- Keep people intellectually and physically active
- Provide communication methods to reduce social isolation and foster social inclusion

It is not easy to understate the importance of designers considering the effects of cognitive impairment on users. For example, access to the Internet for people with disabilities is often thought to be synonymous with access for people with visual impairment, but people with visual impairment form only a small percentage of the disabled population. Ogozalec (1997, p. 65) pointed out that, if current trends continue in the United States, by 2030, one-fifth of the population will be over 65 years of age and commented, "It is difficult to categorize and draw conclusions about 'the elderly,' since they comprise such a diverse and heterogeneous population." This diversity, particularly of cognitive function, needs to be taken into account if we are to make software and the Internet available to as large a percentage of the population as possible.

To illustrate the many challenges of cognitive impairment, this chapter will describe the major types of cognitive impairment including the effects of aging, and the effects these can have on daily living.

The increasing power and decreasing size of information technology, along with its capacity to provide communication as well as computation and storage, offers the possibility of quite sophisticated help for cognitive impairments. Computers have the potential to act as a scaffolding for cognitive tasks, taking over functions that have been affected by illness, accident, or aging. They can provide support for communication, both spoken and written, prompts for daily living, and entertainment and support systems for people with dementia.

The design and development of systems to support people with a variety of cognitive impairment will be illustrated by specific projects in which the authors have been involved. These examples do not cover all aspects of cognitive impairment, but illustrate an approach to developing assistive technology which has proved successful in a number of application areas.

This chapter will address the development of methodologies that are valuable for designers of information technology systems. These are relevant both to designers of specialist systems to support people with cognitive impairment and for designers of "main stream" systems—so that they are able to take into account the needs of people with cognitive impairments.

37.2 INTRODUCTION

Using technology to augment human cognitive capacity is not a new idea. In its widest sense, it includes all the tools and techniques that humans have developed to help support and/or enhance their cognitive abilities. The first cognitive function to be augmented was probably memory, and mnemonic methods help with this are still in wide use today. One of the most common (the method of loci) is to link what is to be remembered with a well-established memory structure that is easy to recall, such as the layout of a familiar city, or a narrative that has already been memorized. The introduction of written language extended people's cognitive abilities by allowing memories to be recorded externally. At the time, some feared this backwards step would allow people's memory powers to wither, but the overriding effect has been to free cognitive abilities that can further develop on the basis of the external support. This initial response to cognitive support systems is very common and continues today where information processing technologies have substantially extended the potential of most people's cognitive abilities. However, this technology has a similar potential to extend the cognitive abilities of those with some form of impairment or other limitation.

Particular strengths of computers as assistants for people with cognitive impairments include being consistent, tireless, and not becoming emotionally involved. In addition, multimedia and multimodal systems can provide a very rich interaction, which may be particularly advantageous for users with cognitive dysfunction. Such systems have great potential in addressing the problems of memory loss and the related difficulties presented by dementia. Communication systems that use synthetic speech, predictive programs that facilitate writing, and a range of nonlinguistic methods of communication, can be used by those with speech and language dysfunction caused by cognitive impairments.

37.3 COGNITIVE IMPAIRMENT

The use of the term cognitive impairment implies that two categories of human cognitive systems exist—impaired and unimpaired. However, this is not the case, although it can reasonably be stated that there are normal or average cognitive systems. The vast majority of experimental cognitive psychology literature relates to this normal system. In many contexts, this level of explanation is suitable for indicating of what most people are capable. It should always be borne in mind, however, that in real-world situations there is no marked distinction between that which is normal and that which is not. In other words, everyone has some limits to their cognitive abilities, which are considered normal. Within these bounds of normalcy, everyone will be better at some types of thinking than other types (e.g., math versus language) and often these differences can be relatively extreme. Most of the time, these weaknesses can (to some extent) be compensated for by the strengths, thus general levels of cognitive performance remain effectively normal. However, for a significant minority of people weakness can effectively outweigh strengths and this will generally be considered impairment. Some have a highly specific impairment, some have more diffuse problems, and some experience interrelated constellations of impairments which can be exacerbated by associated physiological impairment. In addition, the cognitive abilities of any one human being will change over longer and shorter periods. Aging can have substantial effects on cognitive ability, which is particularly marked in some age-related conditions, such as dementia.

For ease of exposition, the forms of cognitive impairment identified and described below will in the main refer to general categories. It should be noted, however, that all these categories lie somewhere on a continuum and, while they are delineated on the basis of educational and clinical or medical criteria, such cutoff points are relatively arbitrary in the context of the wide variability of cognitive ability across the population. It is also worth noting that within the context of normal cognitive systems, there is significant diversity among people with regard to differential preferences for types of material and ways of approaching and processing information. For example, some people may be considered primarily verbal and tend to excel in language-based tasks, relative to those considered visuo/spatial (e.g., Lohman 2000). Thus, many of the types of impairment addressed below can be construed to an important extent as the extremities of normal diversity.

37.3.1 Intelligence Quotient

The most widely known dimension of general cognitive ability is probably intelligence. Scientific investigation of this dimension has a controversial past, and many aspects of this are beyond the scope of this chapter (for a more comprehensive account, see Gould [1997]). One underlying reason for such controversy is that the word intelligence has a rather nebulous definition. In day-to-day usage, this is rarely problematic, but the differences between scientific and lay definitions can cause misunderstanding (e.g., Sternberg 2000). Such misunderstanding can lead to controversy as most definitions of intelligence include connotations that are considered socially important and, thus, can often be highly emotive. Despite these difficulties, the investigation of intelligence has provided many insights into a wide range of more particular cognitive abilities, and has developed methods for quantifying general intellectual ability such as the various forms of intelligence quotient (IQ) tests. Again, controversy has surrounded the use of these tests over the years (see Gould [1997]; Kaufman [2000]), but such tests have been widely used and are accepted as a general benchmark of a person's intellectual capability.

An IQ score of 100 is, by definition, normal with about 50% of the population scoring above and 50% scoring below, but it should be noted that elderly people are not generally included in the standardization of these scores. Approximately 50% of the population is considered within the bounds of normality and deviate either side of 100 by no more than 10 points. The nonnormal 50% are distributed approximately evenly above and below this band. Thus, about a quarter of the (nonelderly) population fall below the level of what is considered normal. Although the terminology varies across cultures and over time, around 20% of the population have IQ scores between 75 and 90 and would generally be classified as slow learners. The final 5% will generally have very special needs that overall are best addressed on an individual basis (Kaluger and Kolson 1987). Further to this and as an example of the emotive connotations associated with the issue of "intelligence," it is worth noting that the first official classification scheme (see Detterman, Gabriel, and Ruthsatz [2000]) associated with IQ tests further broke down this latter 5%. These classifications were moron (IQ 50–75), imbecile (IQ 25–50), and idiot (IQ, <25), terms which today would be considered wholly unacceptable as a description of anyone with a cognitive impairment. The above-normal segment of the population has received much less research interest, will tend to be high achievers, and are only mentioned here to highlight that "normal" *could* be construed as "impaired."

An IQ score reflects a person's intellectual ability as a whole. A low score may be due to the whole system functioning at a suboptimal level, but a similar result can also be due to one or more component abilities being impaired. There are many tests of IQ, some of which give an indication of this while others do not. Some IQ tests are explicitly broken down into subtests that reflect the relative levels of ability in the component cognitive abilities, such as the verbal and visuo/spatial abilities mentioned above. The more common forms of cognitive impairment are described below in the context of a brief overview of the cognitive system.

For any information in the outside world to enter the cognitive system, it must first be detected and transmitted by the sensory apparatus. In an important sense, this is not simply the start of the process because aspects of attention will influence what is and is not detected/transmitted, and, to a certain extent, how. Basic perceptual processing creates a sensory specific representation of the stimulus event. Streams of such stimulus events are summated into meaningful cognitive entities (e.g., strokes on a page recognized as letters and numerals are summated into a name and telephone number). These will then be either: passed immediately to short-term memory (STM), further processed by working memory

(WM), or rehearsed for maintenance in STM or for encoding into longer term storage. For example, rehearsal could refer to rote rehearsal of a telephone number between reading and dialing it or to more elaborate processing to associate it with relevant extant memories to improve the chance of subsequent recall (e.g., method of loci, mentioned above).

Output from the cognitive system will generally be initiated in response to some form of external stimulus, or probe, by accessing extant memories relevant to the probe using executive processes to organize them in a task-relevant way and then producing a response. Output of this kind has been most commonly studied with the use of memory tests. This minimizes the influence of intellectual processing (problem solving, etc.) per se, and emphasizes the registration, rehearsal, and encoding of information, the effects of decay, interference and other forms of forgetting, and the effectiveness of different cues (probes) in eliciting specific memories (e.g., recall vs. recognition).

Virtually all aspects of the processing outlined above are shaped by attention, and it is important to note that, regardless of impairment, while we all have some control over attention, it can also be the case that attention can have some control over us. That is, we can utilize attention to focus on searching a list for a particular telephone number while ignoring the chatter of people around us. Having read the number, however, our attention can exert its own control if someone calls our name and asks if we have made that call yet. Despite our best efforts at rehearsal, it is likely that our attention will be grabbed by our name, and the ensuing question and this brief distraction can be enough to lose the information from temporary storage.

In general terms, mild to moderate global cognitive impairment will be associated with decrements in efficiency across most of the processing stages outlined above and in aspects of the utilization of attention. The following will describe some of the main decrements in cognitive ability related to interacting with computer-type systems.

37.3.2 Attention Deficit

Many of the constraints imposed by cognitive impairment can be further shaped by decrements in various aspects of attention. One major aspect of this is generally referred to as "selective attention," which allows people to focus on salient aspects of a task and at the same time helps them actively to ignore irrelevant aspects. The efficiency of selective attention is markedly diminished in most forms of cognitive impairment. This factor further supports the recommendation to present the user with just one thing at a time, which will avoid them erroneously devoting time and cognitive resources to processing irrelevant information. Similarly, if the nature of the interaction requires the user to attend to some critical information at a particular time/location, appropriately obvious highlighting should be used to attract the users' attention. These issues become emphasized in situations where selective attention must be maintained over periods of more than just a few minutes.

Another aspect of attention known to be less efficient in cognitive impairment is referred to as "divided attention." In general, this refers to the ability to allocate cognitive resources appropriately when trying to do two or more distinct cognitive tasks or distinct portions of the same task at the same time.

37.3.3 Autism

Another distinct form of global cognitive impairment is autism, including a set of rarer but related syndromes (Kaluger and Kolson 1987). The precise causes of autism are not clearly understood. Briefly stated, it is a general neurological disorder that impacts the normal development of the brain particularly in relation to social interaction and communication skills. Its effects will usually become apparent within the first 3 years of life. People with autism typically have difficulties in verbal and nonverbal communication and social interactions. The disorder makes it hard for them to communicate with others and relate to the outside world, they also tend to have relatively low IQ scores. Closely related to autism is Asperger syndrome. People with Asperger's experience similar social communication difficulties, but generally demonstrate a normal IQ. Further to this, there are several generally similar conditions, some of which have varying physical and behavioral elements associated with them. These come under the collective heading of pervasive developmental disorders and all tend to produce difficulties with communication. An important element of these social communication difficulties in the context of the present chapter is an inability to grasp the implications of metaphorical or idiomatic language. Similar effects occur in dementia but in autism tend to be more profound. There is some evidence that people with autism or Asperger syndrome are more able to communicate with computers than with people, or with people via computers, rather than face-to-face, and thus properly designed computer systems may have potential for assisting such user groups.

37.3.4 Aphasia and Complex Communication Needs

Cognitive limitations can have a major impact on the ability to encode and decode traditional orthography. People with acquired cognitive impairments (e.g., aphasia resulting from a stroke or cerebral vascular accident) can experience varying degrees of difficulty with both expressive and receptive language. A person with aphasia may have slight word-finding problems through to more pervasive problems in understanding spoken language. Although some individuals may retain some literacy skills, damage to the language processing centers will usually also affect symbolic representations of language.

Individuals with congenital language and/or intellectual disabilities (e.g., developmental delay and Down syndrome) may never become literate. The physical inability to speak (e.g., dysarthria resulting from cerebral palsy) may also impact literacy learning, as basic skills required for reading and writing (e.g., phonemic awareness) may be absent. Children with complex communication needs (CCN), for example, as a result of cerebral palsy, have a combination of physical, speech, and/or intellectual impairments that impact on the development of speech and language.

37.3.5 Cognitive Effects of Aging

It is well known that aging brings about changes in a person's abilities. Perceptual (vision and hearing) and motor declines, for example, are well documented and a number of best practices and design guidelines exist that help designers with resulting interface needs (see, e.g., Arch [2008]; Coyne and Nielson [2002]; Hanson et al. [2009]; Kurniawan [2009]; Morrell et al. [2002]). In contrast, there is less understanding about cognitive declines that accompany aging, and certainly less consensus on ways to support older users who find computing challenging due to some of these declines.

In healthy aging, there are a number of cognitive activities that can affect ability to use technology (Chin and Fu 2010; Czaja et al. 2010; Fairweather 2008; Hanson 2009; Park 1992; Rabbitt 1993; Sayago, Camacho, and Blat 2009). The rate and degree of cognitive decline vary from person to person, but, as a general statement, cognitive declines can begin in middle age and continue throughout the rest of one's life. A distinction between *crystallized intelligence* and *fluid intelligence* is often made to help understand the complexity of cognitive abilities and aging. These two terms encapsulate aspects of intelligence that have different patterns of decline with age. Crystallized intelligence refers to verbal ability and general knowledge. It characteristically remains intact throughout a person's lifetime. In fact, there is generally a slight increase in crystallized intelligence abilities until old age, at which point slight declines begin. In contrast, fluid intelligence refers to a set of cognitive abilities that decline steadily (albeit at different rates for different individuals) beginning in middle age. Fluid intelligence includes such skills as STM, speed of processing, and problem-solving ability. Critically, fluid intelligence abilities are exactly those needed to be able to learn new computing skills (Czaja et al. 2006) and successfully perform technology tasks such as web searching (Czaja et al. 2010). Rabbitt (1993) has shown that, in many circumstances, relevant accumulated knowledge can ameliorate declines in fluid ability. However, in other circumstances the opposite can be the case, wherein a well-learned, but essentially inappropriate, strategy can put a relatively greater burden on the associated fluid abilities.

37.3.6 Dementia

Various forms of dementia can exaggerate the relatively mild effects of normal aging on the cognitive system. At the age of 60 years, about 1% of the population is diagnosed with dementia. This percentage approximately doubles for every subsequent 5-year-age band (e.g., 4% at 70 years and 16% at 80 years; Bäckman et al. 2000). Of the elderly population with dementia, Alzheimer's disease accounts for about 60%, depending on the diagnostic criteria used and a further 25% is vascular dementia (e.g., related to circulatory problems). Most of the vascular dementias are referred to as "multi-infarct dementias" and tend to be caused by series of mini-strokes, and thus, they tend to have more diffuse and less predictable effects on ability than a major stroke. The remaining 15% of dementias are made up of various relatively rare conditions (Bäckman et al. 2000).

Regardless of the various causes and effects, all forms of dementia involve damage to the brain, such damage being more or less widespread, affecting cortical and/or subcortical areas. In general, damage to the cortex results in cognitive/perceptual impairment, whereas damage to the subcortical areas is more related to physical impairment. However, there are a number of well-known problems related to the diagnosis of dementia. Two of these are relevant here. The first involves the grey area between the worst effects of normal aging and the initial effects of pathological aging at the onset of dementia. The second is that the effects of depression in later life can closely mimic those of dementia. These additional complexities further expand the overall diversity of cognitive impairment in relation to human-interface design, both in regard to the general level of ability and in the variation of that level over periods of days, weeks, months, and even years. The convolution of this situation is further added to by the effects of a relatively greater probability of ill health among older people. It is estimated that around 80% of those aged 65 and over have at least one chronic illness and that many will have more than one. In addition to the effects of health per se, there is also potential for cognitive ability to be affected by a variety of medication and by interactions between different medicines.

Despite the above, some systematic changes associated with extreme old age and dementia are relevant to human-interface design. In general, the first ability to deteriorate in dementia, particularly with Alzheimer's disease, is episodic as distinct from semantic memory. Episodic memory is memory for events, usually from the viewpoint of personal experience, rather than for facts. That is, remembering, "X is the capital of Y" is the product of semantic memory, whereas remembering when and where you were while you were reading "X is the capital of Y" is the product of episodic memory. This generalized decrement in episodic memory may be related to findings in normal aging research such as disproportionate decrements in source memory (e.g., specifically remembering where an item was rather than what it was) and to prospective memory (e.g., remembering to do something in the future). These changes have important implications for successful navigation in interactive systems. For example, keeping track of where you have just been is often an important prompt to where you are going now.

37.3.7 Dyslexia

Dyslexia is a neurological problem that manifests itself as a language disorder (Dyslexia Research Institute 2010; National Center for Learning Disabilities 2007; Shaywitz et al. 1998).

It can present a number of language-related difficulties and definitions of it have varied. The British Dyslexia Association (2006) offered the following description:

> Dyslexia is best described as a combination of abilities and difficulties that affect the learning process in one or more of reading, spelling, and writing. Accompanying weaknesses may be identified in areas of speed of processing, short-term memory, sequencing and organization, auditory and/or visual perception, spoken language and motor skills. It is particularly related to mastering and using written language, which may include alphabetic, numeric and musical notation.

One of the main features of dyslexia is the individual nature of the disorder. The condition is not typically characterized by one single difficulty, but by a range of difficulties that will vary in combination and in intensity between individuals, giving rise to an enormous variation between individuals in the problems encountered. Each dyslexic person thus has a range of difficulties that need to be addressed differently from those of others. Dyslexia is an example of the need to design for dynamic diversity (see Section 37.12.4).

The wide-ranging characteristics of dyslexia provide a challenge for technological assistance, as a single approach will not be appropriate for the range of problems presented by the population of dyslexic people. Computer technology offers the opportunity to provide reading and writing systems that are highly configurable for each individual user. These systems, however, need to be based on an understanding of the problems that dyslexics have in reading and writing.

Some of the most commonly encountered problems are as follows (adapted from Willows, Kruk, and Corcos [1993]):

1. Number and letter recognition. One of the fundamental problems faced by dyslexics is the recognition of individual alphanumeric symbols. This is often seen when letters that are similar in shape, such as n and h and f and t, are confused. The problem is exacerbated with the introduction of uppercase letters. In addition, many dyslexic adults, who are capable of reading printed letters, have difficulty in reading cursive writing.
2. Letter reversals. Many dyslexics are prone to reversing letters, which results in a particular letter being interpreted as another letter. Examples of these characters are b, d, p, and q. This problem can result in poor word recognition with words containing reversal characters being substituted for other words, such as bad for dad.
3. Word recognition. As well as the substitution effect caused because of letter reversals, words that are similar in their outline shape (word contour) can be substituted by dyslexics. Typical examples of this problem are the words either and enter. Both words have the same start and finishing characters and this, allied with their similar word contours, make them candidates for being substituted for each other when they occur in the text.
4. Number, letter, and word recollection. Even if the ability to recognize numbers and letters is adequate, it can still prove difficult for a dyslexic individual to recall the actual form and shape of a character. Many dyslexics have so much difficulty recalling upper and lower case characters that they continue to print later in life. Similarly, poor visual memory means that dyslexics have little ability to distinguish whether or not a word looks right.
5. Spelling problems. Due to the problems discussed above, dyslexics can have great difficulty with spelling, and many dyslexics have very poor spelling. Much of the spelling of dyslexics appears to reflect a phonic strategy with words like *of* and *all* being spelled *ov* and *ohl*.
6. Punctuation recognition. As with characters, dyslexics appear to have difficulty recognizing punctuation marks.
7. Saccadic and fixation problems. Another problem that is found in many dyslexics is their lack of ability to follow text without losing their places. Many find it difficult to move from the end of one line to the beginning of the next and find themselves getting lost in the text.
8. Word additions and omissions. Dyslexics may add or remove words from a passage of text, apparently at random. This is manifested by words being omitted or duplicated, extra words being added, or word order being reversed or otherwise jumbled.
9. Poor comprehension. With the variety of errors caused by the factors described above, a dyslexic person may perceive a totally different (or impoverished) passage of text from the one that is actually in front of them. Dyslexics thus display poor comprehension skills due to text which they perceive being significantly different from the actual text.

37.4 INTERFACE DESIGN TO SUPPORT PEOPLE WITH COGNITIVE IMPAIRMENT

Specialist information technology has been developed to provide support for people with various types of cognitive impairment, and some such projects are described later. It is also important, however, to address the challenge of providing access to more mainstream technology for people with cognitive impairments. When designing or specifying mainstream technology, it is important to focus on the characteristics of such users and to be fully aware of the range of cognitive diversity, even among those without clinical dysfunction. This is rarely mentioned in human-interface design, where the cognitive diversity of the human race has not been the focus of much research. It is also important to consider the effects of age on cognitive function when designing information technology systems.

37.4.1 Speed

A key aspect of any intellectual task, in regard to interactive technology for people with mild or moderate global cognitive impairment, is speed (Salthouse 1991). Whatever level of performance a person can achieve in any given situation will be made worse if the task must be done under externally imposed time constraints whether actual or simply inferred by the user. Thus, wherever possible, the design of any interaction should allow every step to be carried out at the user's own pace. Attention to text layout can also benefit people with specific learning difficulties, such as those with dyslexia and people with limited literacy levels. Beyond this, clear text and presentation layout will always be worth considering carefully as such aspects have been found to benefit those who do not specifically need it, albeit to a less marked extent (Freudenthal 1999; Pirkl 1994).

37.4.2 Simplicity

Another key concept related to interface design for people with cognitive impairment is the avoidance of complexity. Complexity in interfaces can manifest itself in many different ways and at many different levels. A truly comprehensive coverage of this is beyond the scope of the present chapter, but some illustrative examples will be given to illustrate "cognitive accessibility."

Cognitive accessibility is more difficult to measure than sight and hearing accessibility, but is absolutely vital when designing for people with cognitive impairment. Simplicity supports cognitive inclusion but it is not easy to achieve. Particularly with information technology products, it is often easier to solve design challenges by providing more functionality, forgetting that this may confuse the user. Also many developers of so called "universal design" product interpret that to mean that a product or service should do everything that any individual could want, and that it should be all things to all people (Pullin 2009b). This can lead to a very complex final solution. It should be noted that ability to customize a user interface—with the intension of "simplifying it"—often makes the overall product even more complex. The goal of simplicity—the ability to use a product without thought—should be the goal of designers of products aimed at users with cognitive dysfunction, and this means paring down the functionality of the product as much as possible. In a sense, this is the antithesis of "user centered design" where the user is asked what they want in a product—designers need to be conscious of the "if it is offered why not say yes," response of users. The iPod Shuffle provides an example of the success of a simplified product. It can be argued that focus groups of users would be unlikely to have asked for such a minimal set of functions in a music player, but these devices have been a commercial success.

37.4.3 Language and Interfaces

The use of language in an interactive system should be given careful consideration, and the syntax and vocabulary should be kept as straightforward and commonplace as the context allows. This is particularly pertinent for any form of instruction. If the requirements of a particular stage of an interaction cannot be captured in a few simple concrete statements, then serious consideration should be given to redesigning the interaction itself. Similarly any on-screen display should be kept as uncluttered as practicable and, wherever possible, should present the user with only a single issue (menu, subject, decision, etc.) at any particular point in time. Similarly, but at a larger scale, progression through an interaction should be kept, wherever practicable, as linear as possible. That is, the user should only need to consider one thing at a time. Any requirement to deal with different decisions in parallel will markedly increase the possibility of errors and general user dissatisfaction (Detterman, Gabriel, and Ruthsatz 2000; Salthouse 1985).

As the designers of a system will have a comprehensive understanding of the functions of that system, however, they are unlikely to assess issues of complexity from the users' point of view, particularly that of a novice user. In addition, prescriptive checklists for avoiding complexity will ultimately be inadequate, as the optimum approach will always depend of the specifics of the task the interactive system is intended to support (Carmichael 1999). This is one of the main issues that highlights the importance of early and rigorous user involvement in the design of interactive systems, and is particularly important in the case of young designers developing interfaces for older users and those with cognitive impairment.

37.4.4 Design to Support Attention Deficit

In many software systems, the user is required to do more than one thing at a time, and this can simply demand more cognitive resources than are available. However, declines in the efficiency of divided attention can mean that, even if the tasks involved demand no more than the resources available, they may not be allocated appropriately. Interactive systems should be designed to relieve the user of this kind of burden. It is difficult to be prescriptive about suitable solutions to this problem, as the appropriate approach will depend on the specifics of the interaction involved, but some general concepts are useful to bear in mind. For example, the provision of some form of notepad function may be helpful for temporarily recording information for subsequent use (although great care is needed to ensure that the instantiation of such a function and its utilization does not put further cognitive load on the user). Another possibility is the provision of an overview of the task, which could show or remind the user where they are and what they have and have not done so far.

37.4.5 Design to Support Older People with Memory Loss

Limitations in memory particularly affect older people. Thus, wherever practicable, interactive systems should be designed to take the burden of memory off the user, for example, by judicious use of prompts and reminders. Also, careful consideration of the steps in an interaction and the way they are presented to the user can help mitigate the most common problem of deficient STM and WM. Even with the best design efforts, however, such problems are likely to make users with cognitive impairment relatively error prone. It is thus essential to ensure that the interactive system allows for error correction in an easy to use form. To ensure that the user spots such errors, the system should provide feedback regarding user actions and where appropriate elicit active confirmation from them.

Difficulties with complex page navigation are interpretable in terms of STM and processing changes. Clear and consistent on-screen layout and navigation, therefore, are hallmarks of good design for older adults (Arch 2008; Carmichael 1999; Charness and Bosman 1994; Coyne and Nielson 2002; Holt and Morrell 2002). In the design of web pages, consistent navigation of pages within a site and clearly structured information can reduce problems. Providing feedback about the entire sequence of a multistep event, such as when making online purchases could prove beneficial. Searching can be improved for older adults by nonhierarchical interfaces. Difficulties with browser basics such as the back, history, bookmarks, and search can all be understood as complex activities that tax limited cognitive systems. Better-supported information about visited sites and searched sites is crucial for older users. With interactive systems, other specific remedies to support users have been suggested. For example, judicious use of prompts have been shown to be helpful (Zajicek 2003).

In addition to memory problems, other fluid intelligence abilities that can cause difficulties for older technology users are visuo/spatial, perceptual, and speed of processing abilities. Decline in such abilities can cause difficulty with decoding layouts and utilizing any inherent organization of websites. Difficulties of navigation are exacerbated, particularly in web 2.0 content, by dynamic changes ("change blindness" being particularly strong for older adults), difficulty in identifying clickable areas, and lack of help for ever-changing content.

As declines for older people are often in more than one area, their combination can make accessibility more challenging than for users having only a cognitive limitation. Consider, for example, an older adult who has STM loss, as well as failing eyesight. Trying to learn the commands needed for specialized software to see or have on-screen material read aloud (such as with a screen readers) presents a challenge (Zajicek 2007). Specialized software can present a double burden for learning: both the desired application as well as the specialized software must be learned at the same time. Given problems with STM, the learning task can be significantly more difficult. Understanding the complexity of problems experienced by older adults and how these problems interact, and the "dynamic diversity" of user needs (Gregor, Newell, and Zajicek 2002), is critical to understanding the needs of older adults.

37.5 COGNITIVE SCAFFOLDING AND PROMPTS FOR COMMUNICATION

Augmentative and alternative communication (AAC) are systems which facilitate communication by nonspeaking people. These normally use speech synthesis technology to speak text which is inputted by the user. For severely physically impaired nonspeaking people, even with current speech output technology, however, speaking rates of 2–10 wpm are common, whereas unimpaired speech proceeds at 150–200 wpm.

In an attempt to improve this disparity, some progress has been made by using computers to replace or augment some of the cognitive aspects of communication. One sequence of AAC research projects took as its starting point the improvement of communication systems for physically impaired nonspeaking people. It became apparent that this could be done very effectively by developing models of the cognitive tasks involved in communication. This research has now spawned a new area of development, which is cognitive support for people with dementia, where communicative impairment is just part of their range of difficulties (see Section 37.8).

Although the cognitive processes underlying language use are incompletely understood, a number of theories that attempt to explain language use have been utilized to improve the functionality of communication systems for nonspeaking people. This approach to the problem usually involves taking a sociolinguistic view of language. Instead of focusing on the building blocks, or taking a bottom-up approach, the interaction as a whole is analyzed, paying attention to its goals, or taking a top-down approach to the communication. This may well be a realistic simulation of the natural process, since the production of speech by an unimpaired speaker occurs at such a rate that conscious processing and controlling of the speech at a microlevel is not possible. In common with other learned skills, speech is produced to some extent, automatically, with the speaker being aware of giving high-level instructions to the speech production system, but leaving the details of its implementation to the system.

The nonconscious control of much of speech production has been modeled in the CHAT (conversation helped by automatic talk) prototype (Alm, Arnott, and Newell 1992). This produced quick greeting, farewell, and feedback remarks by giving the user semiautomatic control of what form the remarks would take, within parameters that the user had previously selected. This mimicked the phenomenon of a speaker responding automatically to greetings and other commonly occurring speech routines, without giving the process any detailed thought.

The CHAT-like conversation described illustrates an attempt to achieve a particular communicative goal, achieving social closeness by observing social etiquette. Some recent research efforts have been directed at finding ways to incorporate large chunks of text into an augmented conversation, to help users carry out topic discussion. This has been driven by the observation that a great deal of everyday discourse is reusable in multiple contexts.

Much of this type of discourse takes the form of conversational narratives. Research into the conversational narrative at a sociolinguistic level indicates several interesting characteristics. These include the way in which narratives are told and to whom they are told. For example, a recent event is told repeatedly for a limited time to most people with whom the speaker has contact. As the event recedes in history, the narrative is retold when it is relevant to the topic of conversation. The length of the narrative depends on its age (the older a story is, the more embellished it can become, particularly if it has previously gone down well) and the time available within the conversation. The version of the story (the sequence of events may remain the same while the details or embellishments of a story can differ) depends on factors such as the conversational context and other interlocutors present.

One of the ways to make the retrieval of text chunks easier is to anticipate the chunks that the user may want to use. This has been achieved by modeling conversational narratives using techniques from the fields of artificial intelligence and computational linguistics (Waller 1992). The prototypes developed constantly adapt to the users' language use, thus mirroring the user's perception of where conversation items are stored. In this way, the system adapts to the way the user thinks instead of having the user learn a new retrieval system.

One of the arguments against using such prediction was raised when word prediction systems were first developed in the early 1980s. Therapists and teachers were concerned that nonspeaking people, especially children, would select what was offered on the screen rather than what they originally wanted to say. Although this may happen, research into predictive systems applied to writing suggests that they may carry over the help they offer and have a wider effect on the users' ability development. Some of this research reports an increase in written output by reluctant writers and people with spelling problems (Newell et al. 1992). A general improvement in spelling has also been noted. Children with language dysfunction and/or learning disabilities have shown improvement in text composition (Newell, Booth, and Beattie 1991). This research is in the writing domain, but the results suggest that predictive systems can offer assistance without becoming mere substitutes for creative expression.

Also, in unimpaired conversation speakers often change direction in their communication depending on chance occurrences, or on the sudden recollection of a point they would like to include. Thus, there is a degree of opportunism in all conversations. Another argument in favor of offering predicted phrases and sequences is that the current situation for most augmented communicators is that their conversations tend to be quite sparse, with control tending to reside with unaided speaking partners. If it is not possible to go boating on the lake, easily going off in any direction you please, is it not preferable to build a boardwalk out over the water than to stay on the shore?

One of the motivations to improve communication systems for nonspeaking people is the fact that they are commonly perceived by people who do not know them as being less intellectually capable than they actually are. It is often reported by nonspeaking people that they are considered unintelligent or immature by strangers. The issue of perceived communicative competence is one that needs increased attention (McKinlay 1991).

Related to this, an interesting finding emerged from work in which one of the authors was involved. Here, a prototype communication system was used to evaluate listeners' impressions of the content of computer-aided communication based on prestored texts, compared with naturally occurring dialogues. The nonspeaking user was able to use only prestored texts to conduct the conversations. Most of the text was material about one subject (holidays). A number of rapidly accessible comments and quick feedback remarks were also available. The unaided conversations were between pairs of normally speaking volunteers who were asked to converse together on the topic of holidays. Transcripts of randomly sampled sections of the conversations and audio recordings of reenactments of the samples with pauses removed were rated for social competence on a six-item scale (coefficient alpha 5 0.83) by 24 judges. The content of the computer-aided conversations was rated significantly higher than that of the unaided samples ($p < .001$). The judges also rated the individual contributions of the computer-aided communicator and the unaided partners on how socially worthwhile and involving these appeared. There was no significant difference between the ratings of their respective contributions ($p > .05$; Todman, Elder, and Alm 1995).

This finding came as something of a surprise to the researchers, since the original purpose had been to establish whether conversations using prestored material would simply be able to equal naturally occurring conversations in quality of content. Of course, the pauses in actual computer-aided conversation (removed in the above analysis) do have an effect on listeners' impressions of the quality of the communication, but this finding is of interest, since it suggests that, in some ways, augmented communication could have an edge over naturally occurring talk. A plausible explanation for this finding is that naturally occurring talk is full of high-speed dysfluencies, mistakes, substitutions, and other messy features that listeners tend to discount with their abilities to infer what the speaker is intending to say. Prestored material is by its nature selected because it may be of particular interest, and it is expressed more carefully than quick flowing talk, and thus may appear more orderly and dense with meaning than natural talk.

In addition to conversational narratives, another common structure in everyday communication is the script, particularly where the speaker is undertaking some sort of transaction. Scripts may be a good basis for organizing prestored utterances to attempt to overcome the problem of memory load when operating a complex communication system based on a large amount of prestored material. Users' memory load can be reduced by making use of their existing long-term memories to help them locate and select appropriate utterances from the communication system. Schank and Abelson (1977) proposed a theory that people remember frequently encountered situations in structures in long-term memory, which they termed scripts. A script captures the essence of a stereotypical situation and allows people to make sense of what is happening in a particular situation and to predict what will happen next. Other research (e.g., Vanderheiden et al. 1996) has shown the potential that similar script-based techniques offer to this field.

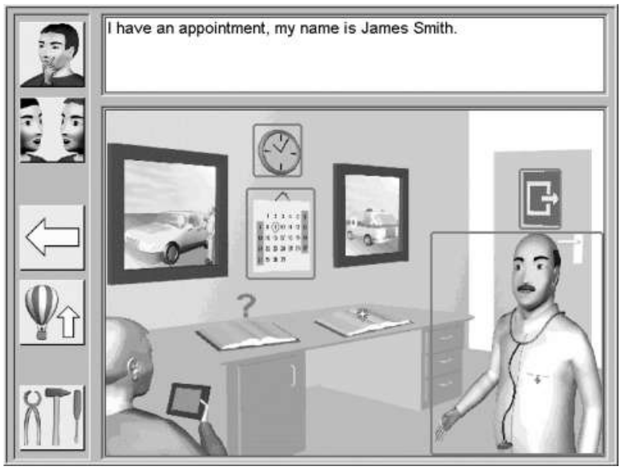
An initial experiment was devised (Alm, Morrison, and Arnott 1995) to investigate the potential of a script-based approach to transactional interactions with a communication system, and a prototype system was developed to facilitate this experiment. The aim was to ascertain whether or not a transactional interaction could be conducted using a script-based communication system. It was decided to simulate a particular transactional interaction that could reasonably be expected to follow a predictable sequence of events, for example, one that would be amenable to the script approach, to find out whether a computer-based script could enable a successful interaction.

The transaction chosen for the experiment was that of arranging the repair of a household appliance over the telephone. Although the script interface was a relatively simple one devised for the purpose of this experiment, it was successful in facilitating the interaction, and produced a significant saving in the amount of physical effort required.

To take this work further, a large-scale project was undertaken to incorporate scripts into a more widely usable device. The user interface of this system is made up of three main components as follows: (1) scripts, (2) rapidly produced speech acts, and (3) a unique text facility. The scripts component is used in the discussion phase of a conversation and consists of a set of scripts with which the user can interact. The rapid speech act component contains high-frequency utterances used in the opening and closing portions of a conversation and in giving feedback and consists of groups of speech-act buttons. This facility is based on previous work with CHAT. The unique text component is used when no appropriate prestored utterances are available and consists of a virtual keyboard, a word prediction mechanism, and a notebook facility.

To provide access to a set of scripts, an interface was devised that involved a pictorial representation of the scenes in the script. The pictorial approach was taken to give users easier access to the stored material and to assist users with varying levels of literacy skills. In this interface, scripts are presented to the user as a sequence of cartoon-style scenes. The scenes give the user an indication of the subject matter and purpose of the script and assist the user to assess quickly if the script is appropriate for current needs. Each scene is populated with realistic objects chosen to represent the conversation tasks that can be performed. Thus, the user receives a pictorial overview of the script, what happens in it, and what options are available. This assists the user to see quickly what the script will be able to do in the context of the current conversation. An example of the interface for the system is shown in Figure 37.1, which shows a scene within the doctor script.

Research into picture recognition and memory structures has demonstrated that groups of objects organized into realistic scenes corresponding to stereotypical situations better assist recognition and memory compared with groups of arbitrarily placed objects (Mandler and Parker 1976; Mandler 1984). The scene-based interface using a realistic arrangement of objects within a scene was therefore chosen to facilitate recognition and remembering by the user and thus reduce the cognitive load required to locate suitable objects during a conversation.



I have an appointment, my name is James Smith.

FIGURE 37.1 The script system user interface showing a scene from the doctor script.

As it would be impractical to provide scripts for every conceivable situation, it was decided to provide users with a limited number of scripts together with an authoring package with which they can develop their own custom scripts with help from their therapists.

A text preview and display box appears at the top of the user interface. The main interface area (bottom right) contains the scene image. The function buttons on the left side of the interface are, from top to bottom: “I’m listening” rapid speech-act button; button to access the main rapid speech-act interface; scene navigation backtrack to previous scenes button; scene navigation overview button; and tool button to access the notepad and additional system control facilities.

It was initially decided to develop six complete scripts. These were chosen after discussions with a user advisory group about situations in which they found difficulty communicating. The scripts developed were at the doctor, at the restaurant, going shopping, activities of daily living (ADL), on the telephone, meeting someone new, and talking about emotions.

The system uses the script to guide the user through a dialogue. There is a prediction mechanism, which predicts the next most probable stage in the dialogue that the user will need (based on the script), so the user can usually follow a predicted path through a conversation. This prediction mechanism monitors the sequences of objects selected and uses this information to modify future predictions.

Despite encouraging results with prototypes, the phrase-storage approach to social communication set out above has not gained widespread acceptance by users. The reasons for this are complex, but include: the relative inflexibility of prestored material; the costs associated with authoring the material and keeping the material up-to-date; and the vastly different nature of the approach and different training requirements necessary to achieve success.

37.6 SUPPORT FOR PEOPLE WITH COMPLEX COMMUNICATION NEEDS

AAC systems can be used when a physical disability alone precludes speech. Such systems can also provide methods to compensate (either temporarily or permanently) for the impairment and disability patterns of individuals with CCN. Some individuals will learn to read and write using traditional orthography (spelling) in combination with nonverbal means (e.g., facial expression) to communicate, and many AAC interfaces use traditional orthography (the written word). However, children with CCN are at great risk of not acquiring literacy. Visual images, photographs, and drawings are used to provide augmentative and alternative ways to access communication. Such images can be used to enhance text-based interfaces. In addition, sets of symbols (e.g., the Picture Communication System, PCS, Rebus, and semantic-based writing systems such as Blissymbolics), can be used as an alternative to text (Beukelman and Mirenda 1998; Wilson 2003). The type of picture, symbol, or graphic used will depend on the iconicity (ease of recognition), transparency (guessability), opaqueness (logic organization), and learnability of the image. For instance, a photograph of a house may be transparent—for example, it is easily recognizable—while a Blissymbol (see below) representing the emotion of happy has logic (heart five feeling; up arrow five up) and is thus opaque and requires learning (see Table 37.1). The more concrete a representation, the more recognizable it will be. However, representations of abstract meanings, such as emotions, will involve less-transparent images necessitating a longer learning curve (see Table 37.1)

One of the many challenges in the field of AAC is to provide novel, appropriate vocabulary for nonliterate children with CCN. Conventional speech output communication systems rely on literate helpers to store static vocabulary. This restricts the vocabulary of users as generation of new words require literacy skills. The ongoing BlissWord project (Andreasen, Waller, and Gregor 1998) is investigating ways in which users with physical and cognitive limitations can explore new vocabulary. Blissymbolics is a semantic-based natural written (graphic) language, similar to Chinese. Because of its generative characteristics (BlissWords are spelled using a sequence of one or more Bliss characters), predictive algorithms can be applied to Blissymbolics to assist users in the retrieval of words. BlissWords are sequenced beginning with a classifier (e.g., all emotions begin with a heart). As illustrated in Figure 37.2, selecting a shape from the Bliss keyboard, the interface produces a list of BlissWords which begin with classifiers using that shape. Frequency and word lists can be used further to refine the BlissWords that are displayed. Users do not need to be literate to explore language and vocabulary. It is envisaged that video clips and spoken explanation could further augment learning through exploration.

37.6.1 Use of Natural-Language Generation Techniques

Natural-language generation (NLG) is an area of research in natural language processing by computer. NLG systems have been harnessed to support language development for children with language disorders by providing opportunities to extend both their vocabulary and the type of conversation in which they can engage (Waller 2006). The STANDUP project (Waller et al. 2009) demonstrated the use of pun generating technology for children with CCN. A graphic-based interface

was designed to provide children with independent access to novel puns. An evaluation of the system with nine children with cerebral palsy showed that all the children were able to generate increasingly sophisticated puns. Language tests administered before and after a 4-week intervention program indicated an increase in the children's ability to categorize words into groups. Although no generalization can be made, it suggests that such systems can have an impact on underlying cognitive and language abilities.

Another project focusing on narrative illustrates how NLG can support the reporting of personal experience within conversations. Although it is relatively straight forward to provide script-based interactions and novel puns, conversational narratives emerge spontaneously within interactions. Early research into narrative has shown that nonspeaking individuals and their caregiverss had great difficulty in anticipating what personal experiences might make a good story (Waller et al. 1997). NLG systems which generate texts in English and other human languages from nonlinguistic input (Reiter and Dale 2000) can provide access to personal experience without the need for others to input information, especially when users are not literate. The "How was school today?" project (Reiter et al. 2009; Black et al. 2010) has produced a working prototype which uses sensor data to generate stories for conversations.

The prototype was developed in a special needs school which provided a constrained research environment. The system had access to three kinds of input as follows: (1) location, (2) interaction, and (3) voice messages. Location data was acquired automatically by using a radio-frequency identification (RFID) sensor which picked up RFID tags on doors while interaction data was provided by teachers who swiped cards through an RFID reader. Teachers could also record voice messages about interesting events during the day. The input data (filtered to reduce noise) was analyzed by a knowledge-based system which had access to a domain knowledge base and the child's daily timetable; this system identified a small number of reportable (i.e., interesting in the narrative sense) events. These were displayed (using graphical symbols) as a timeline; an editing interface allowed the child to delete events she did not wish to discuss, and also to add simple evaluations (annotations) such as "I liked it." Finally, a narration interface allowed the child to narrate the story. This interface was designed to support interactive story-telling, allowing the child to narrate events in any order and to add additional evaluations.

Results showed that this type of technology can both enhance interactive conversation and support storytelling skills and memory sequencing. The system could support simple but effective interaction and story-telling, enabling users to engage in extended conversations, rather than responding using single-word responses.

Reiter et al. (2009) have been exploring the use of NLG to produce conversational utterances in communication support systems designed for social interaction. The aim is to automate the production of readable or listenable text from abstract information held by the system. In the case of a communication system for a physically disabled nonspeaking person, the user would input only a small amount of information, which the system could then expand into a large number of utterances.

It is possible that using NLG might address some of the difficulties observed in prestorage systems. For instance, the generation component could theoretically produce a range of utterances and speech act types automatically from the same underlying data and adapt these somewhat to the interactional context. Using NLG would also have the benefit of offering control over the well-formedness of the output, an important consideration given the difficulty some AAC users have in achieving literacy. The fact that the system has an inherent awareness of the semantic content of the linguistic output, rather than simply being stored as canned text, is also a potential benefit. In other words, NLG might offer a level of automaticity and flexibility that traditional prestorage systems cannot offer, as well potentially as reducing the level of pre-authoring required from the user.

A growing line of inquiry in the NLG community is the generation of language from ontologies (Mellish and Sun 2005). An ontology is a logical and hierarchical model of the different concepts and the nature of relationships between concepts in a particular domain. These concepts and relationships can be mapped onto linguistic constructs to allow for the production of natural language descriptions of parts of the ontology. In a prototype AAC system, conversational topics that would be of interest in social conversation between users of the system and their co-conversationalists are modeled with ontology. The current categories of topic include travelling, listening to music, visiting the cinema, and attending concerts. Many categories are based on a simple event model that defines the basic characteristics common to all events, such as a time of occurrence. Concepts such as "person and place" are included, which are associated with events, to form a logical model of a particular event type. A separate knowledge base is created unique to each user which is linked to the original model. This is filled with data inputted by the user. In essence, what is being modeled is the Who, What, Where, When, and Why of different topics so that a set of utterances can be produced which describe them.

The knowledge base is then turned into useful conversational utterances through a template-driven utterance generation system. A large set of templates has been authored which convert the computer representation into natural language utterances. The templates are created as concrete syntax trees containing unspecified "slots" and parameters (figure). These syntax trees map out the syntactic structure of the template and are linked to a particular class in the ontology so that only appropriate templates are applied to each individual. Slots are used to add contextually relevant clauses to our utterances. For example, a template might contain a "time" slot, the contents of which are derived from the time of the event in question. For instance, the slot might be filled with "next Tuesday evening," "a month ago," or "this morning," depending on the context. Example parameters include the tense with which the utterance should be generated, and whether a pronoun or full noun phrase should be used to refer to the subject of the utterance.

Iterative evaluations of the system so far have concentrated on training the users in its operation, updating conversational material, and implementing changes based on the user feedback. In initial trials, it has been found possible to hold pleasing conversations lasting around 10 or 15 minutes with unfamiliar partners, with the aided communicator speaking at a rate of around 35–40 wpm. There also seems to be higher incidences of initiations on the part of the user, with them making good use of both the scripted NLG material, the quick fire phrases (including the contextual quick fire phrases), and their own prestored material. The topic progression feature is currently being underused but the users are responding well to training sessions on how best to use this to reduce their response time.

37.7 SUPPORT FOR APHASIA

Communication systems for nonspeaking people have been described, which in some way model the cognitive processes underlying communication. In the case of most physically disabled nonspeaking people, this is needed to speed up the communication process. However, in the case of speech problems that are caused by a stroke or other trauma (aphasia), the person trying to communicate will also have cognitive problems to deal with. Interestingly, the objections that conversation modeling might provide an active prompt to communication suggested a way of possibly helping people who might need such a prompt to initiate communication at all.

In a research project investigating the possibility of prompting people with Broca's aphasia in their communications, a predictive communication system was developed with a very simple interface (Waller et al. 1997). The system held personal sentences and stories, which were entered with the help of a caregiver. The user could then retrieve the prestored conversational items, with the system offering probable items based on previous use of the system. The interface was designed to be as simple as possible and to be usable by people who were unfamiliar with technology, had language difficulties, but had retained the ability to recognize familiar written topic words.

To access the sentences and stories, the user is led through a sequence of choices on the screen. First, they are offered a choice of conversational partners, a list of topics most likely to be appropriate for the chosen partner, and then a list of the four most common sentences for that partner and that topic. The user can choose to speak one of the sentences through a speech synthesizer, or have the system look for more suggestions. The sentences and topic categories are personal to each user, and the order in which topic words or sentences are presented depends on the past use of the system. Thus, the system is specific to users, both in the information content and in how it adapts to individual ways of communicating.

The system was evaluated with five adults with nonfluent aphasia, who were able to recognize but not produce familiar written sentences. There was little change in the underlying comprehension and expressive abilities of the participants while not using the system. When making use of the system, the results showed that some adults with nonfluent aphasia were able to initiate and retain control of the conversation to a greater extent when familiar sentences and narratives were predicted. In other words, users' existing/residual abilities (e.g., small vocabulary, pragmatic knowledge of conversation) were to a degree augmented by the computer functioning as a cognitive prosthesis. This project indicated that a communication system based on prompting could be of help to people with cognitive and communication difficulties.

37.8 SUPPORT FOR DEMENTIA

Dementia, which involves the loss of short term memory (STM) in elderly people, is a very serious problem for the person and for their families and caregivers. It can rule out most social activities and interactions, since these depend on a working STM for effective participation. This includes even the essential ability to communicate.

37.8.1 Support for Reminiscence

As well as being valuable with all older people, reminiscence is an important tool used to help elderly people who have dementia (Sheridan 1992; Feil 1993). This is because, while their short-term memories may be impaired, their long-term memories are often more or less intact (Rau 1993). The difficulty is accessing these long-term memories without the capability of keeping a conversation going, which depends on STM. Activities that do not require patients to maintain the structure of a conversation can help, for instance, looking at and commenting on a series of photographs, which can provide a framework for meaningful person-to-person interaction.

The tools used in such reminiscence work can also include videos, sound, music, and written materials. However, traditionally these are all in separate media, and it can be very time-consuming searching for a particular photo, sound, or film clip. Bringing all these media together into a digital multimedia scrapbook could mean easier access to content for more lively reminiscence sessions.

An investigation was undertaken to determine which aspects of multimedia would be most helpful for such a reminiscence experience, and the best way to present them. The intention of this project was to develop a system that could act as a conversation prosthesis, giving the user the support needed to carry out a satisfying conversation about the past. A number of prototype interfaces for a multimedia reminiscence experience were developed. These included text, photographs, videos, and songs from the past life of the city. The materials were collected with the assistance of the University, Dundee City archives, and the Dundee Heritage Project. The prototypes were demonstrated for people with dementia and their care staff at a day center run by Alzheimer Scotland Action on Dementia. The following issues were addressed in the following evaluation sessions:

1. Is it better for the display to use the metaphor of a real-life scrapbook or a standard computer screen? Six of the staff members preferred the book presentation, three preferred the screen, and two had no preference. Interestingly, this was almost a reversal of the preference shown by the people who had dementia, with the majority preferring the screen presentation. The preference shown for the screen presentation could be due to reduced cognitive ability. The book presentation is a metaphor that may not be interpreted suitably by the person with dementia.
2. How should the scrapbook material be organized—by subject or by media type? The majority of the staff evaluators preferred the arrangement by subject saying it was more logical, some were unsure; however, no one showed a preference for the arrangement by media. The clients with dementia reflected these findings. Despite preferring the arrangement being by subject, the majority of evaluators could see benefits from having access to both arrangements. It was concluded that for basic reminiscence sessions the arrangement by subject is preferable. But access to the arrangement by media should be an option, to make the software available for use in other ways.
3. How do the sounds, pictures, video, and music add to the reminiscence process, and what are their differential effects? Most of the videos and photographs and all the songs were able to spur conversations. However, it was found that with videos the clients were able only to identify strongly with them when they triggered off specific personal memories, whereas songs and photographs were more generally appreciated. Attention remained focused longest on the songs, which were particularly enjoyed when played repeatedly with everyone singing along. However, the staff felt that some individual clients had enjoyed the videos most.

One general finding was that the multimedia presentation as a whole produced a great deal of interest and motivation from the people with dementia. The staff was also very keen to see the idea developed further. In addition to its benefits for the person with dementia, participation in reminiscence activities has been shown to have a positive outcome for the caregivers who take part. Thus, help for reminiscence is not only a tool to stimulate interaction, but also a contributor to improved quality of life for the person with dementia and his or her family.

Recent work on using videos to present life histories for people with dementia has shown that new technologies, where sensitively and appropriately applied, can bring a substantial added impact to supportive and therapeutic activities for people with cognitive problems (Cohen 2000). We hope the reminiscence system developed will have the immediate application described above and will also serve as an exploration in developing a range of computer-based entertainment systems for people with dementia.

On the basis of this preliminary work, a communication support for people with dementia was developed (Alm et al. 2007). The system, called computer interactive reminiscence conversation aid (CIRCA), consists of a hypermedia structure with reminiscence material as content. It contains photographs, music, and video clips, all from the years 1930–1980. The system attempts to relieve the caregiver or relative of the job of continually supporting the person with dementia in a conversation. An obvious advantage of a computer-based system over using traditional materials is the bringing together of the various media into one easily accessible system. It was also speculated that such a hypermedia structure could in some way mimic the way memory is used in conversations, thus presenting the material in a way that seems natural in the context of a conversation.

An iterative design approach was used to develop the first prototype. Forty people with dementia were identified who expressed an interest in helping us to design and evaluate the system. Thirty relatives and caregiverss also agreed to take part as advisors and evaluators for the project. As a first step, the group commented on suitable content for the system, and ideas for themes which the system might include (such as national events, local industries, street life, and celebrations) were suggested by means of high-quality photographs. Using the photographs, discussions were held with people with dementia and their caregivers to help decide on the best choices for content for the system.

Based on feedback from the user population, the three themes chosen for the prototype were as follows: (1) recreation, (2) entertainment, and (3) local life. The system allowed the users to select and play video clips related to the theme selected. The video clips had a short duration because people with dementia may not be able to follow a long video clip because of their working memory (WM) problems. In addition, these clips were intended to act as conversation prompts and not be too immersive.

The system allowed the users to select and play music related to the theme selected. Music has proved be a powerful stimulant to long-term memory. Often people with dementia who have stopped speaking can be engaged by music and can proceed to sing entire songs word perfect with evident enjoyment. The difficulty in presenting musical prompts is the physical process of accessing a particular song and playing it without having to set up equipment and materials beforehand. Having touch-screen access to songs and music provided an instant way to produce a wide variety of musical prompts. Work by another research group on a touch screen "Picture Gramophone" with images as buttons to access music has established the usefulness of making familiar music instantly accessible for people with dementia (Topo et al. 2004). Rather than simply having a static screen while the music played, the system displayed the type of device that particular music would normally be coming from, with animated movement where appropriate. A record player, radio, or tape recorder was displayed depending on the theme selected. This representation of the music producing device acted as a conversation prompt in itself.

A series of evaluations were performed during the development of the prototype, and of the final prototype version. The prototype was evaluated with people across the range of dementia severity. People with mild to moderate dementia were able to make full use of the system. More severely affected people could not actually engage with changing the system display, but did show a marked reaction to any musical items which came up. The fact that music can reach even those with severe dementia is well known, but the difficulty of accessing music without setting up an organized session for it means that less music is used than caregivers would ideally like. The system was used both in one-to-one sessions and as the center of a group activity. CIRCA was used under conditions of close observation and also left at a residential facility for an extended period, with staff instructed to make whatever use of it they liked. Comparisons were made between sessions involving other enjoyable activities and sessions using the prototype.

One particular question was how using the prototype would compare with traditional reminiscence sessions. The original intention was to make the running of such sessions easier by means of multimedia accessed through a touch screen, and also to establish whether an interactive system had advantages over traditional reminiscence sessions. In a series of videotaped, transcribed, and coded evaluation runs, the system was compared directly with traditional reminiscence sessions. In a traditional session, the caregiver takes the responsibility for guiding the session, and at all points must compensate for the WM problems of the person with dementia. The system was designed to take over the role of supporting the cognitive abilities of the person with dementia, freeing the caregiver to take part in the session more naturally. Each person with dementia and their caregiver undertook a 20-minute reminiscence session: half using the prototype, and half using traditional reminiscence methods. As expected, the caregivers did most of the direct operation of the touch screen. However, both had their attention held by the displays on the screen and the caregiver was often prompted and directed by the person with dementia. With encouragement, a number of people with dementia also made direct use of the touch screen to make selections.

In a comparison with CIRCA with traditional reminiscence aids, it was found that the person with dementia was offered a choice of reminiscence subject/materials more often when using CIRCA ($U = 1.50$, $p < .001$). It was also found that the person with dementia chose reminiscence subjects/materials more often when prompted when using CIRCA ($U = 3.60$, $p < .001$). The traditional sessions were characteristically a series of one question from the caregiver followed by one response from the person with dementia. The CIRCA sessions were more of a conversation, with each person contributing an equal amount, and control of the direction of the conversation being shared. The caregivers asked more direct questions when using traditional reminiscence methods ($U = 5.00$, $p = .01$).

It was expected that providing reminiscence materials in a multimedia format on a large but not intimidating touch panel would have some advantages over traditional methods of delivering a reminiscence session. Reminiscence sessions are known to be valuable, but are not carried out as frequently as would be desirable, because of the preparation time necessary. Also they are normally performed as a group activity, because of considerations of the economies of staff time and availability. One-to-one reminiscence sessions could be very successful, but are not often possible in care settings. Demonstrating and evaluating the system elicited entirely positive reactions from care staff and relatives.

37.8.2 Making Music

Making music is a form of pleasurable communication that requires WM to perform. A project to develop a cognitive scaffolding to allow a person with dementia to compose and perform their own music has been developed, based on a simple but engaging touch-screen interface (Riley, Alm, and Newell 2009).

The system is called Express Play. The user is invited to select a mood (happy, sad, or angry), and then move to one of three screens where they can play either happy, sad, or angry music. The user is then prompted to "drag [their] finger around the screen to play music." When the screen is touched, two types of instant feedback are given simultaneously—audio and visual—and so users hear a chord playing while also seeing a trail of circles appear on the screen under their finger. These circular shapes not only provide instant and constant feedback, but also add interest to the screen. As the user's finger moves, so they begin to draw on the screen, leaving a trail of circles behind. This visual trail provides a continuous prompt that something happens when the screen is touched. This kind of prompting is particularly important for those with severe WM loss.

As the user touches different areas of the screen, chords play of different pitch and volume. Moving up the screen causes the pitch of the chord to become higher, whereas moving down the screen causes the pitch to become lower. The intention here was to provide an intuitive interface where a "higher" note was "higher" up the screen. Volume is dependent on where the user touches the screen on the horizontal axis. As the user moves to the right, the sound will become louder, and as they move to the left the sound will become quieter, in keeping with the normal stereotype of a volume control. As the intended user may have a hearing impairment, volume has been set so that it does not fall below a certain value. During use, if a finger is dragged from the top of the screen to the bottom of the screen, a passage of chords will be played in sequence (starting with a high pitched chord that will gradually get lower). The music produced should sound both harmonious and musical. By touching different parts of the screen, users will play chords of different pitch and volume and may be able to develop a tune, while also playing music that portrays the mood initially selected.

The system was developed iteratively, with the participation of people with dementia and caregivers throughout. A final formal evaluation was carried out to establish whether the system provided engagement, novel music (i.e., that it supported creativity), and music which was particular to each individual. In all three of these aspects, the system showed a positive effect (Riley 2010).

37.9 SOFTWARE TO SUPPORT DYSLEXIA

Both research and commercial software applications have been developed to alleviate some of the problems of dyslexia. Such software tends to provide options, for example, to have on-screen content read aloud and allow text adaptations such as color contrast, text size, and spacing between words and lines of text (e.g., Elkind 2009; *Web Design for Dyslexic Users* 2009). Such manipulations reduce problems with color contrasts and visual crowding and can reduce the amount of clutter on a page. In addition, there is strong evidence to suggest that the use of lexical and spelling aids can greatly assist with spelling problems exhibited by dyslexics (e.g., Newell and Booth 1991). However, merely highlighting an incorrect word and offering a replacement may not be enough, because one of the other problems that some dyslexics face is an inability to tell if a word looks right, thus they will have difficulty in selecting the appropriate corrections.

The importance of providing the ability for individual users to make changes for their own needs is highlighted in research with this population, showing great individual variability, for example, in the font options when using software that allows them to adapt pages to their own needs (Gregor and Newell 2000; Hanson et al. 2005). The following description of the development of one research tool for use by dyslexic readers is illustrative of this need for individual solutions.

The approach adopted in this research by Gregor and Newell (2000) was to offer dyslexic users a range of appropriate visual settings for the display of a word processor, together with the opportunity to configure easily the way in which text is displayed to them. The user can select, by experimentation, the settings that best suit them. These settings are then saved and later recalled each time that person uses the word processor. It will be seen that this approach affords the potential to make computer-based text significantly easier to read than printed text, as well as improving the usability of computer word-processing systems for a wide range of dyslexics.

The first stage of the research was to develop an experimental text reader. This prototype presented the user with an easily configurable interface, which allowed for a number of display variables to be altered. Initially, these were background, foreground and text colors, font size and style, and the spacing between paragraphs, lines, words, and characters. The interface was designed in such a way that it gave visual feedback on selections before they were confirmed and made minimal use of text instruction.

This was evaluated using 12 computer literate dyslexic students from higher education using think-aloud techniques, as well as questionnaires and interviews. At various development stages, the helpers were asked to try out the system with a view to seeing if it was possible for them to put together a display, which improved their abilities to read text from the screen. All the users were able to find a setting that was subjectively superior for them to standard black text on a white background with Times Roman 10- or 12-point type, but the screen layouts that were developed by the test subjects were extremely varied. This highlighted the individual nature of the disorder, and the diverse characteristics of any interface that would be appropriate for this group.

Each appeared to have a favorite color combination, although brown text on a green background was liked by all the testers. Subjects were in greatest agreement about the selection of a typeface: Sans Serif. Arial was rated the best by almost all the testers. All reported that increasing the spacing between the characters, words, and lines was beneficial. The most interesting point that arose during the testing, however, was the fact that at the beginning of the evaluation period the dyslexic subjects did not appear to be aware that altering these variables might be of any use.

A second prototype was then developed based on Word for Windows (Microsoft 1994, 1995) macros to provide the required configuration interfaces. This was based on the concept of an evolutionary system, rather than a fixed prototype. It was clear that there would be a substantial advantage in developing a dyslexic configuration, but this design decision raised an interesting deviation from the received wisdom of the desirability of WYSIWYG (What You See Is What You Get). In the case of a dyslexic user, what you see should be whatever you can read best, and print previewing facilities would have to be used to show how the layout will appear when printed.

This prototype provided a facility to enhance characters prone to reversals (e.g., b, d), by using color font type and size. This idea of coloring reversal characters provided very interesting and unanticipated results, which are described below. Fixation problems were tackled by reducing the page width, and a speech synthesizer that could read the text on the screen was included.

There were two distinct parts to the overall solution, a preference program and a reading/editing program. The first allowed users to experiment with the various parameters and the second made use of these preferences within a reading and editing environment. The preference program menu presents the user with various options and variables, together with a preview facility, to enable the user to experiment with, and finally store his or her data in a preferences file.

The fact that a unique user environment tailored to the need of each individual is provided means that the document is (deliberately) not WYSIWYG. A print option thus allows the user to print the document as it appeared with his or her preferred formatting applied to it, or as it would appear without any special formatting.

This second prototype was developed as an add-on module to Microsoft Word, and was evaluated by seven dyslexic users of 15–30 years old, in a similar fashion to that above. The users found the system easy and intuitive to use, reporting that each of the options had an effect on their abilities to read. The options that allowed the user to change the color scheme of the document appeared to be the most helpful, but font size and spacing, column width, and indications of reversals were also reported to assist reading by some or all of the users.

The reversals option provided the most interesting results of all. However, the reason for the improvement was not always that the reversal characters were clearly distinguished and easy to read. Instead, it was claimed that the sporadic coloring broke the text up and resulted in the user being less likely to get lost, for example, the system was reducing fixation problems rather than recognition problems.

As the testing progressed, the testers appeared to be surprised at times by the effect some of the changes had on their abilities to read the document. Comments included "I would never have thought of doing that," or "I don't think that will do me much good" before finding that a feature did indeed help.

The prototypes were developed from the perspective that the user population was diverse, and that the design process must accommodate potential changes in preferences over time. The fact that dyslexia is a very idiosyncratic disorder and findings that the users were often unaware of how easy it was to improve their reading potentials by changing visual aspects of the reading environment, illustrates how a standard user-centered design methodology is not appropriate for such user groups.

This development of this word processor to assist dyslexics is thus a particularly illuminating example of how the needs of people with a particular type of cognitive impairment can be effectively factored into the design and development process. This research has been described in some depth, as an example of a development and to assist the reader in appreciating the generic importance of this approach, which requires knowledge of the underlying syndrome, and a methodology, which encourages an innovative approach to user involvement.

37.10 COGNITIVE SUPPORT FOR ACTIVITIES OF DAILY LIVING

Moderate to severe dementia can affect the ability of a person to complete basic activities of daily living (ADL). At these later stages, people are usually assisted by a human caregiver, either a family member or a professional, who monitors the activity in question and guides or prompts the person when they are no longer able to make progress. This usually occurs in situations where the person cannot recall what activity they are attempting, cannot recognize important elements of their environment, or cannot perceive affordances of the environment that are critical for the task at hand. The dependence on a caregiver can lead to difficulties including loss of independence for the person in need, and increased burden on family members and other caregivers. These problems become acute for private ADLs such as using the washroom.

These acute problems with moderate or severe dementia can be aided with computerized cognitive assistive technologies (CATs), which are devices or systems that can help this population to complete ADLs more independently by monitoring them during a task, detecting when a problem occurs, and providing assistance automatically when necessary, and in extreme cases alerting a caregiver.

The School of Computing at the University of Dundee has been building a CAT for the ADL of hand washing in collaboration with groups at the University of Waterloo and the University of Toronto. The system uses a camera mounted above a sink to watch a person with dementia who is washing their hands. The video outputs from the camera are fed to a computer vision system that tracks the person's hands and the towel, and categorizes their actions into a set of behaviors, such as *using the soap*, and *turning on the water*. These behaviors are then passed to a monitoring system that maintains a *belief* about where the user currently is in the process of hand washing. The monitoring system uses a probabilistic and decision-theoretic model known as a partially observable Markov decision process (POMDP) that maintains a probability distribution (a *belief*) over the possible states the person could be in. It updates this belief over time as new observations of a person's behavior are detected by the computer vision system. For example, if the system believes that the user does not have soapy hands, an observation of the user's hands near the soap dispenser will make it more likely that the user's hands have become soapy.

The POMDP model then maps its *belief* about the person's progress to an *action* that it can take to help. For example, if the person has not made any progress in the past few time steps, then giving an audio prompt to the person may help them start again. The POMDP decides what *action* to take from a fixed set of possibilities based on a *reward* function. This reward function indicates which outcomes are desirable and which are not. For example, in hand washing, it is good if a person gets their hands clean, but not good if they require a lot of prompting and also not good if the human caregiver needs to be called in to assist very much. The POMDP decides on an action to take based on its long-term expected reward, so can effectively trade-off between short-term gains (e.g., calling a caregiver immediately, a costly action, to get a person to finish the task quickly and with certainty) versus long-term rewards (e.g., helping a person finish on their own, taking longer but preserving feelings of independence and reducing costly caregiver burden). This trade-off is made using decision-theoretic methods, which are justifiable based on the structure of the task and the reward function.

The actions that the POMDP decides upon are then relayed on the person trying to wash their hands as either audio prompts, audio-visual prompts (on a display screen mounted above the sink), or as a call for a human to assist.

This system was tested in a long-term care facility in Toronto, Canada. Six older adults participated in the study—five women, one man, and average age 86 years. Using the Mini-Mental State Examination, five of the subjects were classified as having moderate level dementia, with the one remaining classified as severe. Eight weeks of trials were carried out with each person washing his or her hands once per day. The trails used an A-B-A-B protocol, where in A phases the subjects were assisted by a human, whereas in the B phases, the system performed the assistance. Results showed that for some users, a 100% decrease in caregiver dependence was achieved. For others, the decrease was less, but overall we found a decrease of 25% in requirement for caregiver assistance when using the system.

The results highlight the user-specific nature of such systems, in that what works for one person may not work for another for a variety of reasons. The simplest such reason is the delivery of prompts. Whereas some users found the disembodied voice from a pair of speakers to be acceptable, others found it disconcerting, and would try to find out where the voice was coming from. Some users seemed to pay attention to the video prompts, others not. More details on this system can be found in Mihailidis et al. (2008); Hoey et al. (2010a).

Our work in developing CATs for persons with dementia has extended to other ADLs (mobility, toothbrushing, cooking, and rehabilitation [Kan et al. 2011]), to creative arts therapies (Blunsden et al. 2009; Hoey et al. 2010b; Mihailidis et al. 2010), and to other user groups such as children and adults with autism spectrum disorder. We are currently developing systems for use in the home as well as for use in long-term care facilities. Key to the uptake of such technology in users' homes is the ability for the end users and caregivers to customize the systems to suit their individual needs. This customization can range from the recording of individualized prompts, to the specification of new ADL for which a person requires assistance (Hoey et al. 2011).

37.11 BEYOND COGNITIVE PROSTHESES: THE POTENTIAL BENEFITS OF "BRAIN TRAINING"

There is an emerging interest in interactive systems that support the exercising of cognition with the aim of maintaining functionality and staving off the effects of advancing age. A broad range of research has indicated that age-related cognitive decline is modifiable rather than inevitable with many (positive and negative) factors being identified as influential (see Fillit et al. [2002] for a review). Positive factors such as, physical health, life-long learning, and a range of proactive interventions have been identified as beneficial; among these is the importance of generally keeping the mind active. This has promoted the current wide and increasing acceptance, particularly amongst older adults, of the "use-it-or-lose-it" adage. Various approaches addressing the need for older adults to "use-it" have emerged both in terms of traditional face-to-face activities and also using a variety of interactive systems. Although there are some limitations in the recent research in this area, there is certainly a strong suggestion that it can have benefits for many older adults (see Salthouse [2006] for a review). However, there is notable variation in the range and extent of the impact found and little consistency between the approaches adopted and thus more work will be required to more clearly identify who will benefit from what.

Beyond the distinction mentioned above, between human- and computer-based interventions, it is also worth noting the distinction between "contextualized" and "decontextualized" approaches, which are often referred to as cognitive rehabilitation and cognitive training, respectively (Clare et al. 2003). Simply stated, cognitive rehabilitation involves identifying and addressing individual day-to-day needs and goals, and providing coaching and practice for these in concrete terms, with related training for skills and strategies such as the use of appropriate memory aids. Whereas, cognitive training involves repeated practice with sets of relatively abstract tasks that reflect particular basic cognitive functions, such as memory, attention, or problem solving, which become "strengthened" and better able to deal with day-to-day challenges generally. Thus, cognitive rehabilitation tends to be targeted at those who have already suffered noticeable (and possibly problematic) declines in their cognitive ability; whereas, cognitive training could be of benefit to virtually anyone, but particularly those concerned about the onset of "normal" age-related decline.

It can be seen that these different approaches have differential scopes of impact and challenges to their implementation. The rehabilitation approach can be effective and produce measurable improvements in the targeted skills. However, the two caveats for this are that such improvements tend to be only for the targeted skills and not for (even very) closely related ones and there is also a tendency for the improvements to be relatively short lived (Wilson 1997). This appears to be mainly due to such approaches being based upon repeated drills and rote learning, which in most contexts will produce results, but will also (particularly for older adults) make it difficult to generalize and transfer that which is learned into analogous situations. Further, without repeated practice, the skill will become less effective or simply forgotten about. There also appears to be a further limitation, at least for the rehabilitation of memory problems in that the greater the need for memory enhancement, the less the apparent benefit (Verhaeghen et al. 1992).

In terms of cognitive training, the idea is to exercise and strengthen the component cognitive abilities involved in day-to-day tasks, rather than teach or train the task itself. As mentioned above, there is some evidence that this type of approach can be beneficial, but the wide variation in the types of intervention (and subject samples, etc.) makes it difficult to draw any overall conclusions. Although there are many commercial offerings claiming to be interactive "brain training," most are no more than interactive puzzle sets and few have had their effectiveness validated. However, some are based on the relevant cognitive and neuropsychological literature and support for their effectiveness is emerging in the literature (e.g. Smith et al. [2009]). Most of these rigorous cognitive training programs are provided via PC/Internet (rather than games consoles), and thus unfortunately exclude the many older adults who cannot afford or do not want such equipment. Alternatively, the emergence (and some might say, imposition) of digital television means that all households will soon need digital reception equipment, which has the potential to act as a platform for PC/Internet style services. At the time of writing, one of the authors is involved in an EC-funded project developing a neuropsychologically based cognitive training application compatible with digital television which will also take the first steps to validating any measurable impact on the cognitive status of a cohort of elderly users (Freeman et al. 2009). These training programs are tailored to individual users, usually on the basis of a comprehensive set of assessment tasks, which provide an ability profile, allowing a set of suitable training activities to be compiled which have their parameters set in accordance with the users' "strengths & weaknesses." The subsequent training series (usually of 2–3 months duration) is then set at a suitable level of challenge which taxes the user enough to produce beneficial results, but is also achievable enough to allow the users' motivation to continue to be maintained. To retain this optimum level of challenge over the longer term, the ongoing training follows an assessment-training-assessment cycle.

In general, interactive cognitive training is an emerging area with great potential but a relative paucity of research identifying the impact on people's day-to-day lives and providing suitable information for further development. However, regardless of valid measurable impacts obtained from specific approaches to training, it is clear that there is enormous scope to fend off the effects of age-related cognitive decline, at least to some extent. The main conclusion that can be drawn from the literature is that maintaining a lifestyle that incorporates (among other things) regular intellectual challenges is the best way to minimize the effects of advancing age. This suggests avoiding the sedentary lifestyle stereotypical of "the elderly" and replacing it with interesting and challenging activities; "Even in old age carrying out substantively complex tasks builds the capacity to deal with the intellectual challenges such complex environments provide" (Schooler and Mulatu 2001, p. 466).

For those who have already experienced significant cognitive decline, approaches more related to rehabilitation are required and thus more research is needed to build generalizable guidelines for the most effective approaches and more effort needs to go into providing useful support for those whose general cognitive function may not be amenable to improvement.

37.12 RESEARCH METHODOLOGIES

The research described above gives a flavor of successful approaches to developing human interfaces and software to support people with various types of cognitive impairment. Much of the methodology used in these developments, however, had to be developed *ab initio*. Traditional user-centered design does not have the flexibility for these user groups, and most research and development in the field of communication and information technology to support people with disabilities has, to date, concentrated on the development of special assistive systems and on accessibility features for younger, mainly physically or sensorially disabled people. Similarly, the human interfaces to most computer systems for general use have been designed, either deliberately or by default, for a typical, younger user (Newell and Cairns 1993; Newell 1995; Newell and Gregor 1997). Knowledge from these fields does not necessarily transfer comfortably to the challenges encompassed in universal design (Beirmann 1997; Sleeman 1998; Stephanidis 2001) and, in particular, the widely varying and often declining abilities associated with the range of cognitive impairments.

This section addresses the particular issues for the design process which accompany cognitive impairment and suggests a paradigm and methodology to support the process of designing software that is as near to the universal accessibility ideal as is possible, derived from the approach to specific projects described above.

Software systems, which are aimed at the mainstream (rather than being of a prosthetic nature) need to address the wide variation in the types and severity of cognitive impairment between individuals. This demand is further complicated by the fact that as people grow older their abilities change. This process of change includes a decline over time in the cognitive, physical, and sensory functions, and each of these will decline at different rates relative to one another for each individual. This pattern of capabilities varies widely between individuals, and as people grow older, the variability between people increases. In addition, any given individual's capabilities vary in the short-term due, for example, to temporary decrease in, or loss of, function due to a variety of causes, such as the effects of drugs, illness, blood sugar levels, and state of arousal.

This broad range and variability of change presents a fundamental problem for the designers of computing systems, whether they be generic systems for use by all ages, or specific systems to compensate for loss of function. Systems tend to be developed for a typical user, and either by design or by default, this user tends to be young, fit, male and crucially, has abilities that are static over time. These abilities are assumed broadly similar for everybody. Not only is this view wrong, in that it does not take account of the wide diversity of abilities among the wider population of users, but it also ignores the fact that for individuals, these abilities are dynamic over time.

Current software design typically produces an artifact which is static and which has no, or very limited, means of adapting to the changing needs of users as their abilities change. Even the user-centered paradigm (e.g., ISO 13407 1999; Nielsen 1993; Preece 1994; Shneiderman 1992) looks typically at issues such as representative user groups, without regard for the fact that the user is not a static entity. Thus, it is important not only to be aware of the diverse characteristics of people with cognitive dysfunction, but also the dynamic aspects of their abilities.

It is clear that people with cognitive impairments, whatever their cause, can have very different characteristics to most human-interface and software designers. It is also clear that in these circumstances user-centered design principles need to be used if appropriate technology is to be developed for this user group (Gregor and Newell 1999). However, these methodologies have been developed for user groups with relatively homogenous characteristics. People with dementia, for example, are a diverse group and even small subsets of this group tend to have a greater diversity of functionality than is found in groups of able young people.

An additional complication is that there can be serious ethical issues related to the use of such people as participants in the software development process. Some of these are medically related, but also include, for example, the ability to obtain informed consent. It is thus suggested that the standard methodology of user-centered design is not appropriate for designing for the inclusion of this user group. The importance of research and development taking into account the full diversity of the potential user population, including cognitive diversity was addressed by Newell in his keynote address to InterCHI '93, where the concept of "Ordinary and Extraordinary Human Computer Interaction" was developed (Newell and Cairns 1993; Newell and Gregor 1997).

Market share is clearly an important consideration, and this has been given impetus, not only by demographic trends, but also by recent legislation in the United States and other countries, on accessibility of computer systems for people with disabilities. In terms of the workplace, both the Americans with Disabilities Act and the United Kingdom Disability Discrimination Act put significant requirements on employers to ensure that people with disabilities are able to be employed within companies and to provide appropriate technology so that such employees had full access to the equipment and information necessary for their employment. Increasingly, there is political pressure to increase this access, and more requirements for improved access by disabled people are being enshrined in legislation. However, access does not mean only that people with wheelchairs can maneuver around buildings; it also means that there needs to be provision for people with cognitive (and sensory and other physical) impairments to be able to operate computers and other equipment essential to the workplace.

An important additional factor in the value for money equation is that design that takes into account the needs of those with slight or moderate cognitive dysfunction can produce better design for everyone. An example where this has not occurred is illustrated by the problems that the majority of users have had with video tape recorders. If the designers had considered those with cognitive impairments within their user group, they may have been able to design more usable systems. Another example is an e-mail system specifically designed to be simple to use by older people with reduced cognitive functioning, which was found to be preferred by executives to the standard e-mail system that they were used to.

Some people are impaired from birth, but some may become temporarily or permanently disabled by accident or illness (suddenly or more slowly), or even by normal functioning within their employment. This is particularly noticeable in cognitive functioning. Short-term changes in cognitive ability occur with everyone. These can be caused by fatigue, noise levels, blood sugar fluctuations, lapses in concentration, stress, or a combination of such factors, and can produce significant changes over minutes, hours, or days. In addition, alcohol and drugs can also induce serious changes in cognitive functioning, which is recognized in driving legislation, but not in terms of how easy it is to use computer-based systems.

Most people at one time or another, will exhibit cognitive functional characteristics that are significantly outside the normal range. Although neither they, nor their peers, would consider these people disabled, their abilities to operate standard equipment may well be significantly reduced.

The questions that designers need to consider include the following:

- Does the equipment that I provide comply with the legislation concerning use by employees who may be cognitively disabled?
- To what extent do I need to take into account the needs of employees who are not considered disabled, but have significant temporary or permanent cognitive dysfunction?
- Should I make specific accommodation for the known reductions in cognitive abilities which occur as employees get older (e.g., less requirement for STM, or the need to learn new operating procedures)?
- What are the specific obligations designers and employers have to provide systems that can be operated by employees whose cognitive ability has been reduced due to the stress, noise, or other characteristics of the workplace?

The argument is that it would be very unusual for anyone to go through their working life without at some stage, or many stages, being significantly cognitively disabled. If equipment designers considered this, it is probable that the effectiveness and efficiency of the work force could be maintained at a higher level than would be the case if the design of the equipment were based on an idealistic model of the characteristics of users and their work environments.

37.12.1 Disabling Environment

In addition to the user having characteristics that can be considered disabled, it is also possible for them to be disabled by the environments within which they have to operate. Newell and Cairns (1993) made the point that the human-machine interaction problems of an able bodied (ordinary) person operating in an high workload, high stress or otherwise extreme (e.g., extraordinary) environment has very close parallels with a disabled (extraordinary) person, operating in an ordinary situation (e.g., an office).

High workloads and the stress levels to which this can lead often reduce the cognitive performance of the human operator. For example, a very noisy environment cannot only create a similar situation to hearing or speech impairment, but can also lead to reduced cognitive performance. The stress level in the dealing room of financial houses can be very high and is often accompanied by high noise levels. A significant advance may be made if the software that was to be used in these houses was to be designed on the assumption that the users would be hearing impaired and have a relatively low cognitive performance. It is interesting to speculate as to whether such systems would produce higher productivity, better decision making, and less stress on the operators. Other examples of extreme environments in which people have to operate are the battlefield, under water, or out in space. The stress and fatigue caused by working within such environments means that a soldier's performance may be similar to that which could be achieved by a very disabled person operating in a more normal environment. It is not always clear that the equipment such people need to operate has been designed with this view of the user.

It is very important to describe the users of technology in terms of their functional abilities related to technology rather than generic definitions of either medical conditions, or primarily medical descriptions of their disabilities. Unfortunately, most statistical data is presented as generic and medically categorizations of disability. Gill and Shipley (1999), however, defined disabled user groups in terms of their functional abilities, with specific emphasis on the use of the telephone. They estimated that within the European Union, which has a population of 385 million, there were 9 million people with cognitive impairment that could lead to problems using the telephone. These figures do not take into account multiple impairments, and the authors pointed out that, in the elderly population in particular, there may be a tendency toward cognitive, hearing, vision, and mobility impairments being present to a varying extent and these may interact when considering the use of technological systems. It is this multiple minor reduction in function (often together with a major disability), which means that the challenges to technological support for older people have significantly different characteristics to that of younger disabled people and to the nondisabled, nonelderly population.

There has been some movement in mainstream research and development in technology, both in academia and industry, away from a technology led focus to a more user led approach, and this has led to the development of user-centered design principles and practices in many industries. In addition, a number of initiatives have been launched to promote a consideration of people with disabilities within the user group in mainstream product development teams with titles including "Universal Design," "Design for All," "Accessible Design," and "Inclusive Design." (http://www.design.ncsu .edu/cud/ud/ud.html. http://www.stakes.fi/include. http://www.trace.wisc .edu. http://www.w3.org/WAI) The "Design for All/Universal Design" movement has been very valuable in raising the profile of disabled users of products, and has laid down some important principles. However, their approach has tended not to place too much significance on cognitive impairment, and, particularly if this is included as a factor in the design process, then it becomes more difficult to use traditional user-centered design approaches.

Newell and Gregor (2000) suggested that a new design approach should be developed, which would be based on the already accepted user-centered design methodology. There are some important distinctions between traditional user-centered design with able-bodied users, and the approach needed when the user group either contains, or is exclusively made up of, people with cognitive dysfunction. These include the following:

- Much greater variety of user characteristics and functionality.
- The difficulty in finding and recruiting representative users.

- Situations where design for all is certainly not appropriate (e.g., where the task requires a high level of cognitive ability).
- The need to specify exactly the characteristics and functionality of the user group.
- Conflicts of interest between user groups, including temporarily able bodied.
- Tailored, personalizable, and adaptive interfaces.
- Provision for accessibility using additional components (hardware and software).

The balance in the design process also needs to shift from a focus on user needs to one on the users themselves. There will be additional problems when considering people with cognitive dysfunction, which will include the following:

- The lack of a truly representative user group.
- That a different attitude of mind of the designer is required.
- Ethical issues (Alm 1994; Balandin and Raghavendra 1999).
- It may be difficult to get informed consent from some users.
- Difficulties of communication with users.
- The users may not be able to (sufficiently) articulate their thoughts, or even may be incompetent in a legal sense.

Thus, there can be particularly difficult ethical problems when involving users with cognitive impairments in the design process. In addition, it is often necessary to involve clinicians when such users are involved, so some of the user-centered design actually focuses on professional advice about the user, rather than direct involvement of the user. Even with these problems, however, it is possible to include users with cognitive dysfunction sensitively in the design process.

37.12.2 Inclusion of Users with Disabilities within Research Groups

In Dundee users with disabilities have a substantial involvement in the research, and they have made a significant contribution both to the research and to the commercial products that have grown from this research. Users are involved in two major ways as follows:

- As disabled consultants on the research team, where they act essentially as test pilots for prototype systems.
- By the traditional user-centered design methodology of having user panels, formal case studies, and individual users who assess and evaluate the prototypes produced as part of the research.

The contribution made by clinicians is also vital to the research, and these are full members of the research team. Dundee's Applied Computing Department is also one of the few computing departments that have had speech therapists, nurses, special education teachers, linguists, and psychologists (both clinical and cognitive) as full-time researchers.

37.12.3 User Sensitive Inclusive Design

Some significant changes must be introduced to the user-centered design paradigm if users with disabilities are to be included, and this is particularly important if the users have cognitive impairment. To ensure that these differences are fully recognized by the field, the title "User Sensitive Inclusive Design" has been suggested. The use of the term inclusive rather than universal reflects the view that inclusiveness is a more achievable, and, in many situations, appropriate goal than universal design or design for all. Sensitive replaces centered to underline the extra levels of difficulty involved when the range of functionality and characteristics of the user groups can be so great that it is impossible neither to produce a small representative sample of the user group in a meaningful way, nor often to design a product that truly is accessible by all potential users.

37.12.4 Design for Dynamic Diversity

In addition to the aspects of user sensitive inclusive design described above, it is necessary to make designers fully aware of the range of diversity which can be expected with cognitively impaired people, and also the changing nature of the cognitive functioning of people. Thus, Gregor and Newell (2000) suggested that this be drawn particularly to the attention of designers by introducing the concept of "Designing for Dynamic Diversity." This process, described above, entails recognition that people's abilities are diverse at any given age and that as they grow older this diversity grows dynamically; it also involves a recognition that any given individual's abilities will vary according to factors such as mood, fatigue, blood sugar levels, and so on. Only by taking on board, the factors associated with Designing for Dynamic Diversity will software design produce artifacts which are not static and which have no, or very limited, means of adapting to the changing needs of users as their abilities change.

As has been seen above, metaphors and processes in use at present are limited in meeting the needs of this design paradigm or addressing the dynamic nature of diversity. New processes and practices are needed to address the design issues; awareness raising among the design, economic and political communities has to start; and research is needed to find methods to pin down this moving target.

37.12.4.1 Story-Telling Metaphor

In addition, researchers need to consider how best to disseminate the concepts behind universal usability and the results of user sensitive inclusive research. User sensitive inclusive design needs to be an attitude of mind rather than simply the mechanistic application of design for all guidelines. This offers a further challenge to the community. The dangers of using such studies to produce more extensive guidelines has been referred to above, but it is important that the results of user sensitive inclusive design are made available to other designers and researchers. However, it is too early to lay down principles and practices that must be followed by designers, and it may even be impossible to do this for some of the contexts and environments in which designers work. Thus, it is suggested that we follow a story-telling approach, in which information about accessibility issues, and design methods which focus on accessibility is presented in narrative form, with particular examples to illustrate generic principles. This is, in some sense, an extension of the single case-study methodology. This methodology could provide very useful insights to designers in a form that they will find easy to assimilate and act. Thus, this will assist in their educations and will help them to design more accessible products, and better products for everyone.

37.12.5 Use of Theater

As an extension of the story-telling metaphor, the research group in the School of Computing at Dundee University has investigated the use of dramatic techniques and theater as a way of addressing the challenges of user sensitive design. In particular, they have investigated the use of professional theater for both awareness raising with designers and also for requirements gathering with older adults (Newell et al. 2006a). They have commissioned a number of live performances and professional narrative videos to illustrate the output of long-term research into the challenges older people find with new technologies. These have been produced as an educational tool for human interface engineers, software designers, managers, and procurement executives. They are designed to provoke and facilitate discussion with both developers and potential uses of technology about the needs and wants of older people. Morgan and Newell (2007) describe the methodology of using professional theater in research of this nature.

37.12.6 Theater for Awareness Raising

In the UTOPIA (Usable Technology for Older People: Inclusive and Appropriate) project (Dickinson et al. 2002), they worked in collaboration with the Foxtrot Theater Company (Perth, Scotland) to use theater to encourage interaction between (older) users of technology and designers. The outcome was the "UTOPIA Trilogy," a series of short-video plays addressing problems that older people have in using technology (Carmichael et al. 2005). The films were developed to be amusing and entertaining dramatizations of some of the issues the researchers had encountered during the project. These films were based on real events, conversations, and observations, and they were the amalgamation of many and are intended to convey older people's experiences with technology and the situations they encounter. They are amusing and entertaining. These videos were evaluated with a variety of audiences including academics, practitioners, software engineers, relevant groups of undergraduates, and older people. This established that the videos provided a useful channel for communication between users of technology and designers, and changed the perceptions of both students and more mature designers of IT systems and products about older people's requirements. Subsequently in collaboration with MMTraining (http://www.MMTraining.org) whose artistic director was the artistic director of the Foxtrot Theater Company (http://www.foxtrot-theatre.org.uk) and Soundsmove (http://soundsmove.com), a professional video production company. They have produced a range of videos and live theater events. The videos "Relative Confusion" and "Relatively PC" (which can be viewed at http://www.computing.dundee.ac.uk/projects/iden) address the issues older people can have with digital television and the use of the Internet, respectively (Newell 2009). In an amusing way, these videos illustrated many of these challenges older people can have with the technology including the following: users' ability to learn and their memory for new control methods, the effects of poor eyesight and manual dexterity, the interaction of poor eyesight and memory, loss of control due to complex interaction techniques, visual distractions intergenerational differences, the consequences of jargon, operational anxiety, and the effects of stressreasons for technophobia, and the challenges provided by technical language and metaphors. Although older users are represented in these videos, the lessons illustrated apply to many other groups of naïve and cognitive impaired users.

37.12.7 Theater for Requirements Gathering

A similar technique has also been used in the requirements gathering phase for IT systems. Within a project developing systems designed to monitor older people in case of falls at home (Marquis-Faulkes et al. 2003, 2005), a series of short films were produced that illustrated how such systems worked and gave examples of ways in which they may operate inappropriately. In keeping with our methodology (Morgan and Newell 2007), these were narratives rather than documentaries and they used conflict and humor to present questions to the audience. Groups of older people were shown the videos, which were used to facilitate discussion on the characteristics of the system that the users required. Although it was not appropriate within this project to make comparisons with traditional focus groups, the use of theater did produce very lively discussion and the authors believe that it was unlikely that some of the conclusions would have been arrived at without this type of presentation.

Rice, Newell, and Morgan (2007) describe the use of live theater for requirements gathering for a project investigating potential applications of interactive television for older people. This technique was particularly useful for the conceptual stages of the design process. The researchers were investigating a number of different systems (including a video phone and a "memory box"). The use of theater with its "suspension of disbelief" and use of props meant that the use these systems could be illustrated in a clear and meaningful way in real contexts at a predevelopment stage. Morgan et al. (2008b) have used live theater in their investigations of the required characteristics of supportive environments for older people. Focus groups of older people, facilitated by live theater produced very useful data. As a demonstration of this technique, they mounted a live theater event at CHI 2008. A play showing a couple of older people living within a "supportive home of the future" was followed by a session in which the audience was encouraged to question the actors who stayed in role. This produced a very lively discussion session. The use of theater has proved to be a very useful way to encourage audience discussion at both this and other international conferences (Newell and Morgan 2006, 2008a,b,c; Morgan et al. 2008a).

37.12.8 Use of Professional Actors to Simulate Users with Dementia

The research described above has focused on older people without any major cognitive dysfunction. In his research into cognitive support for daily living (see Section 37.10), Hoey (2010c) has conducted a pilot project where he used actors to simulate people with dementia. He used actors, who had been well briefed in the characteristics of people with dementia to provide training data for an adaptive prompting system. There would have been significant ethical issues in the use of people with dementia at this stage of the project, and the data gathering would have taken very much longer. This use of actors is being continued in a joint project with the University of Toronto.

37.12.9 Conclusions on the Use of Theater

This research has shown that the use of theater can be a very powerful method of encouraging dialogue between various professional groups particularly in a clinical environment, for keeping a focus for discussions, and also for providing a channel for communication between users of technology and designers (Carmichael, Newell, and Morgan 2007). The researchers view is that the success of this approach was in large part due to the plays being narrative based rather than having a pedagogic style. That is, they illustrated the issues involved within interesting story lines, with all the characteristics of a good narrative—humor, tension, human interest, and antagonists and protagonists. In addition, the quality of the production, having been produced by theater professionals, played a major part in the success of the venture.

Newell et al. (2006b) discussed the various ways in which actors and theater can play a part in the design process for human–computer interfaces. This could provide a particularly valuable methodology for the design process when the target users have cognitive impairment and thus may not be appropriate for including within standard user-centered design methodologies. For example, the use of actors removes any ethical issues which may arise if researchers were to use "real people," especially those with cognitive dysfunction, for early experiments with very novel technology and/or to illustrate challenges that novel technologies may provide.

37.13 USE OF ART-SCHOOL-TRAINED DESIGNERS

37.13.1 Esthetics

Researchers working with people with dementia have identified a heightened artistic appreciation and emotional response (Pullin 2009a, p. 83—citing Orpwood et al. 2005). This would indicate that the esthetic design of objects for people with dementia or other cognitive dysfunction is just as important as—perhaps even more important than in mainstream design. However, there is a tendency for "rehabilitation technology" to exhibit symptoms of a lack of esthetic considerations in the design process. Many such products show evidence that the teams that design them do not engage emotionally with the users groups and assume that older and disabled people lack any esthetic sense, and, unlike other user groups, are motivated entirely by the functionality of products.

There is an interesting contrast between hearing aids and eyeglasses in this context. Hearing aids have always been considered to be a medical product and have been designed to be as invisible as possible. However, eyeglasses moved from being a medical product that, in the 1930s, were described by government as "needing to be adequate," to a fashion accessory by the 1980s (Lewis 2001). Ironically, unlike eyeglasses, most hearing aid users would benefit greatly from advertising the fact that they were hearing impaired in the sense that this would encourage conversational partners to speak more clearly. In a further contrast, a range of very fashionable wheelchairs existed in the nineteenth century, but wheelchairs became much more obviously a medical product for most of the twentieth century. This changed in the 1970s due to pressure from Veterans Association of North America, and a much more varied and exciting range of wheelchairs became available in the latter part of the 1990s (Woods and Watson 2004). Thus, although some branches of assistive technology have developed as fashionable devices, this is the exception rather than the rule. There can be an assumption that the additional constraints involved in considering older and disabled people mean the abandonment of novel and beautiful concepts. If these attitudinal constraints are over emphasized, the design team will be focused exclusively on the ergonomic and technical aspects of the product, which can lead to products that patronize and further stigmatize the very people they are designed to help.

This lack of sensitivity to the cultural needs of users of assistive technology, and the lack of esthetic considerations and empathy between the designers and the customers could well be a factor in the very high level of abandonment of assistive technology of products. Hocking (1999) reports that in the United States, 56% assistive technology is quickly abandoned, and 15% are never used.

The culture of problem solving, particularly prevalent in rehabilitation engineering circles, can often see fashion as the antithesis of good design. Thus, creative designers are less likely to be part of an assistive technology development team. To ensure that software and hardware products are esthetically pleasing, it is important that the design team does include art-school trained industrial and interaction designers as well as medical engineers, human–computer interaction experts, clinical professionals, caregivers, and the people with cognitive impairment themselves (Pullin 2009a, p. 83). In addition art-school trained designers can contribute a range of design techniques which are not usually found in engineering design, and these can be particularly valuable when designing for cognitively impaired users. These include experience prototyping and critical design.

37.13.2 Experience Prototyping

There are a range of ethical issues when using participatory design techniques when the user population has cognitive impairments. An earlier section has suggested that actors could act as substitutes in some situations, but there will be points in the design process, however, when people with actual cognitive impairment will provide an invaluable input, as in some cases their reactions may be counter intuitive, even to their own caregivers. For example Orpwood et al. (2005) describes the development of an audio prompting system where experiments with people with dementia suggested voices for the prompts that neither the caregivers nor the researchers would have predicted. Early and unreliable prototypes, however, can be unsettling, even upsetting to users with cognitive impairments. In these cases, there is an argument for employing "experience prototyping," which often employ hidden human intervention (Pullin 2009a, p. 146). Such prototypes may be more faithful to the users' eventual experience, even at the expense of serving as technical proof of concept prototypes at the same time.

37.13.3 Critical Design

Critical design is the developments of artifacts which are intended to be provocative rather than an attempt at a solution to the design challenge (Dunne 2006). This provides a way of exploring the design space in a playful and open ended way but with a serious purpose. Critical design prototypes may challenge existing cultural, technological, and economic values. They may well address taboo issues or unspoken aspects of the context of use of devices, and may well instantiate these challenges by uncomfortable images and dark humor. They are designed to be used to encourage different insights and perspectives on the issues raised, to inspire new paths, and challenge assumptions on which the product was built. Although at first sight critical design may seem wasteful and self-indulgent, Pullin (2009a, pp. 111–133) gives examples of critical design prototypes and describes a range of issues related to design for people with disabilities which could benefit from such an approach.

37.13.4 Advantages of "Creative Design"

Art schools focus on the overall experience of using an artifact and attach significant value to exploring and feeling, to simplicity and to provocation, identify and expression, and the complex web of sensory and contextual interactions that determine whether a product succeeds or fails. Pullin (2009a) argues that the inclusion of such processes creates an important focus on people's engagement with the experience of using the product and the emotions this generates—these being important complements to the accessibility and usability of the product. It can also encourage an awareness of the important issues of self-confidence and security, and the users feeling of comfort when using a product, all of which can be influenced by the details of the design rather than just its functionality. People with disabilities should not be denied the esthetic pleasure of using devices. This is an important characteristic of many mainstream products, but assistive technology is often designed with esthetics being considered as an afterthought—the final "cosmetic treatment" of a product. As with accessibility, however, such considerations are much more effective and less expensive to provide if considered from the beginning as an integral part of the total design process. Pullin (2009a, p. 173) gives an example of how such characteristics were introduced in a simple communication aid for nonspeaking people, and how these contributed to its final effectiveness. He argues that there is almost inevitably a creative tension between such designers and engineering designers, but that these need to be embraced because anything less is a receipt for mediocrity, which would be more insulting to the potential users of the device than controversy in the design stages. Pullin (2009a) also includes discussions with a range of designers who were not familiar with assistive technology and shows how the contributions of such people could influence the design of assistive technology.

37.13.5 Appealing to Envy

The vast majority of people use both electronic and non-electronic cognitive prostheses—such as diaries, memo pads, alarm clocks, personal digital organizers. The popularity of individual products is due not only to their functionality but also to their ease of use and their design. Some are clearly a fashion accessory as well as a cognitive prosthesis. If these considerations were more obviously considered within the design of the prosthesis for cognitively impaired uses, then they would have a greater chance of being successful. An additional advantage of this approach could well be that such cognitive prostheses find a mainstream market. Newell and Cairns (1993) describes how this has occurred for a range of devices intended initially for use by disabled people, including the typewriter, the cassette tape recorder, and the ball point pen. More recent examples include word prediction and disambiguation as now available in the vast majority of mobile telephones. There is no reason why well-designed cognitive prostheses should not follow this path.

37.14 CONCLUSION

A range of information technology systems have been developed that successfully support people with cognitive impairment. In order to realize the full potential of this technology, however, a great deal more work is required. New knowledge about how cognition works is required and both specialist and mainstream designers need to be aware of the implications of this knowledge.

Although it is not necessary for software developers and human interface designers to be fully versed in all aspects of cognition, it is important for them to have some background knowledge of the area. Because of the wide range of skills and knowledge needed to understand the problems faced by people with cognitive impairment, research work in this field should be multidisciplinary, including psychologists, members of the health and therapeutic professions, and human interface, interaction, and creative designers. It is also vital to involve potential users of the technology as partners at all stages of the research and development of systems and products.

The development of the concept of, and a methodology for, user sensitive inclusive design, design for dynamic diversity, and development of story-telling methods for communicating results will facilitate researchers in this specialized field and will provide mainstream engineers with an effective and efficient way of including people with disabilities within the potential user groups for their projects. If both of these can be achieved, it will go some way towards providing appropriate technological support for people with cognitive impairment. As Christopher Frayling (2003) said: “Let’s bring the users in and let’s bring delight (back) into (everyday) products.” One measure of success might be that of non-cognitively impaired people being envious of the user of a particular device—wishing that they had one.

38 Perceptual Impairments
New Advancements Promoting Technological Access

Julie A. Jacko, V. Kathlene Leonard, Molly A. McClellan, and Ingrid U. Scott

CONTENTS

38.1 INTRODUCTION

The introduction of early computers facilitated new ways for individuals with visual impairment to access information electronically: magnified, in Braille, or aurally via the conversion of digital information. However, the introduction of graphical user interfaces (GUIs) that present digital information via visual metaphors and icons contributed to the digital divide, which can hamper the productivity of this population. In many cases, even access to documents and forms can be a difficult to impossible task when available through the direct manipulation paradigm (Fortuin and Omata 2004). The exclusive reliance of GUIs on the visual interaction paradigm therefore threatens to limit accessibility for anyone whose visual channel is compromised (Dix et al. 1998). This chapter provides readers with (1) an introduction to the visual sensory channel; (2) a review of research approaches, models, and theories that are relevant to human–computer interaction (HCI) and visual impairment; and (3) a discussion of forms of visual dysfunction in the research, design, and evaluation of human–computer systems.

The interaction strategies and related interaction barriers for individuals with visual impairments in the past 15 years has received growing attention in an attempt to inform judicious, inclusive design for accessible information technologies (e.g., Assistive Technologies for Independent Aging: Opportunities and Challenges 2004; Arditi 2002; Brewster, Wright, and Edwards 1994; Craven 2003; Fortuin and Omata 2004; Fraser and Gutwin 2000; Gaver 1989; Jacko 1999; Jacko, Barnard, et al. 2004; Jacko et al. 2002; Jacko et al. 2000; Jacko et al. 2005; Jacko et al. 1999a,b; Jacko and Sears 1998). Visual impairments (that do not lead to blindness) can create barriers to distinguishing fine details of iconic screen targets and to tracking the highly dynamic nature of the pointer used to manipulate these icons (Fraser and Gutwin

2000). This is largely attributed to difficulty in manipulating objects with the pointer due to reduced visual acuity and visual field.

In terms of the visual sensory channel, it is known that user behavior is strongly influenced by the nature and amount of residual vision the user experiences in combination with computer interface characteristics. As an extreme example, a blind user without any functional vision will use fundamentally different coping skills to navigate an interface as compared to an individual with clouded vision due to cataracts (Jacko and Sears 1998). Harper, Goble, and Stevens (2001) emphasized that the differences in orientation, navigation, travel, and mobility of visually impaired versus sighted individuals should be considered in the design of technology because there are differences in the mental map and cognitive processes that occur across the spectrum of visual abilities.

The impetus for this chapter is two parts. First, the number of individuals who report low vision is anticipated to rise sharply with the aging baby boomers (who are, on average, living longer) as they experience age-related changes to their functional vision (e.g., reduced visual acuity, presbyopia, contrast sensitivity, color sensitivity, depth perception, and glare sensitivity). They are increasingly predisposed to acquire ocular diseases associated with older age (e.g., macular degeneration, diabetic retinopathy, glaucoma, and cataracts; for a review, see Orr [1998]; Schieber [1994]). Secondly, the digital divide imposed on the population with visual impairments has been measured in terms of technology access and unemployment (Gerber and Kirchner 2001). Looking beyond the United States, as the need for information increases globally so does the diversity of the people requiring access. As a result, a potentially large number of users may be disadvantaged with respect to gaining access to a variety of types of information without adequate accommodations.

The framework for the structure of this chapter results from an HCI approach first introduced by Jacko and Vitense (2001), and further clarified by Jacko, Vitense, and Scott (2003). Initial work in this research area included a comprehensive review of the literature to facilitate the development of a categorization scheme to account for categories of impairment. From this literature review, five major categories emerged: (1) hearing impairments, (2) mental impairments, (3) physical impairments, (4) speech impairments, and (5) visual impairments. Figure 38.1 illustrates that each of the five, overarching categories is composed of a collection of clinical diagnoses unique to that category (depicted in Figure 38.1 by $A_1,\ldots, A_n$, $B_1,\ldots, B_n$, $C_1,\ldots, C_n$, $D_1,\ldots, D_n$ and $E_1,\ldots, E_n$). Each diagnosis, in turn, influences certain functional capabilities that are critical to the access of information technologies (depicted in Figure 38.1 by $Y_1,\ldots, Y_n$). A subset of these functional capabilities can be directly linked to specific classes of technologies (shown at the bottom of the diagram).

While this framework is applicable to the five identified categories of impairment, its discussion and demonstrated utility in the scope of this chapter will address only visual

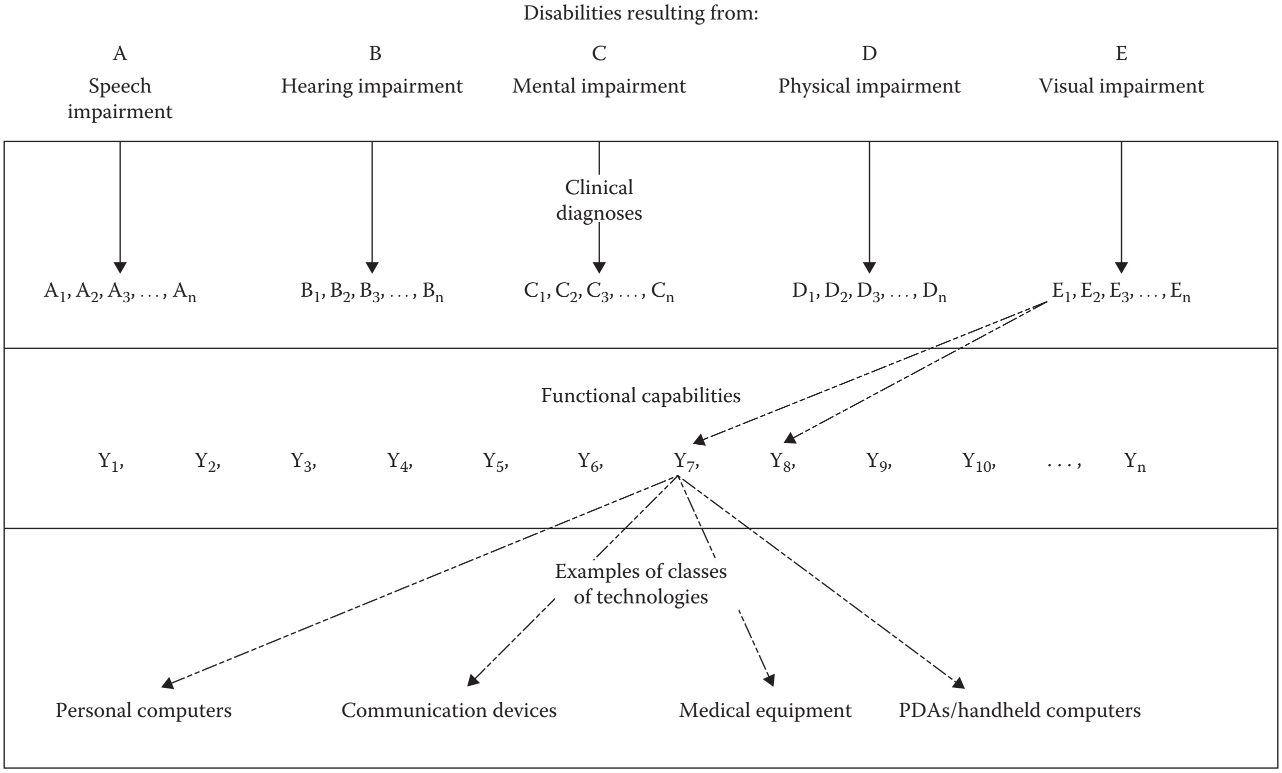

FIGURE 38.1 Framework for the integration of clinical diagnoses, functional capabilities, and access to classes of technologies. (Adapted from Jacko, J. A., H. S. Vitense, and I. U. Scott. 2003. Perceptual impairments and computing technologies. In *Human-Computer Interaction Handbook*, ed. J. A. Jacko and A. Sears, 504–22. Mahwah, NJ: Lawrence Erlbaum Associates.)

impairment. Auditory/speech, cognitive impairments and physical (motor) impairments are covered in this handbook in Chapters 35, 37, and 40. Consider, for example, a person who has been diagnosed with a specific type of visual impairment represented as E_1 in Figure 38.1. This visual impairment results in measurable decrements to certain aspects of this person's functional visual capabilities, Y_7 and Y_8. Observe from Figure 38.1 that the decrement to the functional capability represented Y_8 does not impede a person's access to any of the technology classes depicted in Figure 38.1. In contrast, the functional visual capability represented by Y_7 in Figure 38.1, which impedes this person's ability to successfully access information using all four examples of information technology. From this conceptual representation, it is apparent that much more knowledge is needed for researchers to possess an accurate depiction of the empirical relationships that exist between diagnoses, functional capabilities, and access to specific classes of technologies. More specifically, emerging from this conceptual framework are several key research areas in need of investigation as follows:

1. It is critical to establish empirical links between clinical diagnoses and sets of functional capabilities.
2. It is necessary to define the set of functional capabilities required to access information technologies.
3. It is essential to establish empirical bases for the influence of specific functional capabilities on access to specific classes of technologies.

Following this framework, this chapter introduces readers to the clinical definition of visual impairments and diagnoses, in which visual function is first addressed, followed by a discussion of the leading causes of vision loss in the United States and beyond. Section 38.2.4 also provides a discussion of specific visual functions. Then, the chapter highlights recent advancements in HCI research, which effectively link the three major areas of the framework: clinical diagnosis, functional impairment, and interaction across a variety of classes of technology and impairments. This research is done in pursuit of HCI solutions for the visually impaired including perceptual interfaces, multimedia interfaces, multimodal interfaces, and adaptive interfaces. Finally, examples of technological advancements for this population are presented. While these technological advancements are discussed briefly in this chapter within the context of visual impairments, it should be noted that additional information on HCI and perceptual-motor interactions, hearing and speech impairments, and motor impairments can be found in Chapters 35, 37, and 40.

38.2 VISUAL FUNCTION

38.2.1 Definitions

When considering the impact of visual loss on an individual's ability to use a computer effectively, it is first necessary to understand various dimensions of visual performance. Many different terms have been used to refer to abnormalities in visual function, including disorder, impairment, disability, and handicap (Colenbrander 1977). Although often used as synonyms, there are distinct differences. For instance, while disorder and impairment describe aspects of an organ's condition, the term disability describes aspects of a patient's condition.

Disorder refers to an abnormality in the anatomy or physiology of an organ and, in the case of a visual disorder, may occur anywhere in the visual system. Examples of visual disorders include corneal scar, cataract, macular degeneration, optic atrophy, or occipital stroke. It is important to recognize that knowing the specific visual disorder provides no information concerning the functional capacity of the eye.

Impairment refers to a functional abnormality in the organ. Thus, varying degrees of visual impairment can be measured in terms of specific visual functions, such as visual acuity, contrast sensitivity, visual field, or color vision. While such impairment measures demonstrate how well the eye functions, they do not reveal the impact of the visual disorder on the patient's ability to perform everyday activities. For example, a physician may state that the patient's visual acuity has dropped by four lines on the eye chart, while the patient reports an inability to see well enough to use a computer.

Disability refers to the ability of a patient (rather than an organ) to perform tasks, such as daily living skills, vocational skills, reading, writing, mobility skills, and so on. Since disability implies a broader perspective (the focus is on the person as a whole rather than on a specific organ), it is no longer entirely vision specific. For instance, while computer skills may be reduced due to vision loss, they may also suffer due to such conditions as arthritis. It is the combination of visual and nonvisual skills that determines the abilities or disabilities of an individual. Vision substitution techniques (such as the use of a white cane and increased reliance on memory and on hearing) may be helpful in improving the ability of an individual to perform specific tasks.

A disorder may cause impairments, and impairments may cause disability. However, these links are not rigid. An analysis of these various dimensions of vision loss permits identification of interventions at each link, which may improve the functional status and quality of life of an individual with visual loss (Figure 38.1; Fletcher 1999). For example, if one were interested in improving the ability of an individual with vision loss to use a computer effectively, possible interventions include medical and surgical intervention to impact the visual disorder and impairment, visual aids and adaptive devices to impact visual impairment, and social interventions, training, counseling, and education to impact visual disability. The design of a computer interface that enhances the ability of an individual with vision loss to perceive graphical and textual information would have a beneficial effect on the degree of impairment and resulting level of disability of that individual.

38.2.2 Epidemiology

Low vision has been defined as a permanent visual impairment that is not correctable with glasses, contact lenses, or surgical intervention, and which interferes with normal everyday functioning (Mehr and Freid 1975). Specifically, low vision is defined as a best-corrected visual acuity worse than 20/40 in the better-seeing eye (The Eye Diseases Prevalence Research Group 2004a). Blindness is defined as a best-corrected visual acuity of 20/200 or worse according to the U.S. definition and is defined as a best-corrected visual acuity of worse than 20/400 according to the World Health Organization definition (The Eye Diseases Prevalence Research Group 2004a). Based on demographics from the 2000 U.S. Census, an estimated 937,000 (0.78%) Americans older than 40 years were blind (U.S. definition); an additional 2.4 million Americans (1.98%) has low vision (The Eye Diseases Prevalence Research Group 2004a). Thus, blindness or low vision affects approximately 1 in 28 Americans older than 40 years (The Eye Diseases Prevalence Research Group 2004a). Largely due to the aging of the U.S. population, it is estimated that the number of blind persons older than 40 years in the United States will increase by approximately 70% to 1.6 million (prevalence of 1.1%) by the year 2020 (The Eye Diseases Prevalence Research Group 2004a). Vision loss has been ranked third, behind arthritis and heart disease, among conditions that cause persons older than 70 years to need assistance in activities of daily living (LaPlante 1988).

38.2.3 Selected Visual Disorders

In the United States, the most common causes of decreased vision are age-related macular degeneration (AMD), diabetic retinopathy, and glaucoma.

38.2.3.1 Age-Related Macular Degeneration

AMD is the leading cause of irreversible visual loss in the western world in individuals over 60 years of age. The macula is the part of the retina that is responsible for central vision. AMD affects more than 1.75 million individuals in the United States, and due to the rapid aging of the U.S. population, this number is estimated to increase to almost 3 million by the year 2020 (The Eye Diseases Prevalence Research Group 2004b). The prevalence of severe visual loss due to AMD increases with age. In the United States, at least 10% of persons between the ages of 65 and 75 years have lost some central vision due to AMD; among individuals over the age of 75 years, 30% have vision loss due to AMD.

Risk factors for this disease and its progression include age, sunlight exposure, smoking, ocular and skin pigmentation, elevated blood pressure, and elevated serum cholesterol levels. Recently, race has also been identified as a risk factor since AMD has been found to be more prevalent among whites than black persons (Bressler et al. 2008). Both Hispanics and Asians have a lower rate of AMD than whites, but still a higher rate of prevalence than blacks (Klein et al. 2006). The role of nutrition has not been fully identified as a risk factor, but a diet low in antioxidants and lutein may be a contributing factor.

AMD is a bilateral disease in which visual loss in the first eye usually occurs at about 65 years of age; the second eye becomes involved at the rate of approximately 10% per year. The two main types of AMD are atrophic and exudative. The atrophic (dry) form of the disease is generally a slowly progressive disease that accounts for approximately 90% of cases. It is characterized by the deposition of abnormal material beneath the retina (drusen) and by degeneration and atrophy of the central retina (also known as the macula); patients typically note slowly progressive central visual loss. Although much less common, the exudative (wet) form of the disease is responsible for about 88% of legal blindness attributed to AMD. This form of the disease, which often occurs in association with atrophic AMD, is characterized by the growth of abnormal blood vessels beneath the central retina (macula); these abnormal blood vessels elevate and distort the retina and may leak fluid and blood beneath or into the retina. Vision loss may be sudden onset and rapidly progressive (in contrast to the atrophic form of the disease, where vision loss generally occurs progressively over several months or years). AMD can cause profound loss of central vision, but the disease generally does not affect peripheral vision, and therefore, patients typically retain their abilities to ambulate independently.

Currently, no proven treatment reverses the retinal damage that has already occurred due to AMD. In order to try to prevent further vision loss, recommendations made to patients include eye protection against ultraviolet light exposure (sunglasses with ultraviolet light protection), no smoking, optimal control of blood pressure and serum cholesterol level, and a diet rich in dark green leafy and orange vegetables (antioxidants are believed to reduce the damaging effects of light on the retina through their reducing and free-radical scavenging actions; lutein is a macular pigment). The Age-Related Eye Disease Study (AREDS) was a randomized, controlled clinical trial that demonstrated a statistically significant reduction in rates of at least moderate visual acuity loss in persons with moderate AMD who received supplementation with vitamins C and E, beta carotene, and zinc compared to persons with moderate AMD assigned to placebo (Age-Related Eye Disease Study Research Group 2001). Laser photocoagulation and photodynamic treatment of the abnormal blood vessels found in patients with exudative macular degeneration may help to prevent severe vision loss in some cases. Intravitreal injections of pegaptanib, a pegylated modified oligonucleotide that binds to extracellular vascular endothelial growth factor (VEGF) isoform 165 (the isoform widely considered to be the primary pathologic form of VEGF), are associated with a higher likelihood of visual preservation and a slowing of visual loss among patients with exudative AMD (Gragoudas et al. 2004). Surgical rotation of the retina away from the area of abnormal blood vessels has also been effective in some cases. Other treatment modalities currently under investigation include such drugs as corticosteroids, other anti-VEGF agents, and combination treatments.

38.2.3.2 Diabetic Retinopathy

Approximately 16 million Americans suffer from diabetes mellitus, most of whom will develop diabetic retinopathy within 20 years of their diagnoses. In fact, after 20 years of diabetes, nearly 99% of those with insulin-dependent diabetes mellitus and 60% with non-insulin-dependent diabetes mellitus have some degree of diabetic retinopathy. Diabetic retinopathy is the leading cause of legal blindness in Americans aged 20–65 years, with 10,000 new cases of blindness annually. One million Americans have proliferative diabetic retinopathy, and 500,000 have macular edema. Among an estimated 10.2 million American adults aged 40 years and older known to have diabetes mellitus, the estimated crude prevalence rates for retinopathy and vision-threatening retinopathy are 40.3% and 8.2%, respectively (The Eye Diseases Prevalence Research Group 2004b). The estimated U.S. general population prevalence rates for retinopathy and vision-threatening retinopathy are 3.4% (4.1 million persons) and 0.75% (899,000 persons), respectively (The Eye Diseases Prevalence Research Group 2004c).

The major risk factor for diabetic retinopathy is duration of diabetes; it is estimated that at 15 years, 80% of diabetics will have background retinopathy and that, of these, 5%–10% will progress to proliferative changes. Other risk factors include long-term diabetic control (as reflected in serum levels of glycosylated hemoglobin), hypertension, smoking, and elevated serum cholesterol.

There are two main types of diabetic retinopathy: nonproliferative and proliferative. Nonproliferative diabetic retinopathy refers to retinal microvascular changes that are limited to the confines of the retina and include such findings as microaneurysms, dot and blot intraretinal hemorrhages, retinal edema, hard exudates, dilation and bleeding of retinal veins, intraretinal microvascular abnormalities, nerve fiber layer infarcts, arteriolar abnormalities, and focal areas of capillary nonperfusion. Nonproliferative diabetic retinopathy can affect visual function through two mechanisms: intraretinal capillary closure resulting in macular ischemia, and increased retinal vascular permeability resulting in macular edema. Clinically significant macular edema is defined as any one of the following: (1) retinal edema located at or within 500 μm of the center of the macula; (2) hard exudates at or within 500 μm of the center if associated with thickening of adjacent retina; and (3) a zone of retinal thickening larger than one optic disc area if located within one disc diameter of the center of the macula.

Proliferative diabetic retinopathy is characterized by extraretinal fibrovascular proliferation; that is, fibrovascular changes that extend beyond the confines of the retina and into the vitreous cavity. Fibrovascular proliferation in proliferative diabetic retinopathy may lead to tractional retinal detachment and vitreous hemorrhage. High-risk proliferative diabetic retinopathy is defined by any combination of three of the four following retinopathy risk factors: (1) presence of vitreous or preretinal hemorrhage; (2) presence of new vessels; (3) location of new vessels on or near the optic disc; and (4) moderate to severe extent of new vessels (Diabetic Retinopathy Study Research Group 1979).

Management of diabetic retinopathy includes referring the patient to an internist for optimal glucose and blood pressure control. In the Early Treatment Diabetic Retinopathy Study, focal or grid laser photocoagulation treatment for clinically significant macular edema reduced the risk of moderate visual loss, increased the chance of visual improvement, and was associated with only mild loss of visual field (Early Treatment Diabetic Retinopathy Study Research Group 1995). Intravitreal triamcinolone acetonide and other intravitreal anti-VEGF agents are currently under investigation for the treatment of diabetic macular edema. Panretinal laser photocoagulation treatment of eyes with high-risk proliferative diabetic retinopathy reduced the risk of severe visual loss by 50% compared to untreated control eyes (Diabetic Retinopathy Study Research Group 1981). Surgery is often indicated for nonclearing vitreous hemorrhage and for tractional retinal detachment involving or threatening the macula.

38.2.3.3 Glaucoma

Primary open angle glaucoma (POAG) is the most prevalent type of glaucoma, affecting 1.3–2.1% of the general population over the age of 40 years in the United States. In the United States, the disease is the leading cause of irreversible blindness among blacks and the third leading cause among whites (following AMD and diabetic retinopathy), and is responsible for 12% of legal blindness. Risk factors for the disease include increasing age (especially greater than 40 years), African ethnicity, positive family history of glaucoma, diabetes mellitus, and myopia (nearsightedness).

POAG is a chronic, slowly progressive optic neuropathy characterized by atrophy of the optic nerve and loss of peripheral vision. Central vision is typically not affected until late in the disease. Because central vision is relatively unaffected until late in the disease, visual loss generally progresses without symptoms and may remain undiagnosed for quite some time. While usually bilateral, the disease may be quite asymmetrical. POAG is associated with increased intraocular pressure, but normal-tension glaucoma may cause glaucomatous vision loss in patients with normal intraocular pressure. Thus, normal eye pressure does not rule out the presence of glaucoma.

Treatment of POAG includes topical or systemic medications, laser, or surgery to lower the intraocular pressure to a level at which optic nerve damage no longer occurs. Visual field testing is performed regularly in order to evaluate for progressive loss of peripheral vision, and the optic nerve is examined regularly to evaluate for evidence of progressive optic atrophy (clinical signs of glaucoma in the optic disc include asymmetry of the neuroretinal rim, focal thinning of the neuroretinal rim, optic disc hemorrhage, and any acquired change in the disc rim appearance or the surrounding retinal nerve fiber layer).

38.2.4 Specific Visual Functions

38.2.4.1 Visual Acuity

Visual acuity is the most common measure of central visual function and refers to the smallest object resolvable by the eye at a given distance. It is defined as the reciprocal of the smallest object size that can be recognized. Visual acuity is expressed as a fraction in which the numerator is the distance at which the patient recognizes the object and the denominator is the distance at which a standard eye recognizes the object. For instance, a visual acuity of 20/60 means that the patient needs an object three times larger or three times closer than a standard eye requires. The traditional visual acuity chart presents symbols of decreasing size with fixed high contrast. The visual acuity chart used most often in the clinical setting is the Snellen acuity chart, which is comprised of certain letters of the alphabet; the size of the letters are constant on a given line of the eye chart, and decrease in size the lower the line on the chart. In accurate Snellen notation, the numerator indicates the test distance and the denominator indicates the letter size seen by the patient.

38.2.4.2 Contrast Sensitivity

Contrast sensitivity refers to the ability of the patient to detect differences in contrast and is defined as the reciprocal of the lowest contrast that can be detected. This may be measured with the Pelli-Robson chart, in which letters decrease in contrast rather than size, or the Bailey-Lovie chart, in which letters of a fixed low contrast are varied in size. Contrast sensitivity is considered a more sensitive indicator of visual function than Snellen acuity and may provide earlier detection of such pathology as retinal and optic nerve disease.

38.2.4.3 Visual Field

Visual field is classically defined as a three-dimensional graphic representation of differential light sensitivity at different positions in space. Perimetry refers to the clinical assessment of the visual field. Typically, visual field is assessed with kinetic or static perimetry. During kinetic perimetry, a test object of fixed intensity is moved along several meridians toward fixation and points where the object is first perceived are plotted in a circle. During static perimetry, a stationary test object is increased in intensity from below threshold until perceived by the patient, and threshold values yield a graphic profile section. While peripheral visual field loss often produces difficulty for patients in orientation and mobility functions, macular field loss (either centrally or paracentrally) often causes difficulties with reading. For instance, the presence of central or paracentral visual field loss is a more powerful predictor of reading speed than is visual acuity (Fletcher et al. 1994).

38.2.4.4 Color Vision

Evaluation of color vision may be performed using pseudoisochromatic color plates, which are quick and commonly available; they consist of circles in various colors such that a person with normal color vision function can distinguish a number from the background pattern of circles. Ishihara or Hardy-Rand-Rittler pseudoisochromatic color plates are designed to screen for congenital red/green color deficiencies, while Lanthony tritan plates may be used to detect blue/yellow defects, which are frequently present in acquired disease. With the Farnsworth-Munsell 100-hue test, the patient must order 84 colored disks; the time-consuming nature of this test limits its clinical use. The Farnsworth Panel D-15 is a shorter and more practical version (using 15 disks), but is less sensitive. Most color-vision defects are nonspecific.

38.2.5 Visual Function and Age

This section provides an overview of how levels of visual function vary with age, and to what degree. Aging is synonymous with natural declines in a person's sensory abilities. As such, the process of aging is accompanied by changes to the eye, including the retina and visual nervous system that can impact functional vision (Schieber 1994). Additionally, older adults are more likely to acquire ocular conditions that can compromise visual functioning beyond normally anticipated changes, such as macular degeneration, diabetic retinopathy, and cataracts. Age-related vision loss commonly impinges on the ability to complete near vision tasks such as reading and using the computer (Arditi 2004). An understanding of these functional declines provides direction for strategies aimed to mitigate the negative impact of these changes. HCI designers, developers, and usability specialists should be fully aware of these needs, as the needs of this growing user population will become an increased priority with the shift in demographics of population segment.

Aspects of visual function that are known to normally decline as part of the aging process include the following:

- Visual acuity
- Visual field
- Contrast sensitivity
- Color perception
- Floaters
- Dry eyes
- Increased need for light
- Difficulty with glare
- Dark/light adaptation
- Reduced depth perception (Orr 1998)

Beyond these factors, eye movement efficiency and accuracy are observed to decline with old age. Older adults are known to be less accurate and/or slower in locating a target in the peripheral vision (see also Kline and Scialfa [1997]; Lee, Legge, and Oritz [2003]). Age-related differences have also been observed with the effectiveness with which older adults visually track targets with higher velocities. In both cases, these trends are typically aggravated by the presence of distracting stimuli (visual, auditory, tactile, etc.) in the background or foreground that contribute to the complexity. The perception of moving stimuli, for older adults, is both less effective and less efficient in tasks aimed at the detection of small target movement/change such as those found on dials and controls (Kline and Scialfa 1997). Furthermore, deficits in central, paracentral, and peripheral visual field can pose different demands on vision, resulting in different search strategies related to eye movements (Coeckelbergh et al. 2002). Schumacher and colleagues (2008) examined the reorganization of visual processing and its relation to eccentric viewing in patients with macular degeneration, revealing that visual stimulation of the preferred retinal location (PRL) in patients with AMD increased brain activity in the cortex normally representing central vision relative to visual stimulation of a peripheral region outside the patients' PRL and relative to stimulation in the periphery of age-matched control participants.

Older adults tend to exhibit a greater degree of difficulty with visual search tasks, especially when the number of items to be searched increases (Kline and Scialfa 1997). A recent study explored the hypothesis that older adults are slower due to a greater degree of double checking during visual search than younger adults. The research showed that older adults did double check more often, however speed stress instructions reduced age-related differences in double checking (Mitzner et al. 2010). Older adults have a propensity for longer visual reaction times, especially in cases where attention is divided. Furthermore, this population segment experiences difficulties ignoring extraneous information, or background noise (Schieber 1994). Research also suggests that visual search is slower and less effective for older adults due to a shrinking of the useful field of view to which attention can be simultaneously allocated. The size of the useful field of view, for older adults, is especially susceptible to context-related factors, such as complexity and cognitive task load (Schieber 1994).

38.2.6 Summary

Studies have demonstrated that ophthalmic patients are at high risk for decreased functional status and quality of life (Parrish et al. 1997; Rovner et al. 2011; Scott et al. 2001; Scott et al. 1994). Patients' functional statuses and qualities of life may be improved by interventions that increase visual function, such as surgery to repair retinal detachment or remove epiretinal membrane (Scott et al. 1998) and surgery to remove cataract (Applegate et al. 1987; Brenner et al. 1993; Donderi and Murphy 1983; Javitt et al. 1993; Steinberg et al. 1994). In addition, functional status and quality of life may be improved by interventions, such as low vision devices and services, which permit patients to use their remaining vision more effectively (Scott et al. 1999; Stelmack et al. 2008). In addition, as the proportion of older adults multiplies, the number of individuals experiencing some degree of vision dysfunction that normally occurs with age has created an increased demand for information technology that affords use despite the dysfunction. Prior studies have demonstrated the effect of low vision interventions on objective task-specific measures of functional abilities such as reading speed, reading duration, and ability to read a certain print size (Nilsson 1990; Nilsson and Nilsson 1986; Nguyen, Weismann, and Trauzettel-Klosinski 2009; Rosenberg et al. 1989; Sloan 1968).

However, historically there has been little data available concerning the abilities of people with visual impairments to use computers. It has been even more challenging to find data concerning how modifications of GUI features may increase accessibility of computers to patients with visual impairments. An exception to this is the research agenda established by Jacko and colleagues (see Barreto, Jacko, and Hugh [2007]; Jacko et al. [2005]; Jacko et al. [2003]; Scott, Feuer, and Jacko [2002a,b]; Scott et al. [2006]; and Table 38.1, e.g., has yielded systematically derived HCI performance thresholds for users according to their ocular profile [diagnoses and functional ability]). Table 38.1 summarizes the research products resulting from this effort, chronologically organized by the ocular pathology investigated, the age of the users involved, the GUI interaction investigated and the corresponding specific interface feature in question. It goes without saying that the rapid proliferation of visual displays beyond the desktop to handheld and wearable computers and other mobile devices, such as phones and tablets, increase the importance of GUI innovations that facilitate efficient and rewarding usage by people with visual impairments.

38.3 HIGHLIGHTING TECHNOLOGICAL ADVANCEMENTS IN HUMAN–COMPUTER INTERACTION RESEARCH

With nearly every aspect of today's society involving some type of computer technology, there is an ever-growing need to understand how individuals with visual impairments can access technology. Currently, without special modifications, the typical PC poses several challenges to users who experience limited bandwidth to their visual sensory channels, as well as other perceptual impairments. Furthermore, the widespread mainstream adoption of technologies that leverage touch screen displays, such as MP3 players and smart phones, has introduced novel interaction methods that pose new constraints to use for those with visual impairments. As a result, the HCI research community is placing great emphasis on the design of universally acceptable technologies. According to Stephanidis et al. (1998, p. 6), "Universal access in the Information Society signifies the right of all citizens to obtain equitable access to, and maintain effective interaction with, a community-wide pool of information resources and artifacts." Accessibility has been a term traditionally associated with elderly individuals, individuals with disabilities and others who possess special needs (Stephanidis et al. 1999). However, because of the current influx of new technologies into the market, the population of users who may possess special needs is growing. As a result, accessibility has taken on a more comprehensive connotation. This connotation implies that all individuals with varying levels of abilities, skills, requirements, and preferences be able to access information technologies (Stephanidis et al. 1999). Universal access also implies more than just adding features to existing technologies. Rather, the concept of universal access emphasizes that accessibility be incorporated directly into the design (Stephanidis et al. 1998). Perceptual and adaptive interfaces are two ideal examples of how universal accessibility can be achieved.

38.3.1 Perceptual Interfaces

The concept of perceptual design describes a perspective of design that defines interactions in terms of human perceptual

Note: • indicates that a given topic is addressed by the corresponding investigation, listed in the leftmost column.

capabilities. In a sense, it strives to humanize interaction. The design of perceptual interfaces adheres to the idea that lessons learned from psychological research about perception can be applied to interface design (Reeves and Nass 2000). In adopting the concept of perceptual design, several opportunities surface for the creation of innovative perceptual user interfaces. Interactions with these interfaces can be described in terms of three particular human perceptual capabilities; chemical senses (e.g., taste and olfaction), cutaneous senses (e.g., skin and receptors), and vision and hearing (Reeves and Nass 2000). Although commonly used computer technology limits the effectiveness of chemical senses, the technology can be extended to incorporate the cutaneous, visual, and hearing senses.

In terms of vision, research has focused on topics, such as visual mechanics, color, brightness and contrast, objects and forms, depth, size, and movement. Hearing research includes psychophysical factors such as loudness, pitch, timbre, and sound localization; physiological mechanisms such as the auditory components of the ear, and the neural activity associated with hearing; and the perception of speech such as units of speech and the mechanics of word recognition (Reeves and Nass 2000). With respect to the cutaneous senses, augmented GUIs with haptic feedback have been around since the early 1990s. Akamatsu and Sate conducted the first research with a haptic mouse that produced haptic feedback via fingertips and force feedback via controlled friction (as cited in Oakley et al. 2000). Engle, Goossens, and Haakma found that directional two degrees of freedom force feedback improved speed and error rates in a targeting task (as cited in Oakley et al. 2000).

The strength of perceptual user interfaces comes from the ability of designers to combine an understanding of natural human capabilities with computer input/output devices, and machine perception and reasoning (Turk and Robertson 2000). General examples of how capabilities can be combined with technology include speech and sound recognition and generation, computer vision, graphical animation, touch-based sensing and feedback, and user modeling (Turk and Robertson 2000).

From an applied research standpoint, the concepts of perceptual interfaces are housed within multimedia and multimodal interfaces. Both multimedia and multimodal interfaces offer increased accessibility to technologies for individuals with perceptual impairments. Distinctions can be drawn between perceptual, multimedia, and multimodal interfaces, shown in Figure 38.2. Perceptual interfaces prescribe human-like perceptual capabilities to the computer. Multimedia and multimodal interfaces can be considered applied extensions of this concept. Multimedia interfaces elicit perceptual and cognitive skills to interpret information presented to the user. Whereas multimodal interfaces use multiple modalities for the HCI. Multimedia interfaces focus on the media while multimodal interfaces focus on the human perceptual channels (Turk and Robertson 2000). The strength and capabilities of multimedia and multimodal interfaces with respect to individuals with perceptual impairments are described in more depth in Sections 38.3.1.1 and 38.3.1.2.

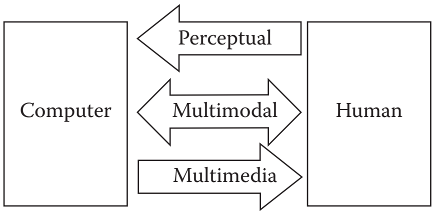

FIGURE 38.2 Perceptual, multimodal, and multimedia interfaces (flow of information).

38.3.1.1 Multimedia Interfaces

Multimedia interfaces have grown from the need to display diverse forms of information in a flexible and interactive way. Multimedia can be simply defined as computer-controlled interactive presentations (Chignell and Waterworth 1997). The broadness of this definition directly corresponds to the broadness of the field of multimedia research. Chapter 6 in this book contains a comprehensive discussion of multimedia including topics dealing with the cognitive implications related to multimedia, selecting media for the message, navigation and interaction and evaluation of multimedia. However, for the purpose of this chapter, the discussion of multimedia is limited to a brief overview of types and potential strengths of multimedia as they relate to enhancing accessibility to information technologies for individuals with perceptual impairments.

There are three approaches to multimedia: performance, presentation, and document (Chignell and Waterworth 1997). In the performance approach, multimedia is a kind of theatrical play that is conveyed through “actors.” The timing of the actors’ performances is orchestrated in an effort to entertain and educate (Waterworth and Chignell 1997). Presentation multimedia is a modern version of slide shows, where video clips and animation enhance a sequence of slides. The goal of the presentation approach is to convey ideas to the user (Chignell and Waterworth 1997). Lastly, the document approach focuses on text and ideas. It can be thought of as an enhanced document that elaborates ideas in the text. All of these approaches provide additional opportunities to convey perceptual information to the user.

Multimedia allows communication between users and computers in a sensory manner. As such, the essential aspect of designing multimedia interfaces is selecting the media and modalities. Information can be taken from one modality and presented in another modality (Chignell and Waterworth 1997). For instance, data presented visually could be converted and displayed audibly. For instance, multimedia could be used to enhance a GUI for a user with a hearing impairment. Information that would be commonly conveyed via auditory feedback could be provided visually. An example of this would be to have an icon display when an error has been committed, rather than the traditional beep sounding. Other examples of how multiple modalities can enhance accessibility to information technologies are discussed in the Section 38.3.1.2.

The potential strength of multimedia interfaces comes from its ability to use images, text, and animation to connect with users. However, in order to facilitate that type of exchange, much consideration must be paid to users' sensations and perceptions via the auditory, speech, and visual channels. For instance when designing graphical images, basic knowledge of color vision is needed to ensure that colors can be discriminated, foreground can be separated from background, highlights will attract attention, and grouping of objects is apparent (Gillan 1998). An understanding of human sensation and perception is necessary if perpetual interfaces are to reach their full potentials. When perceptual interfaces are used, however, they provide individuals with perpetual impairments, such as those related to the visual channel, alternative modalities to access technology. Multimodal interfaces are a second type of perceptual interface that provide this same benefit.

38.3.1.2 Multimodal Interfaces

Multimodal interfaces, as they are discussed in this chapter, are interfaces that support a wide range of perceptual capabilities (e.g., auditory, speech, and visual) as a means to facilitate human interaction with computers. Multimodal interfaces are discussed in a much broader sense (e.g., development of multimodal processing) in Chapter 18.

With the growing complexity of technology and applications, a single modality no longer permits users to interact effectively across all tasks and environments (Oviatt, Cohen, Suhm, et al. 2002). The strength of a multimodal design is its ability to allow users the freedom to use a combination of modalities or the best modality for their needs. These interfaces make the most effective use of the variety of human sensory channels, alone and in combination. Ultimately, multimodal interfaces offer expanded accessibility of computing and promote new forms of computing not previously available to individuals with perceptual impairments.

The development and application of multimodal interfaces for making technologies accessible to users with visual impairments is growing. Some forms of unimodal, bimodal, and trimodal feedback within multimodal interfaces have been investigated and their advantages have been documented for users with visual impairments (Jacko, Emery, et al. 2004; Jacko, Barnard, et al. 2004; Jacko et al. 2005; Jacko et al. 2003). Since most information presented on a GUI is visual, there is great interest in the research community to find alternative ways of displaying this information. One of the common approaches to conveying visual information in a nonvisual way is through the use of the tactile modality. Specific research has been conducted in the realm of tactile displays with respect to visual impairments. Not only can tactile displays provide information regarding a graphic's identity but also the depth, location, and perception of its purpose. The use of tactile systems can also provide navigational information. Research has shown that tactile output of directional information offers support to the blind as they explore images (Kurze 1998). Research has also been conducted in the area of movable dynamic tactile displays that present information to one or several fingertips in a Braille type manner. The Braille dots move in a wave of lifted and lowered series of pins (Fricke and Baehring 1994). Along the same line of research, the use of a bidimensional single cell Braille display combined with a standard Braille cell has been evaluated. Although initial research found this new combined device is not an improvement over a standard stand-alone Braille display, continued research is yielding improvement (Ramstein 1996). Tactile output via force feedback has been looked to as a means of conveying numerical information. Yu, Ramloll, and Brewster (2000) worked on a system that converts data typically displayed visually into haptic and auditory output. Since data visualization techniques are not appropriate for blind people or people with visual impairments, this system translated graphs into friction and textured surfaces along with auditory feedback. Pins presented via a tactile mouse to communicate graphical interface objects have been shown to support users in performing web-based tasks with fewer limitations than using a screen-reader alone (Kuber, Yu, and O'Modhrain 2010). Another common approach to converting visual information in a nonvisual way is through the use of the speech modality. Speech recognition systems serve as an alternative modality for users and computers to interact. These systems recognize human speech and translate it into commands or words understood by the computer. Chapter 40 in this handbook offers an introduction to the technology of speech recognition systems and design issues associated with incorporating speech recognition into applications. However, this chapter's discussion of speech recognition systems concentrates on its use related to Individuals with visual impairments. The integration of speech input and output into applications offers an alternative to purely graphical environments (Yankelovich, Levow, and Marx 1995). This type of technology-driven design allows applications to be suited to a wide variety of individuals with disabilities (Danis and Karat 1995). For instance, individuals with visual impairments can use a computer solely by voice activation. A multimodal web browser is another approach for individuals with visual impairments to access the web. MGSYS VISI-VL is designed to couple tactile keyboard access with the speech recognition process (Ismail and Zaman 2010).

Speech recognition systems are traditionally associated with the concept of dictation. Products such as Dragon Systems, Inc.'s Dragon Naturally Speaking offer a line of speech recognition products for dictation. Some specific packages are geared toward particular professions, such as medical and legal (Cunningham and Coombs 1997). Other common dictation systems are IBM ViaVoice, Lernout & Hauspie Voice Xpress, and Philips Speech Processing FreeSpeech98. Along the lines of recognition engines, Verbex Voice Systems and SRI Corp.'s DECIPHER offer continuous speech recognition technology. Microsoft's Whisper provides speaker-independent speech recognition with online adaptation, noise robustness, and dynamic vocabularies and grammars (Huang, Acero, Alleva, et al. 1995). Speech-driven menu navigation systems, for instance Command Corp. Inc.'s IN CUBE Voice Command for window navigation, have also been developed

(Karshmer, Brawner, and Reiswig 1994; Karshmer et al. 1994).

Often, circumstances may affect more than one sensory channel, and individuals may experience multiple impairments. In addition to providing heightened challenges to interaction, this impacts the efficacy of perceptual interface in meeting users' needs. For example, many disabilities are associated to some degree with speech degeneration, and therefore speech recognition systems may not fully accommodate a user's needs (Rampp 1979). Older adults commonly experience multiple impairments, as all the sensory channels normally decline with age, and are more susceptible to conditions, such as stroke, which can cause reduced speech, vision, and motor skills. For cases in which speech is degraded, speech recognition systems must be sensitive enough to adapt to impaired speech. Regardless of what caused the speech impairment, devices and techniques can be applied to augment the communicative abilities of individuals who experience difficulty speaking in an understandable manner.

Augmentative and alternative communication (AAC) is a field of study concerned with providing such devices and techniques. McCoy et al. (1997) described a prototype system aimed at users with cognitive impairments. This prototype is designed to aid communication and provide language intervention benefits across several user populations. An iconic language approach has been applied to aid individuals with significant speech and multiple impairments (SSMI). Research has been conducted on the use of icon language design based on the theory of icon algebra (Chang 1990) and the theory of conceptual dependency (Schank 1972). These methodologies are then used in interactive interface design (Albacete, Chang, and Polese 1994). Individuals with SSMI also commonly have difficulty with word processing. Using an animated graphical display, phoneme probabilities of speech can be more easily isolated and recognized. This allows users the opportunity to interpret their speech rather than forcing the computer to do it automatically (Roy and Pentland 1998). The more feedback and modalities users are provided, the more efficiently they can interact with speech recognition by assisting the computer to interpret their speech correctly. Speech recognition systems must also take into account the possible extent of cognitive burden placed on the user. If voice is used to navigate through a GUI, certain prosodic features (e.g., pauses) of the user's speech, resulting from a high cognitive load, may affect performance (Baca 1998). Additional challenges associated with the implementation of speech recognition systems are discussed in this handbook as well. Overall, these systems need to account for situations when users with visual impairment experience varying levels of hearing, speech, and cognitive abilities.

The auditory channel serves not only to convey information, but also to receive information. The use of auditory feedback is extremely useful to many computer users. Ongoing research has looked at the use of bidirectional sound as a standard element of an interface environment. A prototype named the Voice Enabled Reading Assistant (VERA), written using an aural-oral user interface (A-OUI) model, was developed to provide bidirectional sound. The A-OUI model captures qualities and functions of plain text files needed for user interfaces to present information to the auditory, visual, and tactile senses. The use of the VERA prototype can be applied to many types of office and Internet text and data. Similar speech-enabled products are Emacspeak and IBM VoiceType Simply Speaking Gold (Ryder and Ghose 1999).

Much work with respect to audio feedback has focused on conveying information from a GUI. For instance, research conducted by Darvishi and colleagues (Darvishi, Guggiana, et al. 1994; Darvishi, Munteanu, et al. 1994) looked at mapping GUIs into auditory domains through impact sounds based on physical modeling. Ultimately, these sounds are used to convey information to the user regarding the objects in a GUI environment. Audio feedback has also been used to provide visually impaired users with a sense of depth perception, by varying the location of the sound sources in a three-dimensional environment. Because depth perception is a function of vision, any cues that can be conveyed though other modalities are vital. This is particularly crucial when working with three-dimensional computer applications, such as a CAD package (Mereu and Kazman 1996). The use of auditory feedback has also been studied with regard to enhancing synthesis speech output. Through the development of spatial audio processing systems, a greater benefit of synthesis speech was achieved (Crispien, Würz, and Weber 1994). IBM's Screen Reader/2 also uses synthesis speech to make GUIs accessible to those who are visually impaired or blind, by converting screen information to speech or Braille. The users are continuously kept informed of screen activity and cursor movement. Reading typed characters, words, and sentences are features that can be made automatic. This software aids in the use of windows, menus, dialog boxes, and other controls (Thatcher 1994). Microsoft Corporation's Whistler, a trainable, text-to-speech system that produces synthetic speech, sounds very natural by reproducing the characteristics of original speech (Huang, Acero, Adcock, et al. 1996). WRITE:OUTLOUD and OutSPOKEN are two additional text-to-speech products commonly used (Friedlander 1997). Regardless of what product is used, text-to-speech software enables information to be collected and utilized in a more rapid manner.

In addition to the benefits already discussed that enable users with visual impairments to access technology, multimodal interfaces also provide superior support of error handling. More specifically multimodal interfaces have been shown to have the ability to avoid errors and recover more efficiently from errors when they do occur. This is a very important element of universal accessibility. Enabling users to use a technology includes not only being able to access the technology but also the ability to use it in an efficient manner. Reducing or avoiding errors is a major key to improving efficiency. A multimodal interface provides better error handling than a unimodal interface for several reasons. The following are factors that represent reasons why a multimodal interface may be better at error avoidance:

- Users will select the input mode considered less error prone for a particular context, which is assumed to lead to error avoidance.
- The ability to use several modalities permits users the flexibility to leverage their strengths by using the most appropriate modality. It is possible that the more comfortable the users, the less likely they are to make errors.
- Users tend to switch modes after systems errors. For instance, users are likely to switch input modes when they encounter a system recognition error.
- Users are less frustrated with error when interacting within a multimodal interface, even when errors are as frequent as in a unimodal interface. The reduction in frustration may be the result of the user feeling as though they have more control over the system because they can switch modes (Oviatt 1999).

Ultimately, multimodal systems aid in reducing errors (error handling) because they offer parallel or duplicated functionality that allow users to accomplish the task using one of several modalities (Oviatt and Cohen 2000). These benefits stem from the user-centered and system-centered design perspectives from which multimodal interfaces are built (Oviatt and Cohen 2000; Oviatt, Cohen, Suhm, et al. 2002). Like multimodal interfaces, adaptive interfaces, also benefit from a user-centered perspective.

38.3.2 Adaptive Interfaces

Adaptive interfaces have great potential for accommodating a wide range of users in a variety of work contexts. As a result, much research has been conducted on the design and implementation of adaptive interfaces. An example of early research in the field of adaptive GUI is illustrated by the work of Mynatt and Weber (1994) with the Mercator project, and the GUIB (Textual and Graphical User Interfaces for Blind People) project (Petrie, Morley, and Weber 1995). Both of these projects focused on making environment-level adaptations to GUIs in order to make them more accessible (Stephanidis 2001a). Mercator interfaces model the graphical objects and their hierarchical relationships. The model serves to predict a user's interaction (Edwards and Mynatt 1994; Edwards, Mynatt, and Stockton 1994). The goal is to provide visually impaired users with an interface that is more accessible. By better understanding how low vision users interact with a computer, interfaces can be designed more effectively. Outputs such as synthetic and digitized speech, refreshable Braille, and nonspeech sounds also make an interface easier to use. Auditory icons and earcons are two predominate areas of nonspeech sound research. Auditory icons, developed by Gaver (1989), are everyday sounds that occur in the world mapped to the computer world. Gaver first applied the concept of auditory icons to SonicFinder. Earcons are a second method for employing nonspeech audio in GUIs. Earcons, developed by Blattner, Sumikawa, and Greenberg (1989), are audio messages that provide the user with information about objects or operations of the computer. The first version of GUIB adapted the GUI by combining Braille speech and nonspeech audio together to construct a nonvisual interface so that users who are blind can access the GUI (Emiliani 2001).

Configurable interface designs based on user models have been heavily researched. The user models have been defined with respect to visual, cognitive, motor, and other abilities. With these models, custom computer systems, including both hardware and software, can be created (McMillan and Wisniewski 1994). Semantic abstraction of user interaction, named abstract widgets, is another modeling approach that provides great flexibility. Abstract widgets separate the user interface from the application functionality. This allows users to interact with interfaces as they choose, independently from their environment (Kawai, Aida, and Saito 1996). The use of adaptation determinates, constituents, goals, and rules are yet another approach of an adaptation strategy. This strategy is based on the fact that these important attributes, which categorize adaptation, can be used to formulate adaptation rules. These adaptation rules, in turn, assist the development of intelligent user interfaces. This approach can be customized to the requirements of different application domains and user groups (Stephanidis, Karagiannidis, and Koumpis 1997). Approaches such as described by the pervasive accessible technology (PAT) allow individuals with disabilities to use standard interface devices that adapt to the user in order to communicate with information technology infrastructures (Paciello 1996). Based on an individual's disability, the implementation of a user interface management system (UIMS) model provides the versatility needed to adapt interfaces to individuals. The selection of input devices, presentation of information on the screen, and choice in selection/activation method, can all be adapted to fit specific user needs (Bühler, Heck, and Wallbruch 1994). Current research focuses on operationally reliable software infrastructures that support alternative physical realizations through the abstractions of objects. More specifically, systems such as Active X (by Microsoft) and JavaBeans (by SunSoft) represent component-ware technology (Stephanidis 2001b). These systems represent a mainstream effort to provide technological structures that provide more adequate support for accessibility. They are also two examples of currently available tools that can be used to generate code for the adaptation of various interface components.

Some hypermedia systems research has focused on adaptive hypermedia applications. These adaptive hypermedia systems keep track of evolving aspects of the user, such as preferences and domain knowledge. This information is stored to create a user model, which in turn is the basis for user interface adaptation (De Bra, Houben, and Wu 1999). Adaptive hypermedia can also be designed based on task models. In the latter case, task models are the basis from which hypermedia systems are developed. These task models support the design and development of hypermedia. Different task models are associated with different types of users (Paternó and Mancini 1998). Task models reflect the user's view of the activities to be performed. In addition to personalizing the content of hypermedia systems, adaptive navigation support has also been researched. Prototype systems have been developed to demonstrate how different navigational possibilities can be made available based on a user model (Pilar da Silva et al. 1998).

Another example of adapting interfaces to users is through the use of the EZ Access protocols developed by the Trace Center at the University of Wisconsin-Madison. EZ Access protocols are a set of techniques that modify an interface to fit a specific user's need. These protocols work across disabilities and with a range of products. The most common use of EZ Access protocols is in touchscreen kiosks (Vanderheiden 1998).

While research and development in the areas of perceptual and adaptive interfaces, like those examples discussed, have gained substantial attention in generating potential solutions for individuals with visual sensory impairments, the majority of work and realized products are positioned in two areas. The most readily available products and the majority of the research have been somewhat narrowly focused on (1) the magnification of screen elements (Fraser and Gutwin 2000) and (2) the accessibility of text (Craven 2003). Comparatively, less has been accomplished in terms of critical aspects of the GUI as has been done with magnification and vocalization of text. While the solutions generated have afforded access to both those individuals who are blind and those who retain a range of visual impairment, they tend to be one size fits all solutions, which entirely abandon the visual sensory channel (as in the case of Braille interfaces or Screen Readers), or focus only on the augmentation of the visual channel (e.g., magnification, increased contrast, increased text size, etc.), and very few are multimodal, or perceptual. Table 38.2 summarizes a selection of popular assistive devices. Following this table, a discussion of research that has evaluated the efficacy of such approaches to accessibility is presented.

Kline and Glinert (1995) presented UnWindows V1, a set of interface tools to support selective magnification of the window area, and tracking the location of the mouse pointer on the display screen. The authors noted, "Magnification is one method commonly employed to help low vision users deal with the small type fonts, illustrations, and icons present in much of today's printed media and computer displays" (Kline and Glinert 1995, p. 2). Key components of the UnWindows system included (1) a dynamic magnifier to compensate for the loss of global context imposed by static magnification and changing display content and (2) visual and aural feedback to aid the users in locating the mouse pointer. Kline and Glinert placed emphasis on the problematic nature of visual tracking in the presence of a screen densely populated with icons and windows. Interestingly, they received mixed reaction to their interface by users with and without visual impairment, especially in terms of the auditory feedback provided whenever the mouse pointer entered a new window (users found this annoying). While no formal empirical testing was performed in relation to UnWindows, questions surface as to the effectiveness of nonvisual, multimodal feedback in a complex display.

A usability review of currently available technologies for the conversion of GUI technology for use by individuals who were blind or possessed low vision, the ability of magnification, synthetic speech, and Braille were reviewed for their ability to provide the respective users 100% access to GUIs on nine test areas (Becker and Lundman 1998). These tests included

- Installing and configuring the device/software
- Uninstalling the device/software
- Performance reliability/stability

TABLE 38.2
Popular Assistive Devices

Competitor	Product Overview	Key Limitation(s)
Screen reader 	Software program that reads to the user elements that appear on an interface via synthesized voice. The program reads left to right, starting at the very top of the screen. When an image is encountered, the program reads the associated ALT text.	Solution abandons any remaining vision the user has, using only their auditory ability. Efficacy depends on the organization of the interface (e.g., anything not modeled in a left to right organization is not compatible).
Braille display 	Similar to the screen readers, but gives the reader the information via tactile cues (Braille characters).	Same limitations as a screen reader, plus the user has to learn Braille, which is not likely if they have residual vision, and are losing vision later in life.
Screen magnifier 	Physical device or software program that enlarges the entire screen image. Software programs, such as Zoomtext, developed by Ai squared, allow for "adaptable" magnification of the interface, and some versions incorporate a screen reader.	A "one size-fits all" solution, that is not adaptable between users For people with visual impairments, magnification is not always the most effective strategy (especially with obstructed visual fields).

- Program manager to read and manipulate windows, menus, and icons
- Word processing-based tasks such as opening and saving files, reading and editing text, text attributes, and toolbars
- Spreadsheet tasks such as reading cells, tables figures, and editing data and formulas
- Internet use, including dialing up, accessing World Wide Web pages, navigating with link buttons, sending e-mail and reading graphics
- Screen searching, such as searching for characters, strings, formats, and icons
- Operating start menu, exploring and controlling settings (Becker and Lundman 1998)

For the assessment of seven magnification programs (synthetic speech and Braille displays are not relevant to individuals with visual impairments who have residual vision), the evaluators comprised of a system engineer, ergonomic engineer, computer science expert, and three individuals with visual impairments.

The use of magnification, as a strategy to afford access to GUIs proved somewhat successful, providing 89% or higher access to GUIs, except for Internet use (84% access) and screen searching (0%) (Fortuin and Omata 2004). It was concluded that the essential problem for the design of interactive systems for users with visual impairments is (1) to determine what the users need and (2) how to represent the requested information based on key psychological and physical attributes of the user. The result of ineffective assistive technologies is a lack of usable contextual cues for the users to provide feedback in the case of errors; and this translates to large amounts of imposed workload on the user and frustration (Fortuin and Omata 2004).

In a case study on an English teacher who was having difficulty reading student papers, typing, and proofreading, Whittaker (1998) discovered that magnification was not affording optimal performance. Typically, the authors found that users with visual acuity of 20/40 or better would respond well to simple optical magnification. The authors investigated other visual functioning to find that the individuals had severely diminished contrast sensitivity (13% contrast threshold, with 2% representing normal sensitivity). Furthermore, this individual's visual field was 20 degrees horizontally (180 degrees is normal). Magnification was likely reducing the number of letters viewable simultaneously in the presence of scotoma within the visual field. The author warned that magnifiers and large monitors are not always the most effective solution for users with impaired vision.

Arditi (2004) addressed the reading difficulties of individuals with low vision. According to the author, successfully overcoming this difficulty is accomplished through the exploitation of remaining vision. The easiest way to do this is through magnification, but as shown in this study, it is not a one size fits all solution. Several parameters of the font, including height, stroke, spacing, and serif size, must be selected in a combination that best suits a given user. Arditi presented the prototype and initial user testing of computer-based software that lets a user customize fonts for maximized legibility. Those users studied were able to adjust font to a usable, legible level, to positively impact reading times and the reading acuity. Arditi and Lu (2008) successfully created a novel web browser front end that goes beyond simple magnification and postconfiguration, no additional adjustments are needed, regardless of document type.

An in-depth review of accessibility tools aimed at improving interactions of computer users with low vision informed the design of MouseLupe (Silva and Bellon 2002). MouseLupe simulates a magnifying glass, enabling users to magnify select portions of text or display graphics, inspired by the problematic nature of screen magnification software. The authors suggested that magnification improves the readability of smaller text, but occludes the visible area of the document. Furthermore, graphics that contain text (like most icons), a critical element of the GUI, when enlarged, are difficult to read (for a comprehensive review of magnification tools, see Silva and Bellon [2002]).

Several researchers have considered the effect of visual impairments on web browsing (Arditi 2003; Craven 2003; Harper, Goble, and Stevens 2001; Murphy et al. 2008; Silva and Bellon 2002). Harper, Goble, and Stevens (2001) addressed this problem in terms of "web mobility." These authors provided guidelines for movement through and around complex hypermedia environments, such as the web, for users with visual impairments. The problem, according to these authors, is that visual impairment inhibits individuals' ability to efficiently assimilate page structure and visual cues that lead to the following problems:

- Failure to get a feel for the content on the website
- Failure to have a sense for the magnitude of the display or where in a website the interaction takes place
- Disorientation
- Obstacles and distracters such as spacer images, tables, and large images
- Too much complex detail that cannot be resolved
- Frustration

Arditi (2003) observed the problems of web browsing in terms of the allocation of screen space resources. According to the author, conflicts arise in the implementation of web browsing solutions for individuals with low vision including (1) high magnification requirements; (2) variable typography color, size, and contrasts of the content presented; (3) embedded text messages to augment web images; and (4) accessible web browsing controls (icons, buttons, menus). The author presented a novel approach for effectively using screen resources, providing evidence that the strategic layout of a display is a critical factor to successful interaction. The layout of screen elements was interpreted as more critical than magnification of the screen elements.

Craven (2003) questioned the accessibility of electronic library resources on the World Wide Web for individuals with visual impairments. The results of her study with 20 sighted and 20 visually impaired users revealed the browsing times of those individuals with visual impairments were significantly greater, depending on the design of the website (layout complexity and distracters). Navigation time for the group of users with visual impairments was significantly longer due to visual functioning, but also due to artifacts of assistive technology use in navigation (magnification and screen readers).

Not only are the tools inadequate for many visually impaired users, but many Web pages do not follow accessibility guidelines set forth by the W3C, the World Wide Web Consortium (http://www.w3.org/wai) or the web accessibility guidelines from the U.S. Federal Section 508 (http://www.section508.gov). The two most popular screen readers are JAWS (Job Access with Speech) and Window-Eyes. Despite their popularity, users have identified issues with their accessibility and usability. In a recent survey of visually impaired users, Lazar et al. (2010) found the following as top causes of user frustration to be

- Page layout causing confusing screen reader feedback
- Conflict between the screen reader and application
- Poorly designed/unlabeled form
- No alt text for pictures
- Misleading links
- Inaccessible PDF
- Screen reader crash

Web 2.0 is causing additional challenges for visually impaired web browsing. Applications supported by Web 2.0 are often visually-dynamic, interactive and capable of replicating desktop functionality. A result, stand-alone screen readers are not able to handle many types of Web 2.0 applications. While additional research is needed in this area, many technologies are rapidly evolving to meet this need. Specifications such as Accessible Rich Internet Applications or WAI-ARIA are currently being developed to provide more semantic information about web components and enable greater accessibility. WAI-ARIA has been used for improved accessibility of Wikipedia, a Web 2.0 collaborative encyclopedia that allows users to edit pages (Senette et al. 2009).

Another web solution has been developed by IBM for the visually impaired. World Wide Telecom Web (WWTW), or the Spoken Web, can be used not only for delivering information and services to those with low literacy and technical skills, but also to the visually impaired. IBM has developed a network of VoiceSites that can be created and accessed by voice interaction over an ordinary telephone. Over 10,000 people worldwide are currently using WWTW (Simonite 2011). IBM research reports that through their usability studies they have found the learning curve to be low, and no extensive training is required (Rajput et al. 2008). The authors suggest that WWTW could be a solution to bring social networking sites to the visually impaired.

38.3.3 Summary

Through technological advances in HCI research, the concepts of perceptual and adaptive interfaces have emerged. These two categories of technologies provide vast opportunities for individuals with perceptual impairments to fully access electronic information. More specifically, multimedia and multimodal systems have been shown to accommodate users of varying abilities. However, while these are the most promising approaches for this population, there still exists a chasm between research and practice. Unfortunately, it is rare to see the knowledge generated through HCI research actually implemented into commercially available products. Much work still needs to be done, both in terms of advancing knowledge—through empirical HCI research—and in terms of increasing awareness. Translational efforts need to be made to help disseminate this new knowledge into the design of technologies and devices, so that individuals with perceptual (and other forms of) impairment can better leverage the increasingly ubiquitous technological tools used in everyday life. An evidence-based need for improved design of technology—especially for individuals with sensory of perceptual impairments—is needed to help ensure that the new knowledge continually generated through research is ultimately used to improve human interaction with technology.

38.4 CONCLUSIONS

To provide a context for the topic of perceptual impairments and computing technologies, Figure 38.1 demonstrated that, in order to achieve universal access across classes of computing technologies, *researchers* must be prepared to address the following very challenging issues:

1. Establish empirical links between clinical diagnoses and sets of functional capabilities.
2. Define the set of functional capabilities required to access information technologies.
3. Establish empirical bases for the influence of specific functional capabilities on access to specific classes of technologies.

Furthermore, *designers* need to be empowered to design and create universally designed products that are fully accessible to people who have perceptual impairments. A key element of this is ensuring that designers can actually make use of the universal design resources that are provided to them during the design process (Law et al. 2008a,b).

This chapter aimed to establish a basis for addressing such issues by examining, specifically, visual impairment, several specific diagnoses, and the resulting functional abilities. Finally, groundbreaking advancements in perceptual interfaces, multimodal interfaces, multimedia interfaces, and adaptive interfaces were discussed, which can be applied across a variety of classes of technology in order to enhance the perceptual experience of people who possess such impairments.

ACKNOWLEDGMENTS

This chapter was made possible through funding provided to the first author by the National Science Foundation, as well as the Intel Corporation.

39 Universal Accessibility and Low-Literacy Populations

Implications for Human–Computer Interaction Design and Research Methods

William M. Gribbons

CONTENTS

39.1 INTRODUCTION

Over the past decade, the topic of universal accessibility has received close attention in the field of system design. Although considerable progress has been made in addressing the needs of the physically disabled and aging, low-literacy populations have largely been overlooked (Gribbons 1992; Newell et al. 2003; Lewis 2006; Friedman and Bryen 2007). With nearly 45 million adult Americans suffering from the debilitating effects of illiteracy, the universal accessibility movement has clearly not been universal. While many have called for action (Dickinson, Eisma, and Gregor 2003; Shneiderman 2000; Shneiderman 2007), an extensive review of the leading human factors and human–computer interaction (HCI) journals revealed a small number of studies focused on this critical issue. And while the number of entries on this topic in the hcibib (http://hcibib.org/) has grown over the past 5 years, this population is grossly underrepresented compared with other disabilities. Most significantly, the topic of low literacy, learning disabilities, and cognitively disabilities remain glaringly absent from the leading HCI and human factors textbooks.

The research that does exist in low literacy and learning disability studies is concentrated, to a large degree, in the fields of educational psychology, instructional design, and health care informatics. Here, a rich research tradition dates back many decades. However, many of these findings are limited to the design of the classroom experience, standalone computer-based training systems, patient interventions, and paper-based communication products. Research in non-educational settings for general interface and interaction design is limited. Compounding the problem, much of this work focuses on children rather than adults. Over the past 5 years, some progress, as noted in this chapter, has been made. Given the size of this population, it is also interesting to note that the fields of marketing and consumer behavior have directed considerable attention to accommodating the unique requirements of this group (Adkins and Ozanne 2005; Ozanne, Adkins, and Sandlin 2005; Viswanathan, Rosa, and Harris 2005). Similarly, the library sciences has considered the needs of this population while considering the accessibility of online library databases (Stewart, Narendra, and Schmetzke 2005; Craven and Booth 2006). And finally, the special needs of this population have been considered in the design of public transportation systems (Carmien et al. 2005).

The ubiquitous nature of the Internet, expansion in the use of information and communication technologies (ICT), e-health and e-government, and consumer electronics has motivated recent progress on accommodations for low literacy and related populations. The Web Content Accessibility Guidelines (WCAG) 1.0 (1999) released by the World Wide Web Consortium (W3C) urges designers to accommodate this population. Unfortunately, emerging guidelines continue to be vague and nonspecific such as those found at the Center for Usable Design. And just as we begin to make progress in one area, new applications of technologies, such as mobile access to the web in developing nations (Shneiderman 2007; and Sherwani et al. 2009) and the rapid growth of e-health technologies in the home (Bogner 1999), raise new issues for designers and researchers alike.

This chapter will address the challenge of accommodating low-literacy users in system design. It will explore the nature of this population and the magnitude of the problem, the relationship between literacy, learning disability, and cognitive disabilities, general characteristics, functional characteristics, and recommendations for design and research best practice. Ultimately, it is hoped that this effort will encourage further research in this critical area and the integration of that work in our profession's educational programs, guidelines, and best practices.

39.1.1 Defining the Population

Part of the challenge of addressing this population is building consensus on the most effective definition of this group. Common labels include "low literacy," "functionally illiterate," "cognitively disabled," "print-disabled," "learning disabled," (a subset of the cognitively disabled group) or specific learning disabilities such as dyslexia (Figure 39.1). Friedman and Bryen (2007) speculate the lack of agreed upon definition of this population is a contributing factor to the lack of focused research. An underlying assumption in this chapter is that these categories are not mutually exclusive nor the boundaries between each well defined. Because of the lack of clear boundaries, this chapter will focus on functional characteristics rather than clinical definitions. It is also acknowledged that a given disability can range from moderate to severe, as depicted in Figure 39.1.

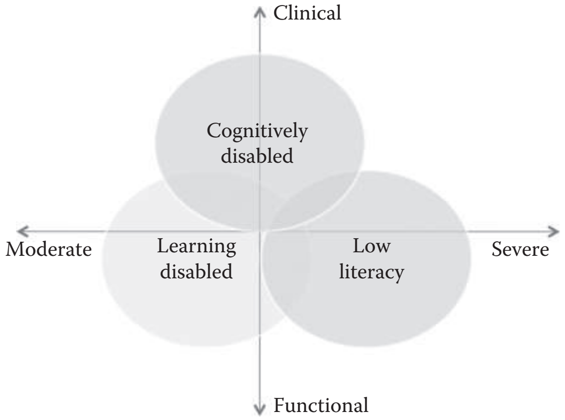

FIGURE 39.1 Comprehensive model of population.

For the purposes of this chapter, discussion will focus on low-literacy and learning-disabled populations and universal design solutions rather than more severe cognitive disabilities requiring assistive technologies. Functional illiteracy, a lack of document and quantitative literacy needed to function in modern society, was selected because it provides the most comprehensive picture of the total population. This perspective brings to the discussion a very detailed set of demographics and statistics. Unfortunately, this perspective is weak on underlying causes and effective accommodations. Fortunately, the learning-disability perspective provides an extensive research base that defines the characteristics of this population, the underlying source of the disability, and possible accommodations. Patterson (2008) summarizes numerous studies associating learning disabilities with low-literacy skills in adults and the persistence of the disability throughout one's life. Learning disability is an umbrella term used to describe a wide range of disorders in information processing and it is generally believed that learning disabilities are linked to a dysfunction in the central nervous system. The complete cognitively disabled category was not chosen since it includes a much broader class of disabilities including Down syndrome, autism, aphasia, emotional disabilities, and Alzheimer's disease. Naturally, these more severe disabilities require more extreme accommodations. However, it is highly likely that some adults identified as low literacy might suffer from an undiagnosed cognitive disability. Consequently, effects of "mild" cognitive disabilities will also be considered. It is estimated that nearly 80% of those diagnosed with a cognitive disability have a mild disability (Carmien et al. 2005).

The causes of low literacy are complex, varied and often inextricably intertwined. Underlying these causes include a lack of educational attainment, social deprivation, learning disabilities, or other cognitive disability. Further complicating matters, many adults with low-literacy skills were never diagnosed with a learning disability as children and entered adulthood suffering the debilitating effects of the disability without knowing the cause. Consequently, it is all but impossible to characterize whether the cause of low literacy in adults is a product of low educational attainment, social deprivation, an underlying disability, or whether an undiagnosed disability was the cause of an individual dropping out of the educational system.

39.1.2 Population Size

The current state of functional illiteracy in the United States paints a shameful picture. According to the 1992 National Adult Literacy Survey, some 23%, or nearly 45 million of approximately 200 million adult Americans, function at the lowest level of literacy, "Level 1." Those at Level 1 literacy are, for the most part, able only to read a simple form or understand rudimentary information in a short news article; others are not capable of even this (Kirsch et al. 1993a). Given the magnitude of these figures, it is surprising that greater attention has not been directed to this population, since the low-literacy population outnumbers all other disability groups combined.

The other literacy levels, two through five, represent progressively higher levels of literacy skills. Not surprisingly, one contributor to functional illiteracy is low educational attainment. The National Adult Literacy Survey states that: "adults with relatively few years of education were more likely to perform in the lower-literacy levels than those who completed high school or received some postsecondary education" (Kirsch et al. 1993a, p. xviii). The National Center for Educational Statistics (2001) reported the following:

> Between 1972 and 1985, high school completion rates climbed by 2.6% points (from 82.8% in 1972 to 85.4% in 1985); since 1985, the rate has shown no consistent trend and has fluctuated between 85% and 87%. This net increase of about 3% points over 29 years represents slow progress toward improving the national high school completion rates. (Kirsch et al. 1993b, p. 25.)

Given the lack of progress in this area, it is highly probable that educational attainment will continue to be a key contributor to lower-literacy skills among adults for the foreseeable future.

In 2003, this survey was re-administered and the results showed no significant improvement in prose and document literacy, with some improvement in quantitative literacy (National Assessment of Adult Literacy). Cleary the data from these two studies show the problem is large and progress is slow.

Unlike the measure provided by the National Adult Literacy Survey, there is no large-scale study measuring the prevalence of learning disabilities in the general population. However, there are a range of estimates from a variety of sources. The National Dyslexia Association (n.d.) estimates that 70%–80% of the population of students receiving special education services has deficits in reading and that 15%–20% of the general population has language-based learning disabilities (how common are language-based learning disabilities simply to document the scope of the problem). Shaywitz (1998) estimates the prevalence of dyslexia among school-age children at 5%–17% of the total population. The Interagency Committee on Learning Disabilities believes that 5%–10% of the population is affected by learning disabilities. The President's Committee on Employment for People with Disabilities found that 10%–14% of the adults in the workforce have learning disabilities. Finally, the National Institutes of Health estimated that 15% of the population in the United States has some type of learning disability (National Institute for Literacy, n.d.). Despite the probable link between those with learning disabilities and the larger lower-literacy population, few attempts have been made to validate this connection.

Not surprisingly, low literacy is not confined to the United States. There are an estimated 876 million illiterate adults in the world, which represents nearly a quarter of the world's population. In developed nations, it is estimated that there are approximately 100 million functionally illiterate people (Kickbusch 2001). In Canada, it is estimated that 30% of adult Canadians have low-literacy skills (Brez and Taylor 1997). In India alone, nearly 45% of the adult population is illiterate according to the 2001 Indian Census (Huenerfauth 2002). These statistics and others clearly convey the global scale of this problem.

39.1.3 Making the Case for Including Functional Illiteracy

The lack of research addressing literacy and learning disability in the HCI discipline was understandable 10 or 15 years ago when this population was unlikely to interact with technology outside of an educational setting. With the ubiquitous nature of information technology in modern society (e.g., the Internet, computers in all aspects of work, public kiosks, ATMs, public transportation, e-banking, e-government, e-health, and consumer electronics), this research gap is now indefensible. Accessible technology is no longer a luxury or an option; rather it is a prerequisite to gaining access to information that affects one's quality of life and health, participation in government, and contribution to the economy. Lewis (2010) cites a Microsoft-commissioned study that estimates that 16% of computer users in the United States have a cognitive disability. A report from the U.S. Department of Commerce (2002, p. 56) stated that: "between December 1998 and September 2001, Internet use by individuals in the lowest-income households (lower socio-economic groups represent a disproportionately high percentage of the lower-literacy population) increased at a 25 percent annual growth rate." The study also reported that: "as of September 2001, about 65 million of the 115 million adults who were employed and 25 or over use a computer at work" (p. 57). Although the percentage of workers using computers was significantly higher for "professional" positions, 20% of those working as operators, fabricators, laborers, farmers, and fishermen use a computer as part of their work (p. 58). Lastly, shifts in the economy from "hands-on work" to "information-and-technology work" will seriously disadvantage lower-literacy groups unless there is a corresponding increase in functional literacy skills.

If the size of this population alone were not enough to mobilize action, the cognitively disabled are a protected group under the Americans with Disabilities Act in the United States, the Disability Discrimination Act in the United Kingdom, Australia's Disability Discrimination Act and similar acts in other countries. In the United States, employers are required to provide workplace accommodations for employees who disclose their disability. That last stipulation of the act could very well be one of the reasons this population is often "invisible." Low literacy carries a stigma for most people and creates a reluctance to disclose the problem and encourages the development of elaborate means of disguising the disability—no disclosure, no requirement for accommodation. Beyond the stigma, Brez and Taylor (1997) report that many low-literacy adults fear disclosure will result in questioning their competency as an adult, parent, or caregiver.

Finally, there is a growing economic incentive for accommodating the needs of the low-literacy user. Viswanathan, Rosa, and Harris (2005) found, in their study of low-literacy consumers, a high degree of brand loyalty toward companies sensitive to their needs. They calculate that this market sector might represent as much as $380 billion in annual spending. We will see additional incentives in Section 39.1.3.1 that follows.

39.1.3.1 Low Literacy and Health Care

Perhaps the most poignant case of a digital divide between the literate haves and the low literacy have-nots is in the health care community. At the most basic level of following written or spoken instructions, low-literacy patients display an extremely low level of understanding of and compliance to instructions. Hussey (1994) reported the problem is particularly acute among older low-literacy patients. Wolf et al. (2006) found in their sample of low-literacy patients rates of correct interpretation of warning labels on prescription medications ranged from 0% to 78%. With the exception of one label, less than half of the subjects were able to adequately interpret the warnings. Although nontechnology based, one can only imagine how these basic information-processing problems are amplified in technology enabled environments. Further, many of the themes underlying the misunderstanding of written labels—multistep instructions, reading level of text, poor icons, poor use of color, and message clarity are common elements in technology-based systems.

Combine these basic information-processing problems with shorter hospital stays, the shift to out-patient care, patient-managed care, and care in the home and the urgency to consider low-literacy users increases dramatically. (Houts et al. 2001; Epstein, Maley, and Suri 2006). Coinciding with these trends is the growing use of fairly sophisticated technologies including infusion pumps, monitoring devices, and dialysis machines in the home. This deployment is more likely to occur in the homes of the elderly—with higher rates of low literacy and diminished cognitive capability—and be operated and maintained by an elderly caregiver or home health aide—workers who are often poorly paid, poorly educated, and not well regulated (Bogner 1999; Stone and Wiener 2001; Henriksen, Joseph, and Zayas-Caban 2009; Epstein, Maley, and Suri 2006). Epstein, Maley, and Suri (2006) warn that the growing use of distributed diagnostics and the expanding home health care industry must address the requirements of patients actively managing their care and a workforce that varies in training and literacy.

After a long delay, the health care community has made progress in using ICT to enhance the quality of patient care, specifically in disseminating health-related information, monitoring patient care, and storing patient information. As a result, the trend for seeking health-related information online has increased dramatically. An estimated 70 million Americans have sought health information online (Cain et al. 2000) from the nearly 10,000 or more health-related websites (Benton Foundation 1999). Birru et al. (2004) estimated that between 40% and 54% of patients use the Internet to search for information on ailments and treatments. This development would be exciting, given the documented contributions of information to improved health, if it were not for the fact that equal access to this information does not exist for all Americans. Similar to the progression that played out in the larger development community, initial design efforts in the health care sector have focused first on the "typical" fully functioning user and then on the aging and physically disabled. Most health care materials—web-based or paper—are written well above the literacy level of the average American, approximately a 10th-grade level or greater. (Doak, Doak, and Root 1996; Birru et al. 2004; Weiner et al. 2004). Kaphingst, Zanfini, and Emmons (2006) examined the accessibility of web sites containing colorectal cancer information and found the average site was written at a grade level of 12.8.

The health care sector has both a moral and economic responsibility to address the needs of lower-literacy populations. Morally, it is only right that all citizens should benefit equally from the value information technology brings to the quality of health care services. Cashen, Dykes, and Gerber (2004) provided support for this position by reporting that literacy is a better predictor of health status than age, income, employment status, education, or race. It is not surprising that low-literacy adults are twice as likely to be hospitalized as their functionally literate counterparts (Birru et al. 2004). There is clearly an economic motivation as well. A conservative estimate places excess health care costs tied to low literacy at $73 billion a year. (Rudd, Moeykens, and Colton 1999).

In recent years, the definition of the digital divide has shifted from economics to literacy. The availability of low-cost equipment and better access to the Internet in public facilities has lessened economic barriers. According to Shneiderman (2000), poor interface and interaction design remain as one of the defining variables between the technology haves and have-nots. And while we might hold out hope that we may one day eradicate low literacy at the source, the fact that learning disabilities are lifelong and that fewer than one in eight low-literacy workers receives literacy training in the workplace (Sum 1999, p. 156) strongly suggests that the burden falls on universal design.

39.2 GENERAL CHARACTERISTICS OF THE POPULATION

Low literacy is often referred to as the "invisible" disability. In many cases, the individual is unaware of the problem; in others, they "hide" the disability. Findings from the National Literacy Survey (Kirsch et al. 1993a,b) suggest that as many as: "66 to 75 percent of the adults in the lowest [literacy] level and 93 to 97 percent in the second lowest level described themselves as being able to read or write English 'well' or 'very well'" (The Literacy Skills of American Adults, p. xvii). In another study by Moon et al. (1998) reported that 70% of the participants reported they read "really well," while in actuality their reading scores reflected a seventh- to eighth-grade ability. Also contributing to the under-reported size of the population is the stigma attached to low literacy that increases an individual's reluctance to disclose the problem. In addition, the many challenges and failures experienced by the learning disabled over a lifetime often result in a poor concept of self-worth and low self-esteem (Gerber 1998).

As previously discussed, a major cause of low literacy is learning disabilities. The learning disability umbrella encompasses a wide range of information-processing disorders, such as dyslexia (language), dyscalculia (mathematics), and dysgraphia (handwriting). The disability is thought to be neurobiological in origin and present itself in various combinations and levels of severity. In addition, an individual with a deficit in one area may have strengths in other areas. Understanding the heterogeneous nature of the learning-disabled population is critical to formulating appropriate accommodations. Learning disabilities generally persist over a lifetime, but the manner in which the disability presents itself will change with life stages as individuals construct increasingly sophisticated coping strategies (Gerber 1998). The lifelong persistence of the disability, combined with the aforementioned lack of adult-literacy training, suggests this problem will not go away soon.

Overall, learning disabilities affect an individual's ability to develop and use reading, writing, reasoning, and mathematical skills (Karande et al. 2005). Sherwani et al. (2009) reported that the effects of low literacy go beyond the processing of written text. Supporting this claim, low-literacy subjects in their study also experienced difficulty with tasks supported by speech interfaces. In addition, Viswanathan, Rosa, and Harris (2005) reported low-literacy consumers are more likely to employ concrete reasoning, basing decisions, trade-offs, and behaviors on the literal meaning of single pieces of information rather than a comprehensive consideration of all available information. Consistent with the use of concrete reasoning, they also report this population struggles with abstract or metaphorical meaning. In the absence of effective information-processing skills, the individual's ability to access, process, and retain (learn) information is severely constrained.

One point where the learning-disabled population breaks with the larger functionally illiterate community is at the level of underlying intelligence. Many individuals with one or more learning disabilities have normal or above normal intelligence (Rowland 2004; Doak, Doak, and Root 1996; Gerber 1998). Consequently, once appropriate accommodations are provided to mitigate the effects of the disability, adequate intelligence exists to accomplish most cognitive tasks.

A final, yet critical, defining characteristic is the incredible diversity within the population—often defined as a "universe of one." Individuals will vary in the range and severity of deficits and the range and type of compensating abilities. Ozannes, Adkins, and Sandlin (2005) suggest literacy skills are also highly contextual—not transferring smoothly from one situation to another. Although their research focused on low-literacy consumers, their findings warrant consideration by those conducting similar studies in HCI.

39.2.1 Low Literacy, Learning Disability, and Aging

One remaining characteristic of this population is the disproportionately high rates of lower literacy in the aging population. Kirsch et al. (1993b, p. 5) reported: "Older adults were more likely than middle-aged and younger adults to demonstrate limited literacy skills. For example, adults over the age of 65 have average literacy scores that range from 56 to 61 points (or more than one level) below those of adults 40–54 years of age." (The Literacy Skills of America's Adults). In the most recent National Literacy Survey, 14% of the adult population is below basic prose literacy skills, with 26% of this group 65 years of age or older (NAAL 2003). As cited in Section 39.1.3.1, the combination of low literacy and aging is particularly problematic when it comes to accurately following instructions, carefully taking medications, and properly using health technologies.

The cause for the disproportionately high percentage of low literacy among older adults is likely a combination of a number of factors including a lower percentage of high school graduates among the older population and the general lack of special education services when they were in school. Also, Patterson (2008) highlights the likelihood that the abilities of the learning disabled decline with age, exacerbated by the general cognitive decline associated with aging. Regardless of the cause, design accommodations that benefit lower-literacy populations are likely to have the added benefit of supporting the broader aging population as well.

The Section 39.2.2 will move from this general overview of population characteristics to a detailed discussion of the functional characteristics of the learning disabled. A sizable portion of the research that fuels this discussion is from the study of dyslexia. The rationale for this focus is twofold: (1) dyslexia is the most common of the learning disabilities, affecting nearly 80% of the learning-disabled population (Karande et al. 2005);

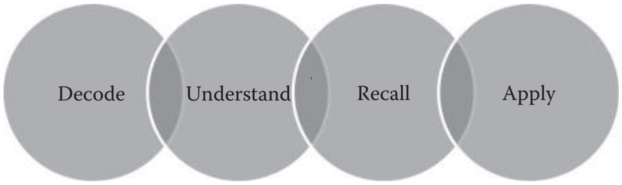

FIGURE 39.2 Four stages of information processing.

and (2) deficits associated with dyslexia are most likely to impact information processing as it relates to HCI.

39.2.2 Functional Characteristics of the Learning Disabled

Because of the previously cited diversity in the learning-disability community and the high degree of overlap among clinically diagnosed subgroups, it is easy to become overwhelmed by the complexity of the area. A more manageable strategy is to identify the functional characteristics shared across disabilities, with close attention to those that affect a particular interaction environment (Brown and Lawton 2001; Bohman and Anderson 2005). Figure 39.2 summarizes a number of proposed groupings.

After carefully examining these characteristics, four dynamically interconnected categories emerge as follows:

1. Reading
2. Memory
3. Metacognition
4. Search and navigation

These categories were selected because of their severity and their widespread effect on the HCI experience. In addition, many of the characteristics in Figure 39.2 are directly linked to deficits in a common underlying process, such as metacognition or working memory. These four categories, as highlighted in the discussion that follows, are not mutually exclusive. For example, skilled reading draws on memory and requires the deployment of metacognitive strategies. Similarly, search and navigation place a load on working memory, draw on long-term memory, and require metacognitive monitoring. The following section will review each of these categories more closely, and Section 39.3 will offer recommendations for accommodating each of these categories in system design.

39.2.2.1 Reading

Given the prominent role of written communication in everyday communication and the more demanding ICT environment, reading is one of the first barriers encountered by the low-literacy user. The alarming rate of poor prose and document-literacy skill was noted earlier. Also noted was the fact that poor reading is often tied to an underlying learning disability, inadequate schooling, or lack of exposure to reading. Typical in this area, an individual can suffer from all three conditions, two, or just one. As shown in Figure 39.2, reading is a multistaged process: word decoding, text processing, comprehension, recall, and application.

A reader could accurately process individual words yet fail to string these words together to achieve a larger meaning (comprehension). Readers can also demonstrate immediate comprehension of a passage yet fail to correctly apply that understanding to similar or different situations in the future. For the poor reader, the reading process is prone to breaking down at one or more of these stages. Mellard, Fall, and Woods (2010, p. 157) describe language comprehension as: “a complex construct that includes knowledge of vocabulary and information, as well as such higher-order abilities as recalling and sequencing events and making predictions and inferences.” The adult learners in their study, for example, failed to shift from a reliance on word recognition to language comprehension. In the following sections, connections are drawn between this complex act and deficits in metacognition and working memory among the learning disabled.

In dyslexic children, the disability affects reading at the most basic levels of phonological processing (Snowling, Deftry, and Goulandris 1996). Deficiencies at this basic level lead to further difficulties acquiring the complex skill of reading, building a rich vocabulary, and decreasing word-retrieval times. Most significantly, disabled readers allocate a disproportionately high amount of their attention to decoding letters and words, a process that is quickly automated by the nondisabled reader (van Gelderen et al. 2004). For the skilled reader, the process of automation frees the attention resource to focus on comprehension, the most critical component of the reading act. Skilled reading requires the management of a complex series of parallel actions, such as recognizing words, connecting those words to what came before, using those words to anticipate what will come next, and relating this combined experience to what one already knows. For the learning disabled, focusing most of the available attention on recognizing letters and decoding words severely compromises comprehension. Birru et al. (2004) reported that even when poor readers were able to read a passage, their inability to express answers related to the passage in their own words suggested minimal comprehension. Naturally, because reading is such a frustrating experience for the learning disabled, they are also less likely to read on a frequent basis, lowering the likelihood they will increase their reading skill through practice (Stanovich and West 1989).

Given the difficulty experienced by this population at the most basic level of decoding, it becomes clear that the problem is greatly exacerbated by materials written at a grade level beyond their ability. When information is presented at a level beyond the capability of the reader, mental workload is increased significantly and comprehension is greatly diminished. From an accessibility perspective, grade-level readability is a persistent problem throughout the web development community. In *E-Government for All*, Darrell West reports that 68% of state web sites and 70% of city sites are legible at the 12th-grade level (in Carvin, Hill, and Smothers [2004]). In an earlier study, West (2003, p. 3) found that

> 89% of government websites are not easily accessible to the citizenry because the site read at higher than an eighth grade

> level of literacy. Fully two-thirds of all sites have language consistent with a 12th-grade reading level, which is higher than the average American [half of all Americans read no higher than the eighth grade level]."

In another review conducted by Croft and Peterson (2002), the investigators found the mean readability score of 145 asthma-related websites was above the 10th grade, with 27 of the websites at the maximum 12th-grade level. Doak et al. (1998), summarizing a variety of studies, reported the average readability level of cancer information is near the 10th-grade level, and consent documents are written at the college/scientific level. Finally, Graber, D'Alessandro, and Johnson-West (2002) conducted a study of the readability level of privacy policies on Internet health websites. They found that the average readability of the policy was at a level equal to that of a second-year college student, far outside the reach of the average American. One large-scale study of the efficacy of a diabetes multimedia application produced disappointing results attributed in part to the readability of the supporting information. The investigators concluded that mere access to the technology was insufficient in the absence of appropriate design accommodations (Gerber et al. 2005).

Beyond basic readability criteria, Doak et al. (1998) documented the challenge presented by concept words (e.g., normal range, incidence), category words (e.g., angiotensin-converting enzyme inhibitors, chemotherapeutic agents), and value judgment terms (e.g., excessive, regularly). Finally, they reported mismatches in logic may also negatively affect compliance. For example, patients may feel it is appropriate to stop taking a medication once they start to feel well.

As previously noted, despite the presence of a reading disability, many in this population possess average or above average intelligence. As a consequence, if materials are presented at the appropriate readability level, the learning-disabled reader is capable of understanding. In separate studies conducted by Nielsen (2005) and Birru et al. (2004), poor readers performed well when interacting with easier-to-read materials.

Although there remains considerable disagreement on how best to measure grade-level reading, or even the appropriateness of such measures (Lewis 2010), certain measures and tests have gained wide acceptance and serve as a useful benchmark. One such test, the Flesch–Kincaid Grade-level readability test, measures readability by dividing the sentence length (number words divided by the number of sentences) by the average number of syllables per word (number of syllables divided by the number of words). The resulting calculation is then correlated with an appropriate grade level. Although this is a far from perfect measure, it does provide a useful benchmark of readability when evaluating the suitability of text for a given population. The Suitability Assessment of Materials instrument examines 22 factors related to reading difficulty. Unfortunately, this test along with others, such as the SMOG Readability Formula and the Fry Graph Reading Index, apply only to prose and not to lists, labels, and headings. With this type of text, the use of familiar words improves accessibility. Designers can consult reference works, such as the Word Frequency Book, (Carroll 1972) to identify the most commonly used words in the English language. Finally, Williams and Reiter (2008) examined text readability at the linguistic level focusing on the efficacy of cue phases, discourse ordering, and sentence structure. Clearly, readability is a complex and multilayered variable.

Because the functionally illiterate commonly experience difficulty with reading; illustrations, audio output, and video are often offered as effective accommodations. Carney and Levin (2002) summarize the general benefits of pictures, including increasing motivation, focusing attention, increasing depth of processing, clarifying text content, exploiting dual processing, and decreasing interference or decay. Houts et.al (2006) concluded that the inclusion of pictures in written and spoken health instructions increased low-literacy patients' attention, comprehension, recall, and adherence. Earlier, Houts et al (2001) found that the use of pictographs enhanced the recall of medical information over significant time periods. Although illustrations can assist the less-capable reader (Doak, Doak, and Root 1996; Weiner et al. 2004), positive effects vary with the reader and nature of the information. According to Beveridge and Griffiths (1987), illustrations contributed positively to reading performance in easier-to-read passages. In contrast, they also noted that illustrations degraded reading performance in the most difficult passages. Viswanathan, Rosa, and Harris (2005) found an over reliance on pictures among lower-literacy consumers, suggesting great care must be taken in the design and use of pictographic information.

In a study related to the supplemental use of animation, Larsen (1995) reported learning-disabled children had trouble due to the distraction of the animation. Similarly, Jiwnani (2001) reported system designers must be careful using auditory output since it has the potential to confuse the learning disabled. Jiwnani recommended the pace of the output must be slow, free of background noise, and repeatable under the control of the user. Finally, Hahn et al. (2004) demonstrated the positive outcomes of audio output for low-literacy users through their "talking touch screen" in a health care setting.

Clearly, interface and interaction designers must consider readability, illustrations, audio, and animation and their potential benefits for low-literacy users. Readability is the first barrier in design encountered by the low-literacy users. If this population is unable to process the language used in the display, all other accommodations are meaningless.

39.2.2.2 Memory

39.2.2.2.1 Long-Term Memory

The long-term and working-memory systems each have implications for the low literacy and learning-disabled population. As noted in Section 39.2.2.1, this population reads less often and fails to benefit from a major means of acquiring new knowledge. Without well-established domain models, interacting with web-based information or a software system is considerably more demanding. Doak et al. (1998) report that cancer information is most often organized according to the "Medical Model" doctors learned in medical school rather than models more appropriate for patients. This disconnect between doctor and patient models creates an often times insurmountable barrier to understanding and using information. Cognitive science has long recognized that long-term memories supplement and extend the limited capacity of working memory. This topic will be explored further in Section 39.2.2.4. Equally problematic is the tendency of the learning disabled to use the knowledge they do have without carefully evaluating its appropriateness, a metacognitive skill also discussed in Section 39.2.2.3 (Wilder and Williams 2001). In each of these cases, we see further evidence of the interconnected nature of these factors.

Although the underlying learning disability can make the acquisition of expertise more difficult, it would be wrong to think this population does not bring some level of learning and a variety of conceptual models to an interaction experience. As with so many other variables in accessibility design, we must recognize that the goals and models of the lower-literacy population may not align with those of the general population. Dickinson, Eisma, and Gregor (2003, p. 63) reported that: "users made remarks which indicated that they were not trying to understand the system or find generic rules that could help them to use it better." In other words, they were not attempting to understand the model underlying the system; they were simply trying to get something accomplished. System design should focus on that goal and avoid excessive functionality and extraneous information. From a development perspective, it is always easy to imagine occasions when one user or another might need this feature or that piece of information. Unfortunately, the lower-literacy population comes to the system with a greatly limited need, for both functions and information. Accessible design must consider these needs. Interface clutter increases mental workload on users as they attempt to locate information and features that align with their needs, a difficult challenge given their attentional impairments.

39.2.2.2.2 Working Memory

Cognitive science has long recognized the limited capacity of working memory and the major bottleneck it represents in information processing. Although learning disabilities vary in their clinical definition and in how they manifest themselves, one consistent variable in all learning disabilities is working-memory capacity. The dynamic interaction between memory capacity and the time information can be actively maintained imposes severe constraints on the learning disabled. Debate has raged for years whether the learning disabled suffer from diminished working-memory capacity or whether the complex dynamics of the underlying cognitive deficiencies place an excessive burden on a "normal" capacity (Daneman and Carpenter 1980; Poissant 1994; Swanson 1993; Vellutino et al. 1996; Ransby and Swanson 2003). Sabatini (2002) suggested that a combination of processing speed and working memory may affect the reading ability of adults with low literacy. Palmer (2000) suggests that dyslexic learners use phonological codes less efficiently, negatively affecting working-memory capacity. And finally, recognizing differences across the reading disability population, research by Swanson, Howard, and Saez (2006) found that different components of working memory explain the differences across various subgroups of reading disabilities. Sutcliffe, Fickas, and Sohlberg (2003) concluded that working-memory problems caused many users in their study to become disoriented when completing assigned tasks.

At the most basic level, the attention devoted to low-level decoding places a heavy demand on working-memory capacity. In addition, the increased likelihood of weaker mental models minimizes the opportunity to "offload" processing burden from the working memory, draw inferences, and make predictions. Further, the load imposed by metacognition, as discussed in Section 39.2.2.3, places additional demands on this limited resource. Finally, the high level of anxiety and frustration experienced by this population also operates in working memory and will negatively affect performance (Lee 1999). Anxiety is triggered by many variables including embarrassment, new situations, and fear of being labeled incompetent and testing situations.

In short, limited working-memory capacity accounts for the problems the learning disabled experience with search, decision making, sequenced operations in software, or in retracing their paths of travel navigating a website. When one considers the combined effects, it becomes clear why working memory, more than any other factor, guides for many of the design and support recommendations in Section 39.2.3. Interface and interaction designs must compensate for the limitations of working memory or suffer the consequences of lower performance, increased errors, and avoidance or abandonment of the task.

39.2.2.3 Metacognitive

Another critical deficiency in most dyslexics is in metacognition (Wilder and Williams 2001); the process of thinking about thinking (Flavell 1979). Metacognition takes many forms, including strategic planning, monitoring, self-appraisal, document-processing strategies, and reading strategies. Metacognition operates actively in working memory, parallel to the main information-processing task. Consequently, this activity is yet another process competing for limited resources. Also, because these strategies are learned behaviors, it suggests an interaction with long-term memory. Although nondisabled learners acquire most of these strategies without formal instruction, studies have shown these strategies can effectively be taught to the learning disabled (Collins et al. 1998; Wilder and Williams 2001). Unfortunately, for the small number of adults engaged in literacy training, most of the instruction is focused on decoding rather than higher-order comprehension and monitoring (Wilder and Williams 2001). Again, we must be reminded that skilled readers become skilled through years of practice with different reading materials that were processed to support diverse purposes. Because proficient readers and learners use these strategies on a frequent basis, they migrate, over time, to the level of an automatic skill. In contrast, the absence of persistent exposure to reading places the learning disabled at a further disadvantage.

Mokhtari and Reichard (2002) highlight the general agreement among researchers that awareness and monitoring of one's comprehension processes are a prerequisite for skilled reading. Cromley (2005) indicated that the learning disabled are less likely to know when they do not understand and are less likely to reread, synthesize, generate questions, or make predictions. They are also more likely to "satisfice" and accept partial or incorrect information rather than persevering to gain a more complete understanding. A distinguishing attribute of good readers is their ability to monitor the information-processing activity; in other words, they ask themselves: "Do I understand what I am reading? Do I see the relevance of the information to the task? What do I expect to follow in the next passage? How does this relate to what I already know?" Corley and Taymans (2002) organized this activity in three parts: (1) setting goals before the task and establishing a plan; (2) monitoring comprehension and understanding while engaging the task; and (3) evaluating one's learning after the task and making adaptations when faced with similar tasks. Danielson (2002), referencing users navigating the web, suggested that once goals are made, strategies are selected for achieving that goal. Further, strategies are constantly assessed and adjusted many times in a successful interaction experience. Given the mental demand of these activities, monitoring and adjusting activities pose a challenge for the disabled. Sutcliffe, Fickas, and Sohlberg (2003), working with cognitively disabled users, reported most of the identified usability problems could clearly be classified as metacognitive in nature. Finally, Britt and Gabrys (2002) indicated that document literacy requires four metacognitive skills: (1) sourcing (evaluating the credibility of source), (2) corroboration (seeking independent confirmation), (3) integration (creating mental representation of information), and (4) search (a skill woven throughout the other three areas).

The inability of the learning disabled to engage in self-evaluating activities is evident in the work of Birru et al. (2004). Although most of the participants in their study failed to answer the questions correctly, seven out of eight reported feeling "very comfortable" or "comfortable" with their Internet search experience. On the sourcing and corroboration skills, five out of eight used information provided on sponsored sites, yet still reported it was "very easy" to find trustworthy information on the Internet. Kruger and Dunning (1999) concluded that "less-skilled populations" lack the metacognitive ability to self-assess performance resulting in an overly inflated self-assessment. This finding has possible implications for any research conducted with this population that requires self-assessment of individual performance. Similarly, Viswanathan, Rosa, and Harris (2005) report that low-literacy populations display post-decision coping strategies whereby that rationalize outcomes to shift responsibility away from the self.

In short, metacognition requires a tremendous amount of cognitive activity, activity that occurs in parallel with the primary decoding task. All of this activity occurs in the executive control component of working memory. As noted in Section 39.2.2.2.2, this is a limited resource for the learning-disabled reader who devotes much of this resource to low-level decoding.

We take for granted that nondisabled users effectively and effortlessly engage in all of these activities. As noted in Section 39.3.4, design support for this variable amounts to providing constant feedback to the disabled user, explicitly connecting the information to the task, establishing checkpoints where the system queries the reader to monitor understanding, and engineering performance support in the form of cognitive scaffolding. On the topic of feedback, Dickinson, Eisma, and Gregor (2003) noted that longer tasks are tolerated by the learning disabled so long as they receive frequent feedback on what is happening and confirmation they are proceeding correctly. In the absence of such feedback, the poor reader becomes anxious, a state that further degrades performance since anxiety occupies the working-memory space. Finally, Sevilla et al. (2007) compared existing web content with its cognitively accessible—redesigned—equivalent. [In their population of cognitively disabled users], they found: "10 participants showed short-term memory problems when interacting with the conventional version and only 4 demonstrated such problems with the adapted version. This indicates how some cognitive deficits appear only when higher demands are made … another question can be asked with regard to the origins of the subject's navigational difficulties: specifically, is it a matter learning to navigate the web, or is it a matter of performing the navigation." (p. 20)

39.2.2.4 Navigation and Search

The learning disabled have traditionally experienced varying degrees of difficulty reading paper-based materials. They experience this difficulty despite the fact the linear format found in most paper-based materials offers considerable support for the reader. In these materials, the author assumes the burden for communicating organization through meaningful structures, logical sequences, helpful transitions, and explicit connections. In contrast, the nonlinear web requires the reader to infer organization and build a coherent model of the subject matter as the information unfolds in less predictable ways (Britt and Gabrys 2002). McDonald and Stevenson (1998) identified disorientation in the nonlinear environment as one of the most challenging elements of the web. Although disorientation is an obstacle that can be overcome by able users, this barrier is often insurmountable for the learning disabled. The source of this barrier is likely a combination of the working memory and metacognitive limitations previously discussed. This population, at the very least, experiences difficulty building a mental model of the information, monitoring where they are in the experience, or retracing their path. Each of these activities draws on their overtaxed working memory.

As one examines the factors affecting readers' ability to navigate, a number of variables emerge as follows:

- Basic navigation skills related to the interface
- Topology formats: nonlinear, hierarchical, and mixed topologies
- Depth versus breadth of the structure
- Navigational aids

39.2.2.4.1 Interaction Skills

Although there is limited research examining the effects of learning disabilities on navigation, the work of Zarcadoolas et al. (2002) suggested, with proper interventions, learning-disabled users can quickly learn and retain basic web-interaction skills. These skills include the behavior of links and the act of scrolling. Participants in this study did require training and prompting to use graphic links. Overall, the positive reaction to the linking convention is encouraging since they also found the participants, when given a choice, preferred following links rather than using search. Worth noting, Birru et al. (2004) found users in their study, although comfortable with the linking convention, would seldom click on more than one or two links to answer questions. Finally, although basic scrolling behavior was understood, none of the participants in the Zarcadoolas et al. (2002) study scrolled to view additional information. Without additional corroborating evidence, it is difficult to generalize from these limited studies. However, the behaviors exhibited in these studies warrant closer scrutiny as we continue to study and observe this class of user. Although not directly tied to low literacy, Sanchez and Wiley (2009) found that a scrolling format reduced comprehension of complex passages for readers with low working-memory capacity. As highlighted earlier, a diminished working-memory capacity is a common characteristic of the learning disabled. Given the possible connection between the action of scrolling and comprehension, the issue of scrolling also warrants further study.

In contrast to the relative ease with which this population learned basic interaction behaviors, a more significant challenge is faced while navigating the larger system. Danielson (2002) suggested users begin the navigation task with a decision about whether they are looking for a specific item, a group of items, or general information about the contents of a domain area. As noted in the metacognitive area, the learning disabled are generally weak at planning tasks, which immediately places them at a disadvantage in the navigation area. Unfortunately, there is little or no research that directly examines the learning-disabled population and the structural issues of nonlinear versus hierarchical, or depth versus breadth. In one study, Summers and Summers (n.d.) found low-literacy subjects, based on their desire to minimize reading, were better at linear text structures and deficient at nonlinear "way finding" tasks involving complex navigational structures. There is appropriate speculation on this issue since performance differences for general-population users are typically discussed within the context of working-memory capacity.

39.2.2.4.2 Topology

The work of McDonald and Stevenson (1998) shed some light on the issue of the efficacy of hierarchical, nonlinear, and mixed (hierarchical with referential links) topologies. Most significant perhaps for the purposes of this discussion, they found novices benefited most from the mixed structure since it offered a balance of freedom and control. The referential links supported exploration of a site without the support of a well-formed mental model, while the hierarchical framework served to constrain movements and minimize disorientation. Although the strict hierarchical structure provided the greatest control and guidance for participants, it proved inefficient when participants wanted to make distal movements in the structure. Finally, the nonlinear structure simply provided too many options and placed the heaviest demands on expertise and working memory. In an earlier study, McDonald and Stevenson (1996) found users stopped reading too soon when faced with too many decisions related to "what" and "how much" to read. In each of these situations, it is easy to speculate that the problems faced by the participants in these studies would only be exacerbated for the learning disabled, given their underlying deficiencies in working memory and metacognition.

39.2.2.4.3 Depth versus Breadth

The efficacy of breadth versus depth in the hierarchy is also open to speculation. As with topology, the depth issue is framed by limitations of working memory and the users' ability to distribute the navigation workload to their own conceptual models of the domain. In this discussion, we see greater diversity of opinion. In the world of web design, best practice favors breadth over depth, resulting in a greater number of choices at the highest level. Lewis (2007) discusses the challenges deep structures pose for the cognitively disabled. A study by Larson and Czerwinski (1998) suggested that a medium depth produced the best search performance over either the broader or the deeper options. Benard (n.d.) suggested depth versus breadth is not the best framing mechanism. Instead, he suggests the shape of the hierarchy is the best predictor of search performance, finding a broad first level, a narrow middle level, and a broad base to be most efficient. Although not based on a controlled study, Kolatch (2000) proposed a simpler top-level interface, offering fewer choices and a deeper structure for cognitively disabled users. Kolatch was careful to point out that this contradicts most research on the topic. Until research suggests otherwise, the balanced structure proposed by Larson and Czerwinski (1998) provides guidance consistent with our understanding of the adverse effects of too many choices and the mental load imposed by deep structures.

39.2.2.4.4 Navigation Aids

Danielson (2002) suggested that a variety of visual navigational aids can mitigate the aforementioned problems encountered in navigation. Navigational aids fall into two categories: (1) index and table of contents lists and (2) site maps. Danielson noted that graphical site maps are superior to lists and tables of contents at conveying the relationships between distal nodes on the site. The study also showed that the site maps benefited unknowledgeable users more than the knowledgeable. Finally, compared with a control group without site maps, Danielson reported that subjects with maps were less likely to abandon the task, reported information-seeking confidence, moved deeper into the site, and made more movements outside the hierarchy. Given the previously defined tendencies of the learning-disabled population, it is highly probable that they would benefit from the assistance offered by site maps. Supporting this theory, Mirchandani (2003) found detailed site maps helped the disabled user find information within a click or two.

39.2.2.4.5 Search

Research is slowly emerging related to the learning disabled and the search task. Not surprisingly, this research reports the learning disabled experience difficulty with search tasks. In an ethnographic study conducted by Zarcadoolas et al. (2002), the authors found a preference for following links versus using search. At the most basic level, the poor spelling displayed by many in the lower-literacy population creates a major barrier to successful searches. Search engines, such as Google, that offer alternative spellings are best. However, Sitbon and Bellot (2008) highlighted that dyslexic users are not assisted by the traditional spellchecker since they tend to write phonetically and sometimes group their words together. They suggested that this group requires special cognitive prosthetics designed to accommodate this tendency. Compounding search-related difficulties, weak self-monitoring skills also decrease the likelihood that the user will recognize that a spelling error was made. Even when search terms were spelled correctly, Birru et al. (2004) found that subjects rarely retyped search terms to locate more relevant items—a serious problem because they also found the low-literacy adults in this study rarely used optimal search terms as they attempted to retrieve health-related information. Birru et al (2004) concluded by highlighting the benefits of a categorizing search engine as one means of minimizing the adverse effects of poor search and long lists of results. This engine would sort results by category and minimize the need to evaluate long, unsorted lists. This is a good example of a technology assuming the burden for a weak metacognitive skill in the disabled population. Finally, Kodagoda and Wong (2008), in their inquiry of low-literacy search performance found the low-literacy subjects take eight times longer than high-literacy users on search tasks without producing a corresponding increase in search accuracy. Compared with their high-literacy counterparts, low-literacy users

- Spent one-third more time on each page visited
- Were far less focused as evident by the fact that they visited eight times more web pages
- Were 13 times more likely to backtrack
- Were four times more likely to revisit pages and 13 times more likely to be lost (p. 173)

39.2.3 Guidance for Research Methods and Testing

McGrenere, Sullivan, and Baeker (2006); Van Der Geest (2006); Wolf et al. (2006) each recommended including and accommodating the cognitively impaired in our research and evaluation methods. Since all of our methods involve communication, information processing, and interaction, it is reasonable to speculate that our methods require substantial modification consistent with the adjustments advocated throughout this chapter for design and support. As one reviews the functional characteristics highlighted in Section 39.2.2, it is likely that many of the necessary accommodations can be traced to metacognitive activities, workload demands on working memory, language difficulties, and the embarrassment associated with the disabilities.

The first challenge faced in working with this population is recruiting subjects. McGrenere, Sullivan, and Baeker (2006) suggest the variability within the cognitively disabled population makes it all but impossible to achieve a truly "representative" sample and challenges the notion of a typical or representative user. It also calls into question the notion of generalizability. Given this variability, it is disturbing that many of the studies purporting to support accessibility by including disabled users do so by mixing a small sample of cognitive and physical disabilities. Highlighting the challenge we face on the recruiting front, Ozanne, Adkins, and Sandlin (2005) distinguished between four classes of low-literacy consumers based on coping behaviors, with each behavioral class requiring different accommodations. At least one class, "the alienated consumer," exhibits highly developed avoidance and nondisclosure behaviors. One has to speculate whether this class would even participate in a study or if they did, would they reveal their disabilities? This is one of many variables we must consider.

On a practical level, recruiting low-literacy and cognitively disabled users requires considerably more time and effort. Utt (2010) suggested a 6–8-week lead time. Experience in our center has taught us that you experience a greater no-show rate with this population and you will experience a greater number of sessions that will need to be rejected for varied reasons. Consequently, always recruit extra participants to compensate for this potential loss. Our experience suggests that agencies and organizations that provide services to the adult-literacy community and cognitively disabled population are the most productive source for participants. Not only is this convenient, but many times they have done the formal testing and screening of clients. Establish a long-term relationship with these agencies so they will be assured you will treat their clients with dignity and respect. Viswanathan, Rosa, and Harris (2005) recommended longer term volunteer work with this population to build a relationship of trust and foster a heightened sensitivity to their needs. Finally, Brez and Taylor (1997) cautioned that care must be given to administering literacy screeners given the stigma attached to this disability. This was discussed in detail in Section 39.1.1. When forced to screen for literacy, the health care industry has developed a number of literacy screening tests such as the Wide Range Achievement Test, the Rapid Estimate of Adult Literacy in Medicine, and the Test of Functional Health Literacy in Adults. Finally, with more severely disabled populations, some researchers employ proxy users.

Unfortunately, caregivers do not always have perfect knowledge of the abilities, behaviors, and goals of users. Quite simply, their motivations are often different.

Great care must be taken to ensure appropriate informed consent. Recommendations on this issue vary, with the protocol within a particular group dictated by internal review boards (IRB). Generally speaking, consent forms should be written at the appropriate level and read aloud to the participant. Ask the participant to tell you, in their own words, what the form means before asking them to sign it. When in doubt about a participant's ability to provide informed consent, solicit the input of a counselor, friend, or caregiver.

There is an emerging pattern of findings suggesting that many of our traditional methods are inappropriate and ineffective for these populations. Small et al. (2005) reported their cognitively disabled participants exhibited difficulty with the think-aloud protocol, a strategy they quickly abandoned in favor of a guided walkthrough approach. Viswanathan, Rosa, and Harris (2005) cautioned against traditional research techniques such as interviews and surveys and recommended a more hermeneutical approach. Lepisto and Ovaska (2004) found the think-aloud protocol did not work well with the cognitively disabled population. Instead, they used a variety of techniques interviews, observations, expert reviews, and informal walkthroughs. Findings from each of these sources were compared and integrated in the analysis phase. Finally, the investigators also stressed the need to adjust each method to meet the highly individualized needs of the population.

A growing body of work with low literacy and cognitively disabled populations demonstrates the effectiveness of the ethnographic method (Zarcadoolas et al. 2002; Carmien and Fischer 2008). Dawe (2007) combined the ethnographic method with evolving technology probes (prototype). Dawe found the ability of subjects to interact with the probe helped to overcome subject's limited language skills. By observing users in natural settings, they could show and demonstrate rather than describe their needs and opinions through abstract or hypothetical scenarios. Dawe highlighted the critically important contribution of the technology probe by showcasing the users' tacit knowledge displayed through action. As noted in Section 39.2.2, this population exhibits difficultly with this class of thinking activity. Ethnographic study is emerging as one of the most productive research techniques based on its ability to mitigate the various communications and thinking barriers exhibited by this population.

Other investigators have also reported success with methods similar to ethnography including grounded theory, task artifact theory, and hermeneutics. Grounded theory is a systematic method for generating theoretical statements from case studies. Wolf et al. (2006) used a grounded theory approach to explore the basis for low-literacy patients' incorrect interpretations of design alternatives through an analysis of their verbatim responses. Based on cognitive interviews, grounded theory guided the inductive process of organizing content derived from patients' comments. For this study, patients' misinterpretations were reviewed and classified using both predetermined and emerging coding schemes. Sutcliffe, Fickas, and Sohlberg (2003) recommended a similar approach in the "task artifact theory," a framework that describes an iterative approach to research and design. "It asserts that well founded HCI designs should relate to theoretically grounded knowledge. The designs are produced after a detailed task analysis and application of existing theory; then the design is evaluated, revised, and design principles are extracted as psychologically motivated design rationale" (p. 578) Ozanne, Adkins, and Sandlin (2005) used an iterative hermeneutical approach in their study of low-literacy consumers, shifting back and forth between the data collected and the literature to identify a logical claim of evidence and arrive at a coherent framework. Finally, as noted above, Viswanathan, Rosa, and Harris (2005) recommended a more hermeneutical approach in their investigative work with this group of users. Although further consideration of these methods is warranted, the iterative nature of these methods, grounded in appropriate theory, likely compensates for the diversity and lack of predictability within this population.

Because of varied communication barriers, compounded by possible embarrassment and anxiety, traditional structured interview techniques are particularly challenging for low-literacy populations. Huenerfauth, Feng, and Elhadad (2009) found adults with intellectual disabilities had difficulty with simple yes/no questions and Likert-scale questions. In contrast, they noted positive outcomes with multiple choice questions with three answer choices, each illustrated with a simple illustration or photo. As noted elsewhere, this population has difficulty choosing among alternative and speculating on hypothetical or abstract situations. Milne, Clare, and Bull (1999), focusing on police interviewing techniques, discussed the relative merits of the cognitive interview technique with adults with mild learning disabilities. When compared with the structured interview technique, the cognitive interview enhanced recall of events but also produced an increase in confabulations. They reported that people with learning disabilities were significantly more likely than the general population to quickly submit to closed yes/no questions. Short-answer questions are also prone to incorrect answers with this population. The effectiveness of the cognitive interview is attributed to the use of cognitive mnemonics (Bekerian and Dennett 1993), which mitigate the previously described shortcomings. The technique uses four mnemonic strategies: (1) encourage the interviewee to restate the context, (2) report everything, (3) recall events in a different order, and (4) change perspectives.

There is strong support for integrating multiple methods as a means of overcoming the many challenges we face working with low-literacy users. One of these methods is the usability inspection. As documented earlier, many of the guidelines and inspection heuristics used in accessibility inspections are general and vague. Romen and Svanaes (2008), through controlled usability tests, reported that only 27% of the identified website accessibility problems could be identified through the WCAG produced through the W3C. They reviewed other studies producing similar results. This study confirms the inadequacy of current heuristics for expert reviews focused on accessibility and highlights the need for further work in this area.

Finally, there appears to be a number of issues surrounding our use of the think-aloud protocol and usability testing in general. As discussed previously, Small et al. (2005) reported their cognitively disabled participants exhibited difficulty with the think-aloud protocol. This problem most likely results from metacognitive deficiencies and the work load demands of the think-aloud protocol on limited working-memory resources. Traditional usability "testing" is also likely to trigger anxiety and further drain the working-memory resource. There also appears to be problems with the accuracy of self-reporting with this population, Sherwani et al. (2009) noted concerns for the inability of low-literacy subjects to accurately distinguish between information acquired through the system under examination and prior knowledge. They recommended that subjective feedback requires validation from other sources since, in their experience; this information is often unreliable for a multitude of reasons. For example, low-literacy users in their study reported a preference for the touchtone interface even though they performed better with the speech interface. There also seems to be concerns for the accuracy of performance and attribution as evident in the work of Birru et al. (2004) and Viswanathan, Rosa, and Harris (2005).

When testing is unavoidable, consider the appropriateness of timed tasks for a population with processing speed problems. Lepisto and Ovaska (2004) confirmed this concern, reporting that timed tasks do not work well with this population who often complete tasks at their own rate.

Tremendous progress has been made over the past 10 years understanding the shortcomings of our traditional methods. These deficiencies are not surprising since these methods were developed and refined over many decades working with the general population. In their place, we find promising new methods and suitable refinements of existing techniques that will help us better understand the requirements of this group and evaluate the appropriateness of our design solutions.

39.3 DESIGN ACCOMMODATIONS

Given the documented characteristics of this population, it is clear that design accommodations are necessary to make products accessible. Before moving into specific recommendations, based on the four-part classification strategy proposed earlier, we will first examine broader strategies for managing these accommodations. There are four generally accepted approaches to accommodating the needs of the low-literacy and learning-disabled population. Each of these recommendations is informed by the previously discussed characteristics of this population, as follows:

1. Assistive technologies: Building technologies customized to compensate for the disability
2. Layered design: Designating special sections of the website or ICT for a disabled population
3. Personalization: Preference profiles created once and then applied to different web resources (http://www.fluidproject.org/)
4. Universal design: Adopting design practices that enable the learning-disabled population while benefiting the larger population as well

The following sections will briefly review the first two categories and provide more detailed recommendations for the third category, universal design.

39.3.1 Assistive Technologies

A number of studies have demonstrated the benefits of assistive technologies for the cognitively disabled (Brown 1992; Cole and Dehdashti 1998; Newell and Gregor 2000; McGrenere et al. 2003). A typical application in this genre is a standalone computer-based educational system, designed to assist severely disabled children. Other, less intrusive accommodations, including software agents and embedded scaffolding, have been explored by Shaw, Johnson, and Ganeshan (1999); Quintana, Krajcit, and Soloway (2002); and Shneiderman (2003). Cole and Dehdashti (1998) and Carmien and Fischer (2008) refer to this class of technologies as cognitive prosthetics.

Scaffolding and agents offer performance support to the disabled user in the early stages of interaction with a new product. Shneiderman (2000) described this approach as "evolutionary learning." As the user becomes more proficient with the requirements of the system and task, the scaffolding is slowly torn down, either under the control of the user or through intelligent software agents. Most typically, the agent replaces or supports a deficient metacognitive process by assisting with planning, monitoring, self-appraisal, strategy setting, and feedback. Quite simply, this burden is shifted from the user's working memory to the system. Shneiderman (2000), Quintana, Krajcik, and Soloway (2002), and Carmien and Fischer (2008) highlighted the efficacy of this approach for supporting less-knowledgeable and disabled populations. Quintana, Zang, and Krajcik (2005) demonstrated the value of scaffolding to support the metacognitive aspects of online inquiry by helping users plan, monitor, and regulate the activity. Each of these supported activities were previously identified as deficient in this population. Finally, we see the increased development of systems such a SkillSum that adapt content, presentation, and linguistic structure to accommodate the needs of low-literacy readers (Williams and Reiter 2008).

39.3.2 Personalization

Personalization of the interface, interaction, and information design is increasingly recognized as an effective means of addressing the highly individualized needs of this population. Naturally, this would only work for technologies under the control of an individual. Publically accessed technologies will continue to look to the principles of universal design as the best available solution. Sutcliffe, Fickas, Sohlberg, and Ehlhardt (2003) investigated the efficacy of four different interfaces for a new e-mail system for cognitively disabled users. Although all users preferred interfaces that did not restrict their freedom, no one design proved superior. The authors saw these findings supporting the need to support customization of interfaces for this population. Similar findings were reported by Myatt, Essa, and Rogers (2000). While Petrie, Weber, and Fisher (2005) proposed the use of content management and personalization profiles to adapt content, interaction, and navigation to meet the diverse needs of print-disabled users.

39.3.3 Layered Design

Layered design strategy often requires the design of two versions of the system: one for the general population and one for low-literacy users. Although it is generally preferred not to separate the disabled and general populations, layered design is simply an extension of a practice that has been used for years for separating domain experts from non-experts or native speakers from nonnative speakers. In this case, one area of the site would be written at the population average eighth-grade level, whereas another section of the site would be written at the fifth-grade level or lower. Lobach et al. (2004) described the benefits of a two-tier literacy system in their study. Sites such as this may include other assistance, such as agents, site maps, illustrations, and the like. A variation of this strategy is the levels-of-reading approach where progressively deeper levels of detail are offered to the reader. Poor readers—and others for that matter—can choose the level appropriate to their needs and abilities. A more complex form of language support can be found on the Center for Applied Special Technology (CAST) website (http://www.cast.org/) where the sponsors provide a language tool to support low-literacy users visiting the CAST site.

39.3.4 Universal Design

The first principle of universal design dictates "provide the same means of use for all users: identical if possible—equivalent when not." In contrast to the first two approaches, universal design accommodations are seamlessly embedded in the system interface and interaction design. This class of accommodations is less likely to affect development costs or create an obstacle for the nondisabled. Consequently, these accommodations are more likely to be embraced by the wider development and user communities. Further, it is widely accepted in the accessibility community that these accommodations improve the usability of the product for all users (Shneiderman 2000; Dickinson, Eisma, and Gregor 2003). The following recommendations are organized in the previously defined categories of functional characteristics, although support for a given recommendation is often found in multiple categories. Finally, recommendations designated with an * identify recommendations that require additional research and warrant close monitoring. All others enjoy wide support in the literature.

39.3.4.1 Reading

When designing the language component of any system, support the following:

- Maintain an appropriate reading level (use readability formulas to establish a benchmark; measure word difficulty and sentence length).
- Use active voice.
- Limit information to the key information users need.
- Use the Word Frequency Book to identify common words.
- Place information and instruction in context.
- Employ lists.
- Avoid or recognize the consequences of using concept, categorizing, or value judgment words.
- Chunk information.
- Present content in sequence.
- Repeat information from screen to screen (do not assume the user will carry over).
- Maintain consistency in language and procedures.
- Communicate directly and concretely.
- Emphasize actions users must complete.
- Confirm actions are completed.
- Highlight critical information, information structure, or new information.
- Use familiar terms, and avoid acronyms and jargon.
- Use visual and auditory prompts.
- Provide definitions of critical terms through direct linking to glossary.
- Use illustrations to complement text, communicate structure, and emphasize connections.
- Highlight (using circles, arrows, and the like) critical areas of an illustration and explicitly connect to the text.
- Avoid the gratuitous use of animations and other movement.*
- Use 12-point type.
- Use familiar typefaces (there is conflicting research regarding the efficacy of serif versus sans serif).*
- Avoid tight letter-spacing (makes low-level decoding more difficult).
- Pace auditory output slowly, and allow user control to repeat output.
- Avoid background noise with auditory output.
- Provide "looser" versus tighter line spacing.
- Support easy, user controlled, style changes.
- Make it "look easy" by lowering information density.
- Limit use of italics and uppercase (effects are much more severe than for the general population).
- Maintain higher contrast.*
- Avoid light text on a dark background.
- Use ragged right formats to preserve consistent word space.

39.3.4.2 Memory

In an effort to decrease mental workload, support the following:

- Maintain consistency in all aspects of the design.
- Minimize anxiety.
- Leverage existing knowledge, behaviors, and tasks.
- Avoid splitting attention between two tasks.
- Focus on the user goals.
- Limit information and features to what is really needed.
- Limit chunking complexity for audio output (particularly interactive voice response [IVR]).
- Focus on behaviors and tasks rather than facts.
- Partition tasks in reasonably sized groups.
- Minimize scrolling.
- Avoid the need to retain information over long tasks or across multiple screens.
- Support mental calculations, decisions, and comparisons.
- Complete mathematical calculations.
- Limit choices.
- Provide a list of options for entry fields.
- Complete information automatically in forms and fields whenever possible.
- Use advanced organizers.
- Use mnemonics.
- Minimize screen clutter.
- Provide extra time for tasks.
- Eliminate the anxiety of timeouts.

39.3.4.3 Metacognitive

In an effort to strengthen or replace deficient metacognitive processes, support the following:

- Maintain a consistent design.
- Provide guidance, status reports, and feedback.
- Use headings to identify critical information.
- Convey associations between new information or process and that which is known.
- Communicate goal or purpose of the site immediately.
- Communicate prerequisite knowledge for the task and provide convenient links.
- Communicate required sequences or organizational structures.
- Allow the user to interact with the information.
- Use checklists to support self-monitoring.
- Avoid choices that require fine discriminations or close monitoring.
- Design for immediate/early success (which lowers anxiety and builds confidence).
- Align with user goals, and provide reward or convey value proposition (motivation).
- Support cooperative work activities.
- Provide reminders.
- Communicate task status.
- Provide source information for material presented.
- Minimize embedded links.
- Avoid taking user to other pages for ancillary information.
- Use error prevention and recovery support.
- Query when choices or decisions are required.
- Review information entered or validate the successful completion of a process.
- Use auditory and visual cues to mark stages of a work cycle, helping the user self-monitor.

39.3.4.4 Navigation and Search

In an effort to improve the effectiveness of search and navigation, support the following:

- Make information and features supporting goals readily accessible to minimize navigation and search.
- Provide persistent presentation of path history.
- Limit distractions.
- Offer persistent opportunity to exit, backup, or return to start.
- Provide status indicators.
- Minimize scrolling.
- Label all links.
- Provide linked paths supporting probable scenarios.
- Maintain alerts onscreen until dismissed by user.
- Place information or process in context.
- Partition information into categories defined by clear rules.
- Use site maps, tables of contents, and indexes.
- Use a topology that is primarily hierarchical with referential links to areas aligned with goals.*
- Maintain a medium breadth and depth—not too broad, not too deep.*
- Use clear, thematic labels at each level.
- Provide productive terms for search.
- Offer suggested spellings.
- Use categorizing search engines.
- Provide performance support for evaluating search results (corroboration and sourcing).

39.3.4.5 Guidance for Research and Usability Testing

To produce the most reliable data and protect the well-being of participants, support the following:

- Consider ethnographic studies rather than structured interviews.
- Use cognitive interview technique.
- Use grounded theory or hermeneutical research methods.
- Consider technology probes to provide observational opportunities while reducing reflection demands.
- Avoid embarrassment or humiliation (anxiety lowers performance).

- Greatly increase recruiting time.
- Build relationships with organizations working with this population.
- Include councilors or caregivers with the more severely disabled.
- Consider ethical obligations when screening for lower-literacy samples (full-disclosure issues, informed consent, and IRB).
- Minimize anxiety in testing situation.
- Test in context (actual work environment).
- Avoid using the term "testing" since this population equates the term with failure.
- Break tasks in the test script into small, yet logical, units.
- Avoid questions requiring "yes" or "no" answers, such as "Do you understand?"
- Avoid Likert-scale questions.
- Consider the appropriateness of timed tasks.
- Provide multiple choice questions with visual support for each answer.
- Require users to repeat back their understanding of information in their own words.
- Shorten test times to minimize effects of fatigue on performance and to compensate for attention deficit.
- Use direct interaction protocol since users may not freely think aloud (inadequate working memory to support both think-aloud and to acclimate to the task).*
- Accommodate slower processing speeds when setting performance levels (e.g., task times).
- Expect participants to report exaggerated levels of performance or problems attributed beyond self as a means of covering poor literacy skills.
- Invite a trusted caregiver to any session when working with more severely cognitively disabled users.

39.4 CONCLUSION

Fifteen years ago, our concern for the effects of lower literacy was confined exclusively to the processing of print media or spoken instructions. With the explosion of information technology in the workplace and the role of the Internet as the repository for information of all types, literacy has become a major barrier for millions of citizens as they compete for work, attempt to improve the quality of their lives, and participate in civic activities. Although the challenges faced by low-literacy populations with print media are significant, the problems become greatly exacerbated with the increased mental workload imposed by ICT.

As advocated in this chapter, many of the barriers to accessibility require simple modifications in the interface and interaction design. Accessible design is an art, in which the needs of one group are carefully balanced against those of another, and the designer recognizes that "accessible for most" is more achievable than "accessible for all." As one reviews the list of design accommodations required by the low-literacy population, HCI professionals will recognize most, if not all, of these variables as ones considered in each and every interface design. The difference—and a significant one—is that fully capable users exhibit flexible learning, problem solving, and interaction skills that allow them to adapt to less-than-perfect designs. The learning disabled, in contrast, lack cognitive flexibility and suffer varying degrees of performance degradation in nonoptimum design environments. By increasing our understanding of this sizable population and embracing the design practices outlined here, we may finally ensure that universal accessibility is truly universal.

40 Computing Technologies for Deaf and Hard of Hearing Users

Vicki L. Hanson

CONTENTS

40.1 INTRODUCTION

Traditionally, human interaction with computers has relied most heavily on visual perception and motor ability. Graphical user interfaces (GUIs) have dominated computer displays, both large and small, while mouse and keyboard devices have dominated computer input. Increasingly, however, newer interfaces are using sound and speech. The use of attention-grabbing multimedia computer presentations plus the increasing use of conversational speech interfaces are examples.

As exciting as these new technologies may be, they have the potential to disenfranchise deaf and hard of hearing users. This chapter will discuss interface technologies as they relate to the needs of users unable to hear auditory information. In addition, language considerations associated with limited hearing will be discussed.

This chapter begins with a discussion of hearing loss, followed by issues of language acquisition as they relate to hearing loss. Auditory user interfaces that present difficulties will be discussed next, along with information about interface alternatives that enable access for deaf and hard of hearing users. The chapter will conclude with a brief overview of technologies that have been developed to assist with communication.

40.2 HEARING LOSS

According to the National Institute on Deafness and Other Communication Disorders (NIDCD), about 28 million people in the United States have some degree of hearing loss (National Institutes of Health [NIH] [2004]) (see also, Mitchell [2005], [2006]). This is a sizable population to be considered in the design of computer interfaces. Numbers alone, however, obscure some significant differences among the individuals who experience hearing loss. Degree and type of loss, age of onset of loss, as well as family, educational, and societal influences will all contribute to the experience and abilities of an individual who has a functional hearing loss.

Some individuals will have relatively little hearing loss, while others will experience a profound loss. Individuals who are hard of hearing will generally have some hearing. The ability that an individual user will have to make use of their residual hearing, however, is not a straightforward calculation of decibel (dB) loss. People with hearing loss will experience difficulty with pitch, timbre, and loudness, but, critically, will also experience difficulty with speech perception. Factors such as type of loss (e.g., conductive, sensorineural, mixed, or central) will have a major effect on the user experience. People with sensorineural hearing loss (such as resulting from lengthy exposure to loud noises or as a result of aging) generally will have more difficulty perceiving speech than people with conductive hearing losses that result from difficulties in middle ear functioning. The extent to which an individual makes use of this hearing for communication and whether the individual can hear computer sounds, however, varies greatly.

In addition, the way in which an individual having a hearing loss interacts with their environment may also be influenced by societal factors. Whether individuals identify themselves as Deaf (with an uppercase "D" as a member of the Deaf Community), deaf, or hard of hearing is indicative of cultural identity (Lane 1992; Padden and Humphries 1988, 2005).* Membership in the Deaf Community is determined more by shared language and worldviews rather than by results of audiometric tests. For example, people may lose their hearing with age. These people, while deaf by the audiometric definition, would not share the culture of the Deaf Community.

In the United States, the language of the Deaf Community is American Sign Language (ASL). Other countries and locales have their own native sign languages shared by members of Deaf Communities in those areas. Interestingly, these signed languages are not based on the spoken languages of the region. People are often surprised to learn that ASL is more similar to French Sign Language, from which it originated (Lane 1984), than it is to British Sign Language. Beginning with the seminal work of Ursula Bellugi and colleagues in the 1970s, linguists, cognitive psychologists, and brain researchers have studied native sign languages and their users for clues as to the origin of language and the biological nature of language (Emmorey and Lane 2000; Klima and Bellugi 1979; Erard 2005).

Cochlear implants are a medical intervention that has received much attention in the last couple of decades. The decision as to whether or not to have a cochlear implant is often a complex one, as was explored in the movie *Sound and Fury* (Aronson 2000; see also Hyde and Power [2006]). From the standpoint of a user, an implant is not the same as perfect hearing, but does allow the user to hear sounds and, with training, may greatly aid in the perception of speech (Chorost 2005).

40.3 HEARING AND LANGUAGE

Some, but not all, deaf and hard of hearing individuals use sign language. The type of signed language depends on the user's life experiences. Deaf children born to deaf parents, regardless of severity of hearing loss, will generally acquire a sign language, such as ASL, natively as hearing children of hearing parents acquire spoken language. People who lose their hearing late in life generally will not master a sign language. In between, there are many variations. Deaf signers may be exposed to a native sign language as adults and as a result, may only acquire partial mastery (Newport 1990). Other deaf signers will be exposed primarily to manual forms of English (or other spoken languages), rather than natural sign languages. Many schools that use sign language in the classroom do not use a natural sign language, but rather a representation of the spoken language that is signed. Forms of signed English borrow signs from ASL, but these signs are produced in English word order rather than using ASL sentence structures (for an extended discussion, see Lane, Hoffmeister, and Bahan [1996]). Children attending schools that use some form of signed English may not be exposed to ASL. Moreover, schools that educate students using an oral approach, in which speech is the primary means of communication in the classroom, also may not be exposed to ASL.

A person who is profoundly deaf from birth may have difficulty acquiring mastery of the spoken language, be it presented auditorily or in print. It is not surprising that someone who has never heard speech will have difficulty perceiving or producing it. In a large-scale study of deaf and hard of hearing children attending schools using an oral approach to education, Conrad (1979) reported that profoundly deaf children rarely acquired sufficient lipreading skills to allow easy participation in conversations. He found, on average, that these children (with hearing loss greater than 85 dB) could only comprehend about 25% to 28% of the words through lipreading that they could comprehend through reading. Even among these orally educated students, fewer than 20% had speech that was rated even fairly easy to understand. While the statistics are better for hard of hearing children, Conrad found that even these students (with hearing loss less than 65 dB) could only comprehend about 36% of the words through lipreading that they could comprehend through reading. Nearly 85% of these hard of hearing students, however, had speech that was rated at least fairly easy to understand.

Perhaps more surprising may be the fact that many deaf and hard of hearing individuals have difficulty with reading (Conrad 1979; Gallaudet Research Institute 2003). To understand this, it is necessary to realize that reading is based on the underlying spoken language. Spoken languages are composed of sounds, linguistically defined as "phonemes." These phonemes correspond, albeit not always in a one-to-one relationship in English, to letters or letter combinations. This is true of all alphabetic languages. Learning to read is generally considered to be learning to map the print onto the spoken language the person already knows (Brady and Shankweiler 1991). In addition, speech plays a critical role in the short-term memory processes that serve understanding of grammar and text comprehension (Lichtenstein 1998). In the case of deaf readers, however, it cannot be taken for granted that reading will build on a firm understanding of the structure of the spoken language, but there are no absolutes. Some prelingually, profoundly deaf children become excellent readers, while some with lesser degrees of hearing loss do not (Conrad 1979; Hanson 1989).

Interestingly, research has recently turned to an examination of signed languages as an influencer in the development of skilled reading. It has long been known that deaf children of deaf parents, on average, acquire greater mastery of

* Terms such as hearing-impaired and deaf-mute are generally considered to have negative connotations. For a discussion of this, see "What Is Wrong with the Use of These Terms: 'Deaf-mute,' 'Deaf and dumb,' or 'Hearing-impaired'?" by the National Association of the Deaf (available at http://www.nad.org/site/pp.asp?c5foINKQMBF&b5103786). The style manual of the American Psychological Association (APA) recommends use of nondiscriminatory language in all publications (see http://www.apastyle.org/disabilities.html).

reading and writing than deaf children of hearing parents. Is this due to early exposure to sign language? While a number of both intellectual and societal factors have been considered as contributors to this disparity, interest has focused on the issue of language. Evidence is now emerging as to the important role that early mastery of a sign language can have on second language learning for deaf students as they acquire reading and writing skills (Padden and Hanson 2000; Padden and Ramsey 2000).

In short, for any deaf or hard of hearing individual, language experience cannot be assumed. That individual may or may not sign, speak clearly or lipread well, or have reading skills consistent with those of the hearing population. This knowledge has implications for designers who seek to address the needs of deaf and hard of hearing users.

40.4 DISPLAY TECHNOLOGIES

In many ways, computers and other technologies have proven to be of great benefit to deaf and hard of hearing users. The largely visual nature of information on the Internet makes this information accessible to deaf and hard of hearing users. Instant messaging and e-mail facilitate communication with deaf and hearing family, friends, and coworkers, while network-connected wireless devices such as PDAs and pagers are seen as lifelines that can be used in place of cell phones. As would be suspected from the previous discussion, however, effective interfaces for these and other technologies for use by deaf and hard of hearing individuals must take into account both sensory and language considerations. In particular, the increasing reliance on sound and speech interfaces to convey information can have serious consequences for individuals who have a hearing loss.

40.4.1 Audible Signals

Sounds have become increasingly popular in computer interfaces. They have long been used to convey information about new messages and have become popular as problem alerts, such as when an error has been committed. These sound events are considered attention-grabbing events for users whose visual attention may otherwise be engaged. For any user who has a hearing loss, however, sounds will be a problem.

A number of considerations can help provide the necessary visual support for a user who is deaf or hard of hearing (Vanderheiden 1994). It is necessary to provide visual forms for all auditory information. Critically, these visual cues should be sufficiently noticeable so that they catch the attention of a person who may not be looking directly at the computer screen. Operating systems have features that can provide such visual alerts. For example, Windows® has accessibility features that allow users to set up their systems to have captions or visual warnings displayed for sound events. These are helpful, although they may not give the full range of information carried by a sound event. For example, the meaning of a sound event may differ based on the tone of the signal or when the sound is produced. While visual captions and warnings may alert a deaf user that a sound event has occurred, they will be unable to convey these more subtle distinctions. It is important for designers to give careful consideration to sound events to ensure that crucial information is available by a nonauditory means for deaf and hard of hearing users.

Multimodal interfaces, as the name implies, are designed to support a range of perceptual capabilities. In theory, this would seem ideal for users who are deaf or hard of hearing as visual alternatives to auditory materials should be available. Multimodal interfaces, however, do to always present all information on both modalities. The emphasis in many multimodal interfaces is representing information via speech that would otherwise be conveyed by print or some other visual means. To the detriment of deaf and hard of hearing users, often less attention is given to ensuring that all auditory material be visually conveyed as well.

40.4.2 Multimedia Interfaces

Multimedia uses a combination of text, sound, pictures, animation, and video to present information. Traditionally, games and educational software have exploited the richness of multimedia, but the advent of high-speed Internet communications has enabled the use of multimedia for a number of engaging applications on the web. For the present discussion, consideration will be given to multimedia presentations as they may impact access for deaf and hard of hearing users.

Multimedia material is inherently sensory. The technology offers eye-catching visual displays and attention-grabbing sound effects. To the extent that the information conveyed visually and auditorily is the same, information can be reinforced for users who have both channels available to them. To the extent that different information is presented in the two channels, however, users who have a functional loss of one of the channels will not have full access to that information. As it relates to the present discussion, this means that any information that is carried solely by sound or speech will be unavailable to deaf and hard of hearing users. Accessibility guidelines for multimedia products and web pages require equivalent visual presentations (e.g., see Brewer and Dardailler [1999]; U.S. General Services Administration [n.d.]).

Consider the growing popularity of video on the web. Video material is an extremely effective way to convey information and younger generations of computer users have come to expect video to be part of their computer experience. For deaf and hard of hearing users, the voice-over that is common in video will be inaccessible. Words spoken by persons in view of the camera also are largely inaccessible. Even people skilled at lipreading cannot lipread video conversations that have poor lighting or poor resolution, or speakers who turn away from the camera. Additionally, the video may present music or sound events (e.g., doorbells or animals noises) that contribute significantly to events on the video. These, too, are unavailable to deaf and hard of hearing users. Technologies such as captioning and sign-language translation exist to provide alternative presentations of sound events and speech. Designers wishing to make their applications universally accessible should consider these alternatives and incorporate them into their applications.

40.4.2.1 Captioning

Captioning provides a print alternative to speech and sound events. It is much like subtitling, except that it is specifically designed for deaf and hard of hearing users and, thus, will include comments in the captioning about sounds (e.g., "<music playing>" or "<sounds of child crying>") that may not be included in subtitles of foreign language videos. Captioning of certain television programming is mandated in the United States by the Federal Communications Commission and is considered to be beneficial to a large number of users, not only those with hearing loss. It has been shown, for example, to improve reading abilities of children and to benefit second language learners. Designers who use multimedia materials have an obligation to their full audience to provide captioning of audio and video materials. The listing of a number of resources for captioning software is available at the Closed Captioning website (n.d.).

As might be anticipated from the previous review of reading levels of deaf and hard of hearing users, there has been some controversy about what language level should be used for captioning. Simply put, the issue revolves around the question of whether captions should be verbatim transcripts or simplified captioning should be provided. Verbatim captioning is generally preferred by users themselves (NIH 2002) and is often cited as having the potential to improve reading skills (Steinfeld 2001).

40.4.2.2 Signing

For sign language users, there are sign language alternatives to captioning. These sign interfaces have been defined as ways of representing signed languages on a computer such that signing can be stored, displayed, and manipulated to facilitate computer interaction (Frishberg et al. 1993). It should be noted that these interfaces have often been employed not only for making audio and speech materials accessible to deaf and hard of hearing users, but they have also been used for language learning by both deaf and hearing people. A number of software applications have been developed that use sign language as a means of teaching reading skills and writing to deaf signers or teaching sign language skills to individuals wishing to learn to sign.

Importantly, software applications that purport to use "sign language" or ASL differ in significant ways in the language that is being used. Notably, many of these applications use fingerspelling. Fingerspelling is not a natural signed language, but rather is a derivative of print. Specifically, in fingerspelling, there is one handshape for each letter of the alphabet and words are spelled out letter by letter on the hands. Thus, the word "language" would be spelled out by eight distinct handshapes spelling L-A-N-G-U-A-G-E. Other sign language interfaces use a form of signed English, rather than the native sign language. For young children and others not fluent in English, interfaces that use fingerspelling or signed English transliterations of text may not meet their needs.

In many cases, the goal when using sign interfaces is to provide ASL translations. Given the present state of the art, automatic translation from English to ASL is not possible; however, many current efforts are directed at facilitating this translation, acknowledging the need for translation into ASL. In what follows, a few of the options for sign language presentation of audio and multimedia will be discussed.

Ideal in many respects would be to have a live person signing an ASL version of print and multimedia materials. Hanson and Padden (1989, 1990) used videodisc technology in the earliest computer-based attempt at a bilingual ASL/English approach to reading and writing instruction for signing children. The work combined ASL video and the translated English text on one screen. In this and other language learning situations where the users are young children still developing both ASL and English skills, this use of live signing has been particularly effective (Frishberg et al. 1993).

The advent of high-speed networks and Internet video has created opportunities for web applications that use live signing interfaces. For example, classroom applications have been developed (e.g., see King [2000]; Laurent Clerc National Deaf Education Center [n.d.]; for a demo, see "Sample Web Page," Gallaudet University [n.d.]). Additionally, video blogs have created the opportunity for blogs to be signed by the blogger, rather than written (Lamberton 2005), and video e-mail allows signers to communicate through signing by creating video recordings to be transmitted as e-mail messages (e.g., see Road Runner Video Mail [n.d.]; also, Vibe Video Mail [n.d.]).

Although ideal from the language perspective, other constraints may argue against the use of live signing in an interface. Lack of access to high-speed networks for video transmission may be an issue, but often the problem is the desire for automatic translation of software and web content that live signing does not provide. Live signing requires the prior recording of the signed material. Once recorded, changes to the video require a new recording. Because of this, live signing is not practical in applications that require that sign versions of audio or multimedia be created in real time. Short of having an interpreter doing the translations, live signing is not possible in these situations.

One approach to automatic sign presentation is what might be called "concatenated signing" (e.g., see iCommunicator [n.d.]; Signtel Inc. [n.d.]). With this, a software program is used to create word strings or sentences by concatenating signs produced by a live signer. The program starts with a vocabulary of stored individual signs. These signs can be strung together to form phrases and sentences. To prevent a jerky appearance that would occur through the simple

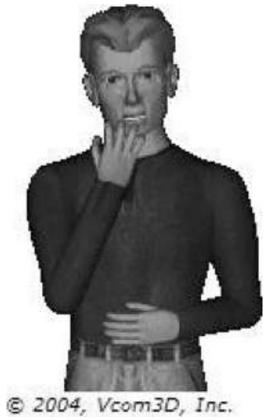

FIGURE 40.1 An American Sign Language sign avatar. The full animation of this avatar can be viewed on http://www.vcom3d.com/ASL.htm. © Vcom3D, Inc., 2004. All rights reserved.

production of a list of signs, algorithms are used to smooth the transitions between these signs. While these transitions are not as natural as live signing, the signing is legible and suggests an interesting approach to sign language interfaces.

A technique that has generated much interest in recent years is signing avatars (e.g., see Cox et al. [2002]; Karpouzis et al. [in press]; Kennaway [2002]; Sims [2004]). These avatars use virtual-reality techniques to produce animated signing. The specific techniques differ for the various avatars, but central to all is that they display computer generated signing. Some systems are able to display not just hands, but full signers, so that facial expressions as well as hand movements are shown. See, for example, the SigningAvatar® shown in Figure 40.1 that illustrates the sophistication of these animations.

Signing avatars have been used in education and have potential for applications such as translation of web pages, television programs, and conversational dialog. Chief among the virtues is that, unlike natural (live) sign language applications that are limited to prerecorded materials, avatars can generate signed versions of English words "on the fly." They also have the advantage of not requiring large downloads for web usage.

While the avatars can sign ASL when preprogrammed, the language translation work needed for automatic translation into ASL (or other signed language) is not ready to support this rendering on the fly. A current research focus in avatar work is on natural language translation and exploring techniques to display native sign languages by avatars (e.g., see Huenerfauth [2005]).

40.5 INPUT TECHNOLOGIES

Standard keyboard and mouse input technologies offer no barriers to users who have a hearing loss. The emergence of new interfaces, however, presents alternatives that will impact the way in which we are able to interact with computers. We consider here both speech and gestural interfaces as they may influence interactions for deaf and hard of hearing users.

40.5.1 SPEECH INTERFACES

Conversational speech interfaces have appeal as a natural means of interacting with computers. These interactions can range from simple, even one-word commands to full dictation of documents and user collaborations. For deaf and hard of hearing individuals, such interactions require consideration of user needs. First, these interactions can involve speech output which, as already discussed, requires a visual display alternative. Second are problems with speech input. Some deaf and hard of hearing individuals utilize speech and would be interested in taking advantage of speech input. Speech recognition, however, may be more problematic for these speakers than for hearing speakers.

As mentioned briefly in a previous paragraph, the speech of deaf and hard of hearing individuals is not always highly intelligible to hearing listeners. Since speech recognition engines can be trained to the voice and pronunciations of an individual speaker, however, couldn't a recognizer be trained to understand the speech of an individual deaf speaker, even if the speech is not completely intelligible to listeners? The difficulty is that recognizers require consistent speech. Research has shown that the speech of deaf and hard of hearing speakers often is more variable than the speech of hearing speakers (McGarr 1987; McGarr and Lofqvist 1988). For example, there is more acoustic variation in the pronunciation of a single phoneme by a deaf or hard of hearing speaker than there is in the pronunciation of that phoneme by a hearing speaker. Hearing listeners are very tolerant of this variability; speech recognizers are less so. Thus, deaf and hard of hearing users who many wish to use their speech for input may well find recognition less accurate than it is for hearing speakers.

Speech interfaces are often seen as useful alternatives to visual interfaces in situations when computers or keyboards are not available. For hearing users, this alternative of a speech interface may be highly desirable. Many deaf and hard of hearing users, however, will not be interested in speech interfaces; others may experience difficulties in using them. Although situational demands may sometimes dictate the use of conversational interfaces, care must be taken that outside of the situational context there exists a means for deaf and hard of hearing users to access the same information that hearing users access.

40.5.2 SIGN INTERFACES

Designed specifically for deaf and hard of hearing users, sign recognition is a specific and complex subset of gesture recognition technologies having the goal of automatically converting signed language to text or speech. These technologies have been investigated for a number of years, primarily to address the need to facilitate communication between signers and nonsigners. They also have the potential to provide an alternative means of natural language input to computers.

The task of recognizing full ASL or other natural sign languages is a difficult problem. The first reason is that an individual sign varies depending upon its context. Take, for example, the sign for the word GIVE. This sign has a specific shape combined with a variable movement. The movement reflects who is giving and to whom. I GIVE-TO YOU, YOU GIVE-TO ME, I GIVE-TO HIM, HE GIVES-TO ME, and I GIVE-TO ALL-OF-YOU each has a different movement that indicates subject and object. A second reason for difficulty in sign-language recognition is that several pieces of linguistic information are produced in parallel. For example, facial expression carries critical grammatical information. Thus, a full language recognizer needs to recognize not only the hand gestures of ASL, but must also recognize certain facial information relevant to the grammar. Such facial elements include eyebrow position, eye gaze, and mouth movements.

As with interfaces that produce signs, many systems that purport to perform sign-language recognition deal with recognition of fingerspelling handshapes rather than recognition of ASL sentences or even ASL signs. Using fingerspelling handshapes rather than ASL signs certainly constrains the size of the problem. Because there are only 26 handshapes in the English alphabet, this represents a much more manageable problem space than the recognition of full ASL signing. While it presents an alternative to keyboard typing of words, it doesn't provide the type of natural language interaction with computers that is afforded by speech interfaces.

Technologies for recognizing signs have tended to use either instruments worn by the signer or computer vision techniques. The first of these approaches has the signer wear a specially designed glove or sensors placed on their joints that allow a computer to track movement (e.g., see Braffort [1996]; Fang, Gao, and Zhao [2003]; Hernandez-Rebollar, Lindeman, and Kyriakopoulos [2002]; Kadous [1996]; Wang, Gao, and Ma [2002]). In contrast, computer vision techniques use cameras to provide input to a computer about a signer's movements and facial gestures (e.g., see Brashear et al. [2003]; Kadous [1996]; Lee et al. [2005]; Vogler and Metaxas [2001]). These inputs are then analyzed using a variety of techniques such as neural networks or Hidden Markov Models that then recognize the sign.

Critically, however, this recognition does not do language translation. Thus, the output will be a one-to-one mapping of a sign into print or speech. As mentioned with the avatar work presented earlier, the ASL/English rules that would be needed for such translation are not developed to a state where automatic translation can occur; however, advances are being made. Recently, for example, Hernandez-Rebollar (2005) presented work designed to translate signed input into English phrases. In that work, the translation was enabled by having a limited number of phrases that the system could recognize, thus constraining the problem space.

The current state of the art for sign recognition is not as advanced as speech recognition. As researchers continue to work on the problem, however, advances can be expected. For signers, it might be the case that conversational sign interactions will one day be possible, much as speech recognition now allows speakers to benefit from conversational speech interactions.

40.6 TECHNOLOGY AND COMMUNICATION

Deaf and hard of hearing individuals have difficulties not only with computer interfaces, but also experience significant difficulties in certain communication situations. Telephone conversations, as well as one-on-one conversations, group discussions, and presentations or classroom lectures, are all problematic. No discussion of HCI for deaf and hard of hearing individuals would be complete without at least a brief mention of technologies that have been developed to aid in these situations.

Telephones have long been a source of difficulty for deaf and hard of hearing people. Alexander Graham Bell was a teacher of deaf students and was married to a woman who was deaf. His interest in finding improved ways to communicate with deaf speakers led to his invention of the telephone. Ironically, however, over the years, telephones created a number of barriers for deaf and hard of hearing individuals in the workplace and other situations. To overcome these barriers, a number of assistive devices have been developed (Lazzaro 1993). Amplification and adapters exist for many phones that will allow hard of hearing individuals or people with cochlear implants to hear phone conversations. Teletype devices (TTYs and TDDs) as well as some computer applications allow deaf users to type conversations that are carried over phone lines.

Operator-assisted relay services have been established to enable conversations between deaf and hearing individuals. The relay personnel serve as a bridge between the two conversation participants, translating typed information into speech for the hearing participant and translating speech into written text for the deaf participant. Hard of hearing speakers can speak directly with others using a captioning service that provides, nearly in real time, a printed transcript of the conversation to support hard of hearing users (CapTel 2005). Various means of enabling signed conversations over the telephone have been explored over the years, but the advent of video phones has now made feasible the option of signed phone conversations.

The current prevalence of conference calls in the workplace has created a new set of problems for deaf and hard of hearing workers. Similarly, classroom situations or lecture presentations also create significant difficulties for deaf and hard of hearing attendees. Even individuals skilled in lipreading have difficulty in these situations because the speaker's face is rarely visible with sufficient resolution for lipreading. Sign language interpreting and captioning are two means of providing accommodation for participants unable to hear or understand the speech in these situations.

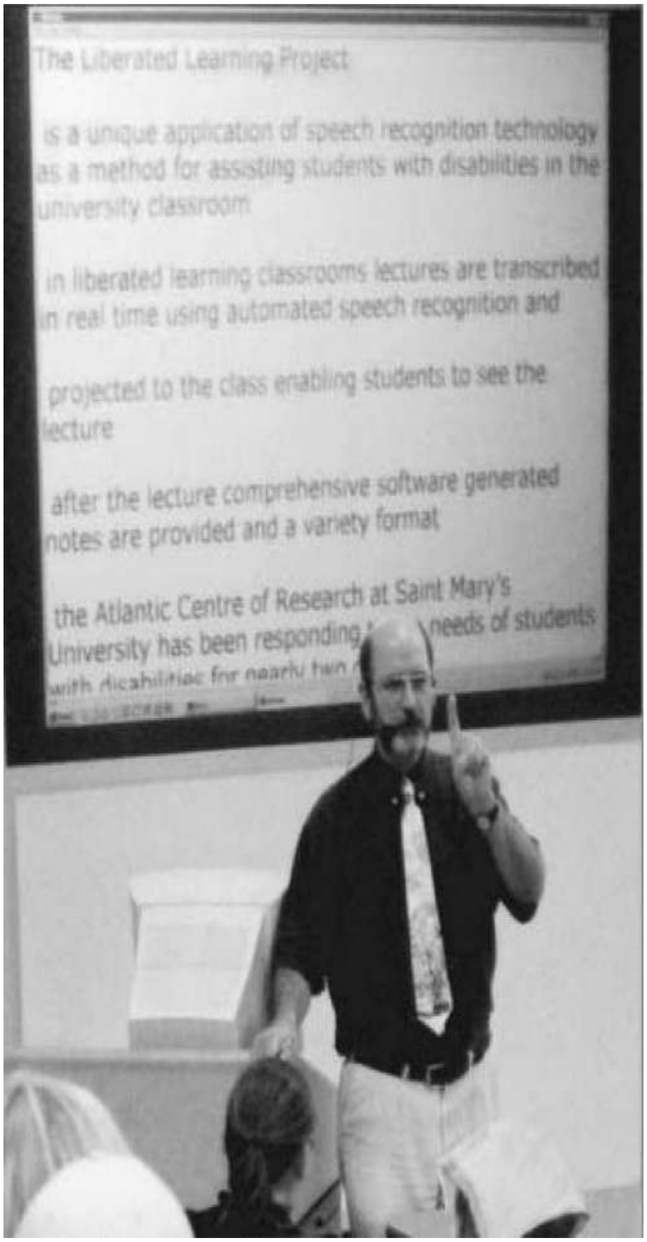
Sign language interpreters allow signers to participate in meetings by providing real-time translation of the spoken conversation into sign. This is a two-way translation service, such that the signing participant is also able to participate by having the interpreter speak their signed utterances. Remote interpreting is a technology that addresses the problem of a shortage of skilled interpreters, particularly in some locations. The interesting aspect of this is that the interpreter need not be present at the location of any of the conference participants. The deaf or hard of hearing participant views the remotely located interpreter on a computer display or TV screen. The interpreter listens to hearing participants by telephone and provides sign-language interpreting for the deaf participant. The interpreter also voices what the deaf person signs for hearing participants. This remote interpreting can be used similarly to the telephone relay service, with participants in different locations (Video Relay Service, or VRS), or in situations where the participants are located in the same room (Video Relay Interpreting, or VRI).

Communication Access Real-time Translation (CART) provides real time captioning, enabling discussions and presentations to be transcribed into text for deaf and hard of hearing participants. Typically, this is done by a person who creates the captions. As with sign language interpreting, the captioner can be physically present or remotely located, listening to the conversation by phone and transmitting the text via a network to a computer screen or projected display. The deaf participant types their questions or comments. That input is then read aloud for the other participants, either by a captioner or using computer text-to-speech technology (e.g., see Caption First [n.d.]; Viable Technologies [n.d.])

The ability to automatically transcribe speech was envisioned more than 100 years ago as a technology that held great promise for deaf and hard of hearing people, even though such technology was hardly imaginable at the time (Fay 1883*)*. As speech-recognition systems have matured over the last quarter century, a number of applications designed for deaf users have been explored (Bain et al. 2005; Stinson and Stuckless 1998).

The Liberated Learning Project is one example of using automatic speech recognition in the classroom (Bain, Basson, and Wald 2002). In this effort, the classroom teacher speaks into a microphone that transmits his or her speech to a computer to perform the recognition. The transcript of the lecture is displayed in close to real time on a screen at the front of the classroom. Shown in Figure 40.2 is a classroom situation for the Liberated Learning Project.

While recognition technologies have improved over the years, they still do not attain 100% correct performance for dictation. To provide students with accurate transcripts for lecture notes, the professors who participate in the Liberated Learning Project review the transcript for inaccuracies and make corrections after a lecture is completed. The corrected transcripts are then made available to students (Bain, Basson, and Wald 2002). Other efforts that use automatic speech recognition for captioning use different methods for correcting errors in transcripts. These other methods include having a trained speaker "shadow" the speech to produce more reliable recognition, and/or having a person correcting errors in real time (e.g., see Bain et al. [2005]; Robson [2001]; Viable Technologies [n.d.]).



The Liberated Learning Project

is a unique application of speech recognition technology as a method for assisting students with disabilities in the university classroom

40.7 CONCLUSIONS

Computer technologies are very important in the lives of many deaf and hard of hearing people. These technologies can ease communication between coworkers, friends, family members, neighbors, and a variety of services. These technologies have also provided access for deaf students, employees, and individuals to have full access to rich multimedia services, shopping, news, and general information. In short, barriers long encountered by deaf and hard of hearing people are now being overcome through the use of technology.

Deaf and hard of hearing users represent a population that, in itself, is diverse in both hearing and language experiences and skills. Applications that offer flexibility of language (e.g., captioning, signed English, or ASL) will be most accessible to users who have a hearing loss. At a minimum, however, developers and designers need to ensure that information is not carried by the auditory channel alone. Paramount is the need to ensure that any audible information, be it a sound alert, speech prompt, or other auditory event, has a visual counterpart. Such considerations are not only good design, but are also mandated by a growing number of regulations worldwide. The ability of everyone to participate in our increasingly technological society is crucial.

ACKNOWLEDGMENTS

I'd like to thank Al Noll, Debra Noll, and John Richards for valuable comments on early drafts of this chapter.

Part VI

The Development Process

Section A: Requirements Specification

41 User Experience Requirements Analysis within the Usability Engineering Lifecycle

Deborah J. Mayhew, and Todd J. Follansbee

CONTENTS

41.1 INTRODUCING USER EXPERIENCE REQUIREMENTS ANALYSIS

As the World Wide Web has matured, the field of traditional software usability (which dates back to the late 1970s) has come to recognize—and integrate with—other qualities of what is now referred to as the web user experience (UX). As web capabilities have increased, graphic design has become a key quality of the UX. And in the case of e-Commerce websites, a relatively new quality of the UX design has emerged: persuasiveness. At this point, any e-Commerce designer or developer needs to recognize the importance of the following five different qualities of the total website UX:

1. Utility
2. Functional integrity
3. Usability
4. Persuasiveness
5. Graphic design

These qualities of the UX design are defined and discussed in Chapter 51. This chapter updates the corresponding chapter in the previous edition of this volume by expanding the topic of requirements analysis beyond traditional usability to address requirements relating to these other aspects of the total UX, particularly in the case of website design.

The following three key ingredients are necessary to ensure that an optimal UX design is achieved during software or website development:

1. Application of established design principles and guidelines
2. A structured methodology for design
3. Managerial and organizational techniques

At this point, well-established UX design principles and guidelines are available relating to usability (Tidwell 2010; Nielsen and Loranger 2006), persuasion (Eisenberg and Eisenberg 2005; Goldstein, Martin, and Cialdini 2008); and graphic design (Beaird 2010), based on objective research, and are reported in the literature. Many of these principles and guidelines are enumerated throughout different chapters in this book. Development organizations need to have access to professionals who are fluent in these design guidelines and who can participate in design efforts, so this general accumulated knowledge will find its way into their applications and websites.

Just having a design guru or two on board does not guarantee that appropriate design principles and guidelines will find their way into final websites or applications. Design is complex, and there is no simple cookbook approach to design that can rely on general principles and guidelines alone. Development organizations also need structured methods for achieving an optimal UX in their websites and applications.

Similarly, a well-structured and documented design methodology must be introduced and managed—it does not happen by itself. Thus, managerial and organizational techniques must be applied to ensure that the design methodology is followed and includes the application of well-established design principles.

Even when good management practices are being applied, either of the remaining two ingredients alone—design guidelines or design methods—is necessary, but not sufficient. Optimal UX design cannot be accomplished by the systematic application of generic guidelines alone, because every application or website and its intended set of users is unique. Design guidelines must be tailored for and validated against unique requirements, and this is what the structured methods accomplish. Conversely, applying structured methods without also drawing on well-established design principles and guidelines is inefficient at best and may simply fail at worst. Without the benefit of the initial guidance of sound design principles during first passes at design, a particular project with its limited resources may simply never stumble upon a design approach that works. For example, formal usability testing is a valuable and an objective method for uncovering usability problems. However, without a clear understanding of basic design principles and guidelines, as well as unique requirements data, solving the identified problems without incurring new ones will not be easy or likely.

Previous sections and chapters in this book refer to a broad variety of design principles and guidelines. Section A (Requirements Specification) in Part VI (The Development Process) of this volume addresses the need for methodology and provides chapters that address a variety of techniques that can be applied during the development process to achieve an optimized UX in their website or application. This chapter sets the stage for this section and, in particular, for the subsection on one stage of the development process: requirements analysis.

The *Usability Engineering Lifecycle* (Mayhew 1999) documented a structured and a systematic approach to address one aspect of UX design—usability—within the application or web development process. Here, we widen the scope from usability to UX, and change terminology as appropriate to reflect this change in scope.

The UX engineering lifecycle consists of a set of UX engineering tasks applied in a particular order at specified points in an overall development lifecycle.

Several types of tasks are included in the UX lifecycle, as follows:

- Structured requirements analysis tasks
- An explicit goal-setting task, driven directly from requirements analysis data
- Tasks supporting a structured, top–down approach to UX design that is driven directly from UX goals and other requirements data
- Objective evaluation tasks for iterating design toward UX goals

Figure 41.1 represents in summary, visual form, the original Usability Engineering Lifecycle (please note that in the figure, "OOSE" stands for Object Oriented Software Engineering). The overall lifecycle is cast in three phases: Requirements Analysis, Design/Testing/Development, and Installation. Specific tasks within each phase are presented in boxes, and arrows show the basic order in which the tasks should be carried out. Much of the sequencing of tasks is iterative, and the specific places where iterations would most typically occur are illustrated by arrows returning to earlier points in the lifecycle. Brief descriptions of each lifecycle task are given below, using the new term UX to widen the scope of tasks as described by Mayhew (1999).

41.1.1 Phase 1: Requirements Analysis

41.1.1.1 User Profile

A description of the specific user characteristics relevant to UX design (e.g., computer literacy, expected frequency of use, and level of job experience) is obtained for the intended website or application user population. This will drive tailored UX design decisions and identify major user categories for study in the contextual task analysis. This volume includes a set of chapters (Part V—Designing for Diversity) dedicated to exploring the unique needs and requirements of different types of user populations.

41.1.1.2 Contextual Task Analysis

A study of users' current tasks, workflow patterns, and conceptual frameworks is made, resulting in a description of current tasks and workflow, and an understanding and a specification of underlying user goals. These will be used to set UX goals and drive work reengineering (i.e., information architecture) and UX design. Section A (Requirements Specification) in Part VI (The Development Process) of this volume includes several chapters on topics related to task analysis.

41.1.1.3 UX Goal Setting

Specific qualitative goals reflecting UX requirements are developed, extracted from the user profile and contextual task analysis. In addition, quantitative goals (based on a subset of high-priority qualitative goals) are developed, defining minimal acceptable user performance and satisfaction

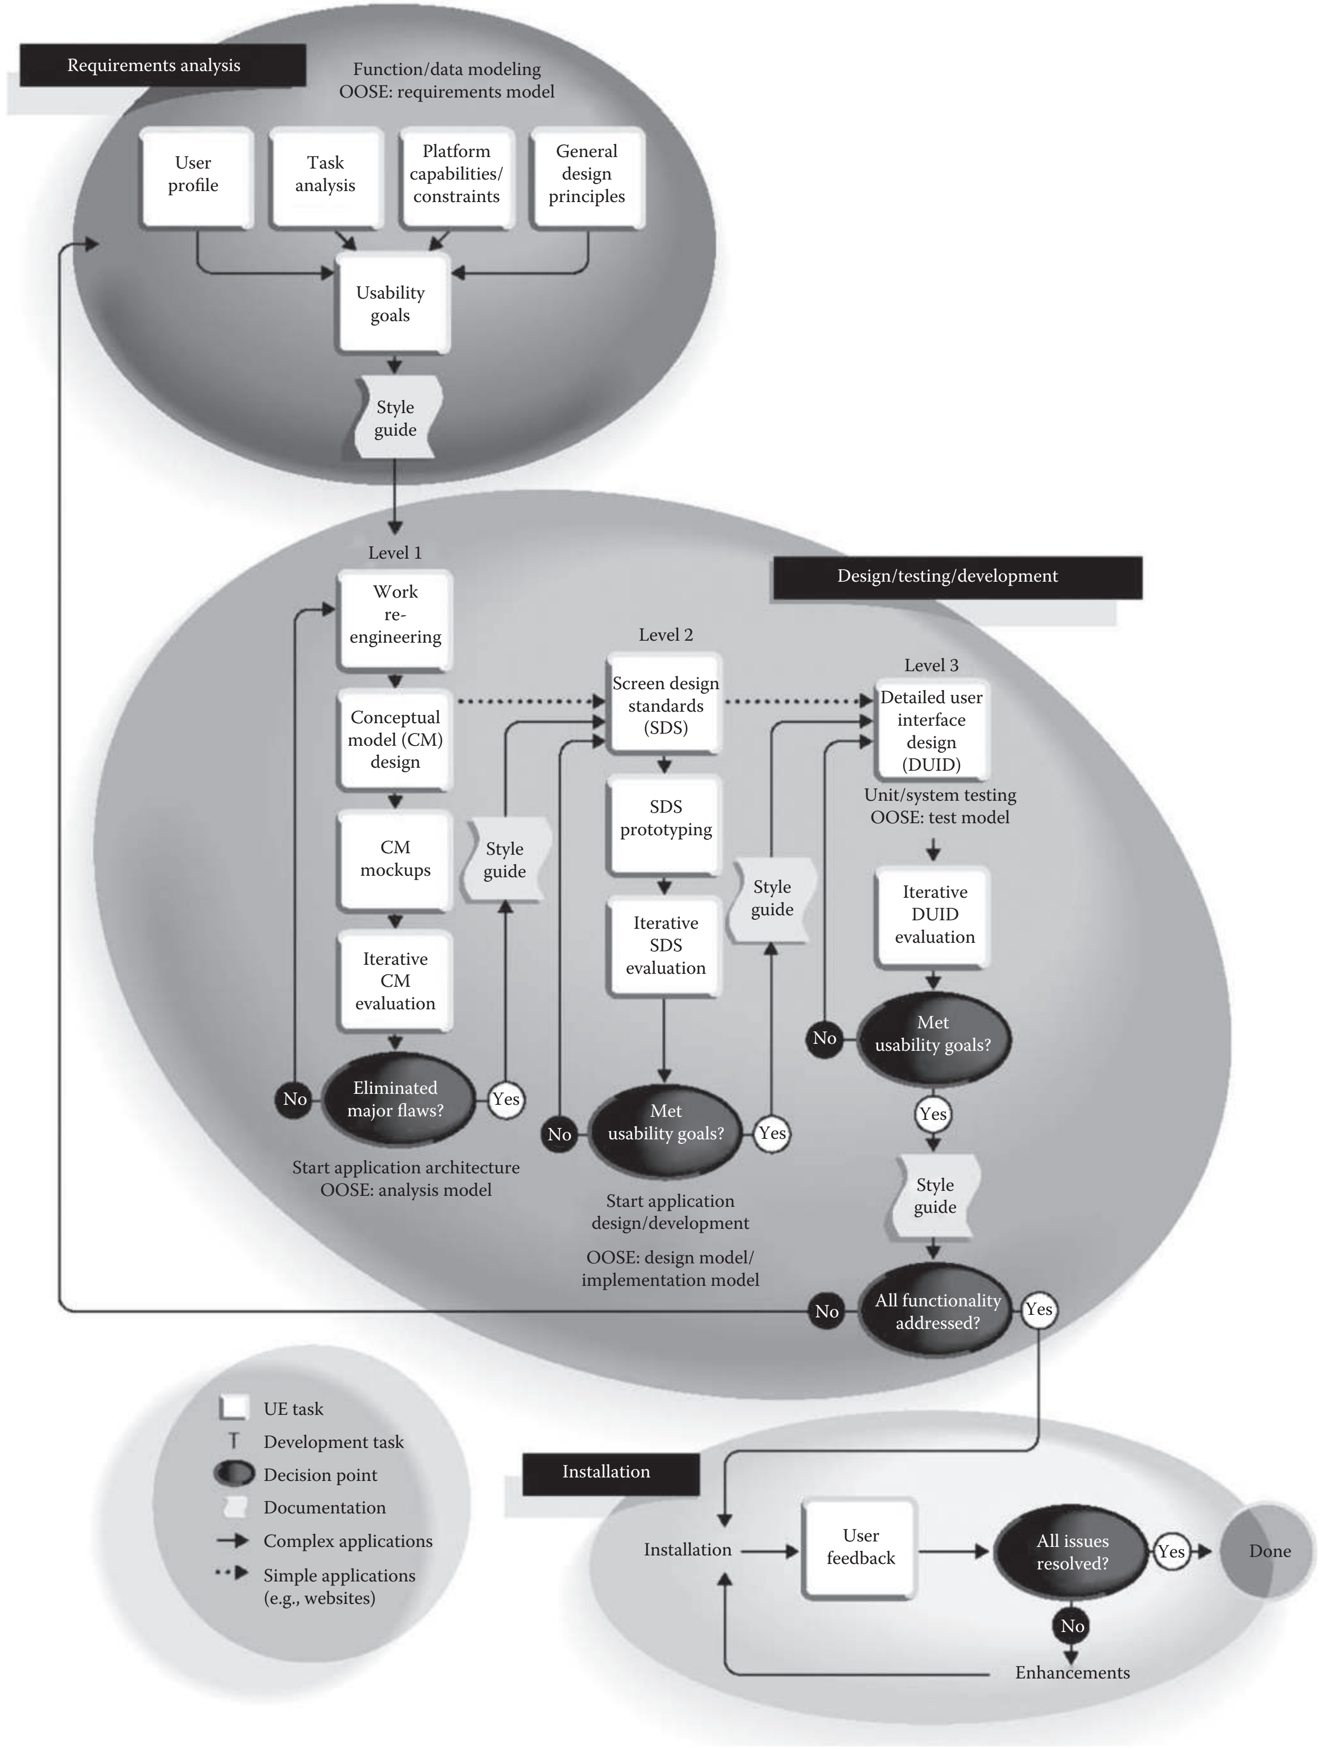

FIGURE 41.1 The Usability Engineering Lifecycle. (From Mayhew, D. J. 1999. *The Usability Engineering Lifecycle*. San Francisco, CA: Morgan Kaufmann Publishers.)

criteria (and in the case of e-Commerce, conversion rates). These UX goals focus later design efforts and form the basis for later iterative UX evaluation.

41.1.1.4 Platform Capabilities/Constraints

The user interface capabilities and constraints (e.g., screen size, screen resolution, browser brand and version, etc.) inherent in the technology platform chosen for the application (e.g., Apple Macintosh, MS Windows, and product-unique platforms) or website (e.g., browser brand and version) are determined and documented. These constraints will define the scope of possibilities for UX design. This volume includes chapters that describe platform capabilities that support many relatively new and innovative types of user interfaces, including multimedia (Chapter 17), adaptive interfaces and agents (Chapter 19), mobile devices and ubiquitous computing (Chapter 20), tangible interfaces (Chapter 21), and wearable computers (Chapter 12).

41.1.1.5 General Design Guidelines

Relevant general UX design guidelines available in the literature are gathered and reviewed. They will be applied in the future design process, along with all other project-specific information gathered in the previous tasks.

41.1.2 Phase 2: Design/Testing/Development

41.1.2.1 Level 1 Design

41.1.2.1.1 Work Reengineering

Based on all requirements analysis data and the UX goals extracted from them, user tasks are redesigned at the level of organization and workflow to streamline work and exploit changing software or web capabilities. No visual UX design is involved in this task, just abstract organization of functionality and workflow design. This task is sometimes referred to as “information architecture.”

41.1.2.1.2 Conceptual Model Design

Based on all the previous tasks, initial high-level design alternatives are generated. At this level, rules for the consistent presentation of navigational controls are established. Screen/page content design is not addressed at this design level.

41.1.2.1.3 Conceptual Model Mockups

Paper-and-pencil or prototype mockups of high-level design ideas generated in the previous task are prepared, representing ideas about high-level functional organization and conceptual model design (see Chapter 47 by Beaudouin-Lafon and MacKay in this volume for a discussion of prototyping tools and techniques). Detailed screen/page design and complete functional design are not in focus here.

41.1.2.1.4 Iterative Conceptual Model Evaluation

The mockups are evaluated and modified through iterative evaluation techniques such as formal usability and/or persuasion testing in which real, representative end users attempt to perform real, representative tasks with minimal training or intervention, imagining that the mockups are a real software or web user interface (see Section C: Testing and Evaluation, Part VI-The Development Process in this volume for chapters on testing and evaluation). This and the previous two tasks are conducted in iterative cycles until all major UX “bugs” are identified and engineered out of Level 1 (e.g., conceptual model) design. Once a conceptual model is relatively stable, system architecture design can commence.

41.1.2.2 Level 2 Design

41.1.2.2.1 Screen/Page Design Standards

A set of specific standards and conventions for all aspects of detailed screen/page design is developed, based on any industry and/or corporate standards that have been mandated (e.g., Microsoft Windows, Apple Macintosh, corporate website standards, etc.), the data generated in the Requirements Analysis phase, and the unique conceptual model design arrived at during Level 1 design.

41.1.2.2.2 Screen/Page Design Standards Prototyping

The screen/page design standards (as well as the conceptual model design) are applied to design the detailed UX to selected subsets of functionality. This design is implemented as a live prototype.

41.1.2.2.3 Iterative Screen/Page Design Standards Evaluation

An evaluation technique, such as formal usability and/or persuasion testing, is carried out on the screen/page design standards prototype, and then redesign/reevaluation iterations are performed to refine and validate a robust set of screen/page design standards. Iterations are continued until all major UX bugs are eliminated and UX goals seem within reach.

41.1.2.2.4 Style Guide Development

At the end of the design/evaluate iterations in Design Levels 1 and 2, we have a validated and a stabilized information architecture and conceptual model design, and also validated and stabilized set of standards and conventions for all aspects of detailed screen/page design. These are captured in a document called a style guide, which already documents the results of requirements analysis tasks. During detailed user interface design (see Section 41.1.2.3.1), following the conceptual model design and screen design standards in the style guide will ensure quality, coherence, and consistency—the foundations of a good UX.

41.1.2.3 Level 3 Design

41.1.2.3.1 Detailed UX Design

Detailed design of the complete software or website UX is carried out based on the refined and validated conceptual model and screen/page design standards documented in the style guide. This design then drives development.

41.1.2.3.2 Iterative Detailed User Interface Design Evaluation

Techniques such as formal usability and/or persuasion testing are continued during development to expand evaluation to previously unassessed subsets of functionality and categories of users and to continue to refine the UX and validate it against UX goals.

41.1.3 Phase 3: Installation

41.1.3.1 User Feedback

After a software application or website is installed and in production for some time, feedback is gathered to feed into design enhancements, design of new releases, and/or design of new but related products. The UX undergoes continuous testing and improvement throughout its life.

41.2 FOCUSING ON UX REQUIREMENTS ANALYSIS

This section (Section A-Requirements Specification, in Part VI-The Development Process) provides in-depth coverage of the different phases (and tasks within those phases) of the UX engineering lifecycle. In particular, the Requirements Analysis subsection describes and discusses different tasks and techniques for requirements analysis in some depth and from different perspectives. The goal of this chapter is to reinforce the importance of this phase of the lifecycle and to provide real-world examples of the benefits of conducting the kinds of techniques discussed in the later chapters of this subsection.

The following three main topics must be studied and understood to tailor design to support unique UX requirements:

- The users
- The users' tasks
- The users' work environments

In the UX engineering lifecycle, the first is addressed in the task called the user profile, and the remaining two are addressed in the task called contextual task analysis.

41.2.1 User Profile

There is no single best UX style or approach for all types of users. Specific user interface design alternatives that optimize the performance of some types of users may actually degrade the performance of other types of users. For example, an infrequent, casual user needs an easy-to-learn and easy-to-remember interface, but a high-frequency expert user needs an efficient, powerful, and flexible interface. These are not necessarily the same thing. Outward facing websites, unlike desktop software, share the need for an easy-to-learn interface. Even in the cases where websites have expert and frequent users, they must be accessible to new users for the site to grow. On the other hand, intranets may benefit from an interface tailored to a frequent user.

Websites face unique challenges if their success is dependent on objectives such as sales, lead generation, or page views. Usability may not even become relevant to a user if the website fails to engage them immediately by creating the right first impression, causing them to exit within seconds of arriving on the home page. A clear understanding of the intended audience helps designers ensure a website's ability to present its potential value to the user within 10 seconds of home page launch. Many user populations also have specific special needs that affect their ability to interact with software applications and websites. This section (Section A-Requirements Specification, in Part VI-The Development Process) covers the special characteristics of the elderly (see Chapter 35), children (see Chapter 36), cross-cultural audiences (see Chapter 39), and users with various kinds of physical and perceptual disabilities (see Chapters 38 and 40).

The more designers know about the specific characteristics of a population of users (e.g., expected frequency of use, typing skill, learning styles, potential anxiety regarding the defined tasks, etc.), the more likely they will be to make optimal UX design decisions. The purpose of a user profile is thus to establish the general requirements of a category of users in terms of overall UX style and approach.

Adlin and Pruitt's excellent pioneering work on the use of "personas" has become a key tool in building effective user profiles (Pruitt and Adlin 2006; see also Chapter 46). Personas are realistic and detailed descriptions of imaginary people who represent the key characteristics, skill sets, goals, top tasks, responsibilities, tools, pain points, and so on of a category of users. Personas can be used to drive discussion and design throughout the development lifecycle, from conception to user acceptance testing. They help keep the focus on users' needs, preferences, and goals, and they give stakeholders a common language with which to consider, discuss, and evaluate design ideas.

Niche-focused sites may make use of deeper user profile research by using tools such as Myer-Briggs personality profiling studies (Quenk 2009) as an alternative or adjunct to persona development. These tools can help designers focus on how to better motivate or communicate with the target audience.

For example, a site focused on a strongly visual audience, such as professional photographers, would be better served by presenting key information using graphics rather than using primarily text. Similarly, software developer personality profiling tells us to keep messages short and direct, and to avoid "marketese" language or an overly "slick" graphical look. When software developers are led to conclusions via inductive reasoning, they are more likely to remain engaged. Similarly, credibility is established with software developers by credibly establishing a product's acceptance by recognized experts rather than by authority figures whose reputation is not based on knowledge.

Besides understanding individual users of different categories, understanding the characteristics of groups and communities is another aspect of user profiling that becomes important in the design of groupware and products aimed at online communities and computer-supported cooperative work. This aspect of requirements analysis is addressed by Olson and Olson (Chapter 24) in this volume.

The user profile task fits into the overall UX engineering lifecycle as follows:

- The user profile task is the first task in the UX engineering lifecycle.
- The user profile task will feed directly into the contextual task analysis by identifying categories of users whose tasks and work environment must be studied in that later task.
- The user profile task will feed directly into the UX goal-setting task in which UX goals are in part driven directly by user characteristics (e.g., a low frequency of use suggests a need for ease of learning and remembering). Thus, different UX goals will be extracted from the profiles of different categories of users.
- Ultimately, the user profile task will have a direct impact on all design tasks, which are focused on realizing UX and business goals, which are in turn based in part on user profiles.
- The user profile task will also drive the selection of UX evaluation issues and test users.
- Output from the user profile task will be documented in the style guide along with other requirements analysis outputs.

41.2.2 Contextual Task Analysis

The purpose of contextual task analysis is to obtain a user-centered model of work as it is currently performed (i.e., to understand how users currently think about, talk about, and do their work in their current environment). In the case of e-Commerce websites, effective "persuasive" design requires an understanding of what is required to establish vendor credibility and adequate product detail. Without contextual task analysis, designers are likely to overlook important product or vendor information that may be a key to motivate users to make buy decisions.

In e-Commerce website development, designers often fail to address the scope of information a visitor needs to make a buy or engagement decision as well as the level of risk a visitor may face. For example, the risks associated with choosing a family vacation, health insurance plan, or a college education vary greatly. In addition, in B-to-B websites, up to as many as 20 different people are involved in the buy decision (McIntosh 2011), so the role of information sharing in consensus building must be addressed. Beyond the actual end users themselves, the following questions needs to be addressed: what are the roles of the decision makers, what risks do they face, and what information do they require?

Finally, without a truly user-centered approach to information architecture, applications and websites often fail to organize and present data within the UX in a way that satisfies the users' needs for timely information. Thus, the purpose of this task is to supplement more traditional types of system analyses to define UX requirements and to point toward ways to meet those requirements. Then, in later tasks, these requirements can be applied directly in making UX design decisions.

Contextual task analysis consists of the following basic steps:

- Gathering background information to define task scenarios
- Collecting and analyzing data from observations of and interviews with users
- Constructing and validating models of how users currently conduct tasks, which sometimes include making buy or engagement decisions

A central, key step in contextual task analysis is the second step, sometimes referred to as "contextual observations/interviews." Here, the idea is that analysts must observe and interview users in their real-life work context to understand their needs and "hot button" motivators as well as the role of consensus in their decisions.

To revisit the software developer example, task analysis for a website selling training for developers might reveal that the typical they may be motivated to purchase and easily able to move to the buy decision, but that they are notoriously poor "sales" people and their blunt communication style will inhibit their ability to gain consensus from the decision makers who hold the purse strings. Analysis could reveal the typical roles of the other decision makers such as IT management personnel. Only by understanding these roles within the context of the software developer's need to convince them can designers integrate the informational tools necessary to empower the software developer to gain necessary approval and complete the buying process.

Thus, data gathered during contextual task analysis allows designers to effectively structure and present functionality and information in a website or application user interface in a way that taps into users' needs and supports their task objectives.

An abstract modeling of users' tasks, which is the focus of more traditional types of business and systems analysis, runs the risk of making fatally flawed assumptions about key aspects of actual workflow and work environment. That is, traditional systems analysis models work in the abstract, without considering the basic capabilities and constraints of human information processing, the particular characteristics of the intended user population, the unique characteristics of the work environment, and how users themselves model, carry out, and talk about their tasks. The result of this analysis approach is often systems that provide all necessary functionality, but in an organization and presentation that simply does not support the natural flow of work and address the current "points of pain" for individual users.

One generic aspect of tasks that has become increasingly important with the explosion of e-Commerce is the issue of security and privacy. Understanding users' requirements for and expectations of privacy is necessary to make users feel confident about providing personal information in the course of online transactions. Contextual task analyses help provides the necessary insights to enable the optimal design of websites to support the goal of gathering personal data. This important aspect of task analysis is addressed by Karat, Karat, and Brodie (Chapter 29) in this volume.

Contextual task analysis fits in the overall UX engineering lifecycle as follows:

- The user profile task will feed directly into contextual task analysis by identifying categories of users (e.g., business to business purchasers, soccer moms, software developers) whose tasks must be studied.
- Contextual task analysis will feed directly into the UX goal setting task by helping to identify different primary goals for different task types (use cases) and by identifying conversion barriers and weaknesses in the current tools that can be reduced through good UX design.
- Contextual task analysis will feed directly into the information architecture task. Current user knowledge and experience are exploited as much as possible to facilitate ease of learning, reduce anxiety, and ensure that adequate product and vendor information is available to make a buy decision.
- Contextual task analysis will be documented in the product style guide.
- Ultimately, contextual task analysis will have a direct impact on all design tasks, and on the selection of UX testing and evaluation issues, as well as on the design of UX testing materials.

41.3 MOTIVATING AND JUSTIFYING UX REQUIREMENTS ANALYSIS

While Sections 41.1 and 41.2 set the stage for Requirements Analysis within the broader perspective of the whole UX engineering lifecycle, this section provides motivation and justification for investing in UX Requirements Analysis tasks and activities, in particular through the reporting of "war stories" from the experience of the authors and other practitioners. The war stories are divided into those relating to user, environment, and task requirements.

41.3.1 User Requirements

Following are three examples from our own experience of the importance of knowing your users.

Company sites that focus on a narrowly defined target audience may benefit greatly from in-depth persona research. We were approached by a client selling advanced in-house training for software programmers. We suspected that the target audience (software developers) fell into a narrow personality profile and a specific learning style. If this is true then we could identify optimal message styles and key motivators. Our research indicated that developers prefer a straightforward, factual, bulleted, "nonmarketese" message style. We also discovered that as intuitive learners, they prefer to be challenged to deduce conclusions rather than being lectured. For example, we can teach programmers far more by asking them to solve a puzzle or coding dilemma and leading them to the result than if we simply explain a process or technique. In addition, the software developers respect knowledge more than authority, money, or status. During the design of a website to market training to developers, we applied this understanding by establishing the expertise of our trainers clearly and immediately. Text content was delivered in a blunt-bulleted style.

User research also revealed that software developers as a group are not comfortable selling, especially to nontechnical people. Selling is a skill that they disdain. Our courses were expensive and time consuming and in the post dot com recession, we knew that training budgets were being scrutinized. The days of easy management approval for training were past. We felt we had to give programmers the tools to sell to their bosses and convince them that our training had value. We prepared easy-to-forward PowerPoint demos, e-mails they could copy, and cost-benefit reviews. Finally, we prepared a developer-focused guide on "how to convince management to pay for your training." It was a simple, humorous set of suggestions about how to get consensus without becoming a "sales weasel." We knew that the tone had to avoid sounding condescending and it had to be simple and direct. We had to empower them to do something out of their comfort zone and give them the confidence to succeed.

User requirements research also made it clear that we would lose great credibility if the website was developed in any technology other than the one on which training was being offered, which was .net. In fact, a great implementation of the .net technology in the training site was one of the most successful ways to demonstrate that not only did the company offer .net training but they were .net expert users as well.

The results of the website design driven by the user requirements research described above were impressive. When the new website was launched, sales increased immediately, and the word spread that our client was a company that "got it." After only two years in business, the company won a prestigious national Reader's Choice award for "Best Training Company." Their entire marketing campaign had been a nontraditional "word of mouth" campaign based on research done in the user profiling task. The profiling research on developer "learning styles" revealed the pitfalls to avoid and the approach to take. Had we skipped this research, it is unlikely that we would have achieved the viral success that our client company found.

For two other clients, we first interviewed project team members (developers) to get a general sense of the user population. Our purpose was to solicit input to the design of a user profile questionnaire that we would later employ to solicit profile information directly from the target users themselves.

In one case, the project team was convinced that their users would have a generally low level of familiarity with the Microsoft Windows platform they planned for their product. They were thus prepared to depart significantly from the Windows platform user interface standards in their application user interface. The user profile questionnaire, however, revealed a generally high level of Windows experience. This, and the fact that the Windows user interface standard was a good fit for the application functionality, led us to strongly advise the client to adopt the Windows standards as closely as possible. They were still interested in creating their own unique user interface, but early testing of several alternative designs that varied in how faithfully they followed Windows standards clearly showed that users learned much more quickly, the more consistent the design was with Windows standards.

On the other project, the development team felt quite confident that users would generally have high levels of computer literacy. However, an extensive user profile questionnaire of more than 800 users revealed that only a very small percentage of potential users had any experience with computer software at all, let alone the Windows user interface standards. In this case, based on this user profile data, we designed (and validated through testing) a highly simplified user interface that departed significantly from the Windows standards.

In all these cases, the following two things are clear:

1. Project team members often have serious misconceptions about the key characteristics of their target users.
2. These misconceptions could lead teams to design inappropriate UX for those users.

41.3.2 Work Environment Requirements

It is also important to understand the environment—both physical and social—in which users will be utilizing an application or website to carry out their tasks, because this environment will place constraints on how they work and how well they work.

By analogy, suppose a screwdriver is being designed and all that is known is the size of the screw head it must fit. So, something like a traditional screwdriver is designed, with the correctly sized blade. But, it then turns out that the user needs to apply the screw from the inside of a narrow pipe to assemble some piece of equipment. Clearly, a traditional screwdriver will be useless in this work context.

Similarly, suppose a software application is being designed for a set of users, but the designers have never gone to the users' actual work environment. They assume a traditional office-like environment and design software that will work on a traditional workstation. But, it then turns out that in the actual work environment, users are constantly in motion, moving all around the environment to get different parts of an overall job done. If software for a traditional workstation is designed, this will simply not work in this environment. Software that will run on a smaller and more portable device that can be carried around with the user, such as the units carried by UPS delivery staff, would be required instead.

In another example, suppose designers have never visited the user's workplace, and they assume users all work in closed offices. So, a system with voice input and output is designed. But, it then turns out that users work in one big open area with desks located right next to one another. The noise from all those talking people and workstations will create an impossible work environment, and most voice-recognition systems simply do not work with acceptable accuracy in a noisy environment. The point is, there are many aspects of the actual work environment that will determine how well a tool will work in that environment, and so the environment itself must be studied and the tool tailored to it.

A real example of the importance of understanding the users' work environment comes from a project we worked on with a large metropolitan police department. Requirements analysis activities revealed that in the typical police station, the appearance of the interior is dark, run-down, and cluttered; the lighting is harsh and artificial; and the air is close and sometimes very hot. The noise level can be high, the work areas are cramped and cluttered, and the overall atmosphere is tense and high pressured at best, chaotic, and sometimes riotous at worst. These conditions most likely have a general impact on morale, and certainly will have an impact on cognitive functioning that, in turn, will impact productivity and effectiveness. A software user interface must be carefully designed to support the natural and possibly extreme degradations of human performance under these conditions.

In addition, it was observed that in the noisy, stressful, and distracting work environment in a typical police station, users will frequently be interrupted while performing tasks, sometimes by other competing tasks, sometimes by unexpected events, unpredictable prisoners, and so forth. A user interface in such an environment must constantly maintain enough context information on the screen, so that when users' attention is temporarily but frequently drawn away from their tasks, they can quickly get reoriented and continue their tasks without errors, and do not have to backup or repeat any work.

In an example of the importance of the social environment, in redesigning a B-to-B site, our user research revealed that their product typically required consensus from a number of management roles. The initial persuasive focus on benefits and features had been targeted to the primary user and in the process our client company had neglected addressing the information needs and associated risks of the other stakeholders in the decision process. While the target user may desire a product because it will make their work lives much easier, failing to address the total cost of ownership, or the impact of the purchase/engagement on other team members could result in other stakeholders derailing the purchase. We recommended providing the user with information that might be nonessential to him but essential to the other key decision makers. By preparing primary users with the necessary information, we enabled them to answer product questions from all stakeholders.

41.3.3 Task Requirements

Besides the users themselves and the environments they work in, the tasks users do have their own inherent requirements.

On e-Commerce websites, users require complete sets of product and vendor information to be comfortable making a decision to buy. By carefully defining the typical user tasks or scenarios and conducting requirements analyses on those tasks, we are able to identify the range of information necessary to motivate buy decisions. The information requirements can vary greatly from one site to another and even though the tasks may be similar at a high level (e.g., purchase product X or search for product Y and add to wish list) unless a project-specific requirements analysis is conducted prior to design, an e-Commerce website may not be optimized to motivate buy decisions in its unique target audience.

Requirements for similar products can vary for many reasons. For example, for the website of a well-known company with a trusted brand, the need for vendor information may be minimal, and might be as simple as assuring the client that the online sale is secure and privacy will be respected. For companies without a known and trusted brand on the other hand, websites will need to establish vendor credibility through, for example, company history and details, testimonials from other customers, and so on.

When redesigning a website for a leading tour operator, we conducted careful research to identify and prioritize what the users felt the critical data was that they needed to know about the vendor. We began direct user testing on competitive sites and discovered that the first impressions on other sites led users to believe that they were targeting “white seniors.” Minorities felt the sites to be “unfriendly” and exclusive. It was easy to find what elements the vendor information set needed to include to ensure that website appealed to the wider target audience. To build the vendor information set of critical data, we first brainstormed a list of every possible question that might arise about the vendor. We checked that list against questions coming in to the call center sales staff and via e-mail to customer service. Next, we prioritized the information and then identified where on the site this information needed to be available. When the site was relaunched, the customer base increased and both custom and group sales improved. An additional benefit was that questions to the call center reduced dramatically and the percentage of online orders increased. Savings to the call center alone were several hundred thousand dollars in the first year. By detailing the task scenarios and carefully building the persuasive requirements based on direct user research, significant revenue increases were realized. Without this research, opportunities would have either been missed or identified later in the process requiring costly changes.

Clearly, it is possible, even likely, to design a UX that does not support users, their tasks, or their work environments, if an adequate requirements analysis is not conducted prior to design and incorporated into design. The chapters that follow describe and discuss a variety of techniques for gathering these all-important requirements.

42 Task Analysis

Catherine Courage, Jhilmil Jain, Janice (Ginny) Redish, and Dennis Wixon

CONTENTS

Successful design comes from a marriage of users' goals and (usually) new technologies. Successful design does not necessarily perpetuate users' current ways of working, but it is built on a deep understanding of those ways and of how a new design will change them.

In this chapter, we explore modern interpretations and uses of task analysis.

Section 42.1 defines the meaning of task analysis in this chapter.

Section 42.3 discusses the following practical issues to consider for task analysis:

- Planning for a task analysis
- Collecting task analysis data
- Analyzing and presenting the data

Lastly, Section 42.4 presents real-world case studies of new methodologies and of task analysis applied to a variety of domains.

42.1 DEFINING TASK ANALYSIS

"Task analysis" has different meanings to different authors. Rather than delve into all of the different interpretations, we give a single definition here. For a thorough comparison of task analysis definitions, see Redish and Wixon (2003).

42.1.1 Task Analysis in This Chapter

Task analysis means understanding users' work. Thus, task analysis encompasses all sorts of techniques, including naturalistic observations and interviews, shadowing users or doing "day in the life of" studies, conducting ethnographic interviews, and observing and listening to users who are performing specific tasks. It includes gathering information that leads to insights about users' lives at work or at home, to scenarios and use cases, and sometimes to detailed flowcharts of work processes or specific procedures.

In our view, a major emphasis of task analysis is predesign, and three types of analysis—user, task, environmental—are necessary input to designing any product. Task analysis is, therefore, an integral part of a triangle that covers users, tasks, and environments. As described in more detail in Section 42.2, task analysis goes hand in hand with understanding users (user analysis) and understanding the users' physical, technological, cultural, social, and political environments (environmental analysis).

Users are absolutely critical to all three types of analysis. In our view, *task analysis requires watching, listening to, and talking with users*. Other people, such as managers and supervisors, and other information sources, such as print or online documentation, are useful only secondarily for a task analysis. Relying on them may lead to a false understanding.

Like Kirwan and Ainsworth (1992), we also believe that task analysis does not stop with design. Task analysis continues to be critical at every stage of the design and development process. Task analysis is the major input to use cases and design specifications. Task analysis helps us understand how the emerging product affects users. It is the key to evaluating designs as scenarios for heuristic evaluations and for usability testing. Task analysis must be the organizing principle for documentation and training.

We recognize that efficiency-oriented, detailed task analyses, such as TAG (Task Analysis Grammar) and GOMS (goals, operators, methods, and selection), have a place in evaluating some products, especially those for which efficiency on the order of seconds saved is important (see Gray, John, and Atwood [1993] for example). However, that type of task analysis is not the focus of this chapter. The focus here is a broad understanding of the world in which the new product will be used.

42.2 CONSIDERING FOUR PRINCIPLES THAT UNDERLIE OUR VIEW OF TASK ANALYSIS

The practical advice for doing task analysis later in this chapter is based on the four principles described in this section.

42.2.1 Task Analysis Is an Integral Part of a Broader Analysis

The first principle is that task analysis by itself is not enough to give you the understanding that you need to design or evaluate a product. The methodology you need brings together information about three interwoven elements:

1. Users: Who are they? What characteristics are relevant to what you are designing? What do they know about the technology? What do they know about the domain? How motivated are they? What mental models do they have of the activities your product covers?
2. Tasks.

3. Users' environments: Physical situation in which the tasks occur; technology available to the users; social, cultural, language considerations.

42.2.2 Task Analysis Includes Understanding Users' Goals

The second principle is that a task is what someone does to achieve a goal. Task analysis is concerned with all the stages of the action cycle, as described by Donald Norman (1988):

1. Forming the goal
2. Forming the intention
3. Specifying an action
4. Executing the action
5. Perceiving the state of the world
6. Interpreting the state of the world
7. Evaluating the outcome

42.2.3 Task Analysis Is Relevant at All Stages of the Process

Our third principle is that task analysis belongs everywhere in the process of planning, designing, developing, and evaluating a product. Task analysis, like so much else in the user-centered design process, should be done iteratively. The focus, methods, granularity, and presentation may change over time as different questions and different types and levels of information become more or less relevant. (See Redish and Wixon [2003] for a detailed discussion of task analysis at different stages.)

42.2.4 Practical Reality Impinges on What We Actually Do

Our fourth principle is that in the fast-paced world of software and web design, in reality, what we can do for a task analysis (or any other aspect of user-centered design) depends on many factors. These factors include time, resources, people, availability of users to observe and talk to, and travel restrictions.

This chapter is meant to help you decide the best approaches to consider for whatever situation you are in. We discuss logistics and provide a practical guide on topics such as planning, conducting, analyzing, and presenting data. For a deeper discussion of how to convince clients or others in your company of the importance of usability techniques like task analysis (i.e., selling task analysis), refer to Chapter 59 in this handbook.

42.3 DOING TASK ANALYSIS

42.3.1 Planning for a Task Analysis

42.3.1.1 Background Research

If there is an existing product, learn as much as you can about that product before you begin your task analysis. Having a level of familiarity with the product provides the advantage of running user observation sessions with fewer interruptions.

Information from server logs can help determine what you want to observe in your task analysis. From these records you can learn about visitors, click paths, time per page, exit point, actions completed.

Other sources for information include the product team, marketing, customer support, early adopter feedback, and competitor product. (See Courage and Baxter [2004], Chapter 2, for a detailed discussion.)

42.3.1.2 Getting into the Project Plan and Sign-Offs

A critical aspect of being able to do task analysis throughout a project is getting this and all other usability activities into the project plan. The extent to which this can happen depends, of course, on buy-in from the project team, but also on other factors, such as whether project plans exist and how much detail is specified. The more strongly a project team uses a formal project plan, the more critical it is to get usability activities, such as task analysis, into the plan. Time, resources, and respect from managers and developers for the information may be dependent on being part of the formal plan.

Another approach that many usability specialists follow is to create a usability project plan, which parallels the system design and development project plan. That is fine if the system people understand and respect the parallelism of the plans.

Whether the usability plan is part of the overall project plan or a parallel track, it is important to get sign-off from the rest of the design and development team with respect to activities that the usability team will do, resources needed for those activities, information that will be brought back from those activities, deliverables (formal or informal) that will come from that information, and dates for those deliverables.

42.3.1.3 Providing Useful and Usable Data

As usability specialists, we help project teams only if we provide useful and usable data when they need it. Therefore, as noted, staying closely aligned with a project plan and schedule is critical.

What else, besides timeliness, makes data useful and usable?

- *Data the project team needs.* As usability specialists, we should approach any project looking for where the team needs data about users (whether they know it or not) and plan to collect, interpret, and present that data in a way that the team can understand and directly use. If there is no rationale for how the data will impact the product (now or later), it is best to invest your time elsewhere.
- *Data that is credible.* Time pressures and limited resources often curtail the extent of any usability activity, including task analysis. In general, we follow the maxim that some data about users and their

work is better than no data. And practical experience tells us that is true, as long as the data is accurate and representative. Good data is collected in a systematic, careful, rigorous way from appropriate users. To do this successfully, you must become familiar with the product and domain. Domain familiarity will not only allow you to identify the appropriate type of task analysis and to formulate the most appropriate questions and observations, but the team will also take you more seriously.

42.3.1.4 Deciding What the Project Team Needs

The task analysis that you want to do will depend in part on the type of product or website that you are working on. Consider at least the following six factors as you think about the project for which you are planning task analyses and other usability activities.

42.3.1.4.1 Where Is the Product in Its Overall Lifecycle?

Upgrading an existing product without changing the medium (a new software release; a revision of a website)? Changing business processes or medium (going from a stand-alone application to a web-based or cloud-based one)? Developing something totally new?

42.3.1.4.2 How Much Time Do You Have to Conduct Your Task Analysis?

Has the team always been onboard with task analysis and they defer to you to determine the appropriate activity and time line? Has the team suddenly discovered that they need some data quickly and they have not allotted for it in their schedule? Does the team believe that there is no time in the schedule for task analysis?

42.3.1.4.3 How Broad or Specialized Is the User Population for the Product?

Is the product for a very broad public market, niche business market where you can easily define the user population and access to them is through account executives (or similar), or special audience (children/the elderly/persons with disabilities, etc.)?

42.3.1.4.4 How Widespread Geographically, Culturally, and Linguistically Is the User Population for the Product?

Is the product global (how far/how many countries/cultures/languages)? Or is it local?

42.3.1.4.5 How Detailed Must We Specify the Tasks?

Is the product safety-critical where tasks are very specific and must be done in specified ways? Do users receive training until they prove their competence in completing the tasks accurately and efficiently? Will it be used by many different types of people for different tasks, which they may do in different ways?

42.3.1.4.6 Is This a Special Type of Product for Which Traditional Task Analysis May Not Be Useful?

Some applications do not fit the traditional approach for task analysis. These are primarily applications that the user does for fun, for example, games. Traditional task analysis would not aid much in the design and development of these applications. As a result, game designers do not typically do task analysis. They are more interested in mood, theme, story, drama, progression, surprise, pacing, and the physical correlates of these experiences. (Also see Chapters 31 and 34 in this handbook.)

42.3.1.5 Deciding on an Appropriate Level of Granularity

Another aspect to consider as you plan a task analysis is the types of analysis to do. Understanding users' goals and their work can be done at several different levels. You might be interested in one or more of the following types of analysis:

- *Analysis of a person's typical day or week*: "A day in the life of" or "an evening at home with"
- *Job analysis*: All the goals and tasks that someone does in a specific role—daily, monthly, or over longer periods
- *Workflow analysis*: Process analysis, cross-user analysis, how work moves from person to person
- *High-level task analysis*: The work needed to accomplish a large goal broken down into subgoals and major tasks
- *Procedural analysis*: The specific steps and decisions the user takes to accomplish a task.

42.3.1.6 Deciding Where to Start

You must first understand how far along in the process the project is. Unfortunately, by the time usability specialists know about the project, the strategic planning and predesign stages may already be considered closed. The project may be at considerable risk if the strategic planning and predesign questions were never answered or were answered based on speculation or internal discussions without users. However, it may be unproductive to spend time and effort collecting data that speaks to those questions if no one is willing to listen to the answers you bring back. If that is the case, a more productive use of the limited time and resources for task analysis and other usability activities would be to understand where the project is and how to influence it from that point forward. In some cases the team realizes (often with your help) that they do need to take a step back to the earlier stages and collect user data in order to prevent the product from going down the wrong path.

42.3.1.7 Gathering Reusable Data

Time, resources, and costs are likely to limit the number of times you can return to users for task analysis. One good approach is to collect extensive data about users' work in a relatively holistic way, capturing that data on video, audio, or in extensive notes so that you can return to the data—rather than to the users—with different questions in mind at different times.

To do this, an open-ended field study method combined with detailed information gathering is best (Wixon 1995). Also, having a relatively detailed log of the raw data is necessary (videotape, audio tape, or verbatim transcripts).

42.3.1.8 Going to Different Users at Different Times

Even if you gather extensive data holistically on early site visits and return to the data, you may not have the information that you need. In that case, go out again—and go to different users.

You can use each set of site visits not only to answer the specific immediate issues and questions but also to enrich the team's general understanding of users, their work, and their environments. Although your immediate focus may be a specific why or what or how question, always drill down so that you are, in fact, seeing the why behind the what or the what and how behind the why.

42.3.1.9 Preparing for International Task Analysis

Selling an international study to management can be hard. Refer to Courage, Redish, and Wixon 2007 for practical issues to consider. International studies add several significant considerations including translators, recruiting, logistics, and background research.

42.3.1.9.1 Translators

If the language of your study participants is not your native language, you will want to employ a translator. This person will need to translate all of your tasks analysis materials beforehand and then translate in real time during the session (simultaneous translation). Simultaneous translators are often known as interpreters, and interpreting is a specialized and expensive skill, as it requires a great deal of concentration and focus over extended periods of time. You will also need to allow time to train the translator in the goals, objectives, and procedures of your study to ensure that as little as possible gets lost in translation.

42.3.1.9.2 Recruiting

Recruiting for an international study is not the same as recruiting for a local study. Factors that often differ include appropriate ways to contact users, recruitment and incentive costs, no-show rates, the times that people are willing to participate, and holidays. Be sure to account for these differences in your plan. If possible, it is wise to engage a local recruiting company. If your company is international, engage the people in the office of the country you will be visiting to help you find users and to learn about the culture in advance (Siegel and Dray 2005; Dray and Siegel 2005).

42.3.1.9.3 Logistics

If you are visiting multiple locations, time your visits so that you can minimize your travel time and costs. You do not want to fly roundtrip to Hong Kong from New York and then 2 weeks later fly to Shanghai from New York. Also, be sure to give yourself some time to adjust to new time zones. Task analysis activities require you to be very alert and attentive. You will not be of much value if you are completely exhausted.

Also consider your equipment. Will it work in the country you are traveling to? Will it be too much to travel with? If you need to scale back, consider this early on. Should you rent the necessary equipment? If yes, where? Thinking through all of the details ahead of time will save headaches as your site visit approaches and while you are on site.

42.3.1.9.4 Background Research

Do as much background research as you can before you go. This will help prepare you for some of the things you may encounter. For example, read travel guides and books on cultural etiquette. Read articles in research papers, professional magazines, and on the web. Examine competitor products that may be thriving in the culture you are going to visit. Use this information to guide you as you create your task analysis plan.

If this sounds like there is a lot of preparation to conduct international task analysis, that is because there is. The good news is that the preparation is worthwhile. As you come to understand a culture and make connections with people from that location, future studies will be easier and less costly. And the understanding that you get from an international task analysis will pay off richly in the product's success in that culture.

42.3.2 Collecting Task Analysis Data

While traditional task analysis focused on time and motion studies, modern task analysis relies more on ethnography and cognitive psychology; and that is the focus we take in this chapter. (For a more detailed discussion of task analysis roots in ethnography and cognitive psychology, see Redish and Wixon [2003].)

For the basics on how to select users and environments, making a convenience sample as representative as possible, conducting site visits, and observing and interviewing users, refer to Courage, Redish, and Wixon (2007).

42.3.2.1 Rapid Task Analysis

As we have said, sometimes, the team needed the data 2 weeks ago; and sometimes, they just do not have the time or resources for a multi-week task analysis. Several rapid data collection methods have emerged for these situations. We discuss three here: narrowing the scope, using multiple teams, and scheduling your sessions around activity peaks.

Note that rapid task analysis is not right for all situations. If your team is designing or redesigning a very complex system, there may be so much to understand that even a condensed method will be time consuming. (See the Section 42.3.3 for a discussion of rapid data-presentation methods.)

42.3.2.1.1 Narrow the Scope

One way to do rapid task analysis is to reduce the scope of your study. Instead of trying to understand everything about the users and all of their tasks, focus on collecting data that you will be able to use immediately to make decisions, especially when you have specific issues or questions that need to be resolved.

42.3.2.1.2 Using Multiple Teams

Another way to do rapid task analysis is to have multiple teams collect the data to shorten the time required. This is a great way to engage the entire project team. It also may be necessary in situations where your study is international and involves different languages and cultures. Involving multiple data collectors is ideal if you are working with a team that understands task analysis.

If you take the team data collection approach, you need to make sure that everyone is on the same page about what will be observed and the types of data that will be collected. Templates are ideal in this situation. We recommend the following templates:

- A protocol that gives the procedures and steps that everyone is to follow when with the users. A useful protocol includes information on how to introduce the session to the participant, how long each part of the session should last, how to end the session, and so on.
- A list of questions to ask either during or after the session.
- An observation guide that includes the issues observers should focus on. This helps guide the observations to ensure that everyone is observing the same types of activities. It is different from the list of questions to ask the user.
- A template for recording data. This helps cue observers as to what behaviors they should be observing and also provides a consistent data collection method. It makes analyzing data much easier.
- A template for reporting on the session. This is a standard worksheet that each observer completes at the end of each session to highlight some of the key observations or discoveries made. It can be very useful when the team first regroups to discuss the data. In some cases, teams create templates based on the form of analysis required by the development process.

If the data is being collected over a number of days, check in with your team at the end of each day to talk about key observations. This can be in-person, by phone, or through web-based voice-over-Internet programs. It is great to discuss when the data is fresh. A daily check-in also gives you an opportunity to resolve any procedural issues that observers may be having.

42.3.2.1.3 Schedule Your Sessions around Activity Peaks

If you schedule your visits during times of peak activity, you may observe more activity during a shorter window of time. While this technique is useful in any task analysis, it may be particularly helpful if you are doing rapid task analysis.

If you plan to go during a time of peak activity, you may want to pay particular attention to our general recommendation that an observation team include two people. In a time of peak activity, one person may not be able to keep up with the potentially rapid pace. In our two-person teams, one observer focuses on asking questions, while the other takes notes.

Be aware, however, that many users may not want you to come at times of peak activity precisely because they are so busy and stressed. They may feel that they cannot cope with any distractions or additions to the environment. If seeing times of peak activity is crucial to your issues, you may need to convince users that you will observe unobtrusively and not get in the way. You may need to forego some of the questions and interview time that you would like to have.

42.3.2.2 Bringing Users to You (Field Studies in the Lab)

The best task analysis, of course, is done in the users' context. However, time constraints, travel restrictions, or security restrictions may make it impossible for you to go to the users. You can still do task analysis. Have the users bring their tasks to you.

Although you will not get a true environmental analysis (seeing the users work in their own settings), you can still get a lot of data about users and tasks. When you do task analysis in the lab, make sure you ask the users to bring artifacts relevant to the task being discussed (Butler 1996). These are any objects that participants use to complete their tasks or that result from the task. Artifacts could be a calendar, a procedure manual, a physical form, a computer-generated report, and so on.

42.3.2.2.1 Using the Lab for Procedural Task Analysis

For detailed procedural task analysis (getting down the steps and decisions in completing a specific task), the lab may be the right environment. If you want to capture details, you probably want a videotape record. It is easier to videotape in the lab than to cart equipment to users' sites, set it up, and take it down—although we do recommend videotaping for most task analysis site visits.

Procedural task analysis can be done either individually or with a group of users. In an individual task analysis, you work with one user at a time and delve into exactly how that user completes the process. In a group task analysis (GTA), you focus on four to six users together and gather the task flow from the group.

Group task analysis has several advantages, including the following three. (Also see Courage and Baxter [2004], for more on group task analysis.)

1. *Seeing the details.* Describing a task flow can be difficult. It is easy to overlook routine steps or to forget about some of the details. Like focus groups, a GTA generates group discussion and a synergy among the participants. Because the users are comparing how

they each complete the task, details tend to emerge in the discussion.

2. *Coming to agreement*. One of the goals of a group task analysis is for the participants to come to agreement on a single task flow that represents a common way that they can work to complete the task. When conducting individual task analysis sessions, the researcher must combine the data and make compromises, rather than having the users make these decisions.
3. *Saving time*. You can often develop a rich task flow with a group of users in 2 hours where you would spend 8–10 hours with individual users. This makes group task analysis another good technique for rapid task analysis.

42.3.2.2.2 Using the Lab for Quantitative Task Analysis

If you want quantitative measures, such as time to complete a task under ideal conditions, the lab may again be the best place to do the study. Someone might ask, in that case, whether you are doing a field study or a usability test, but in fact the line between the two techniques is quite blurry. Both can be done in the field or in the lab. Both can be done on old products or new prototypes. Both can be done qualitatively or quantitatively. Both can be done on the user's own work or on scenarios given to the user. Task analysis is a major part of both field studies and usability testing.

42.3.2.3 Remote Task Analysis

If your focus is software or the web, you can do remote task analysis to collect useful data. You can use a screen-sharing application to see the user's screen as the user works. As with lab studies, you cannot observe the user's physical environment. However, one advantage you have over a lab study is that the users are still in their own environments, you can ask users to describe their environments; and some may even be willing to send photos, which can give you useful insights.

Remote task analysis is sometimes your only option, especially in international studies. You may not have the resources for global travel. Doing remote task analysis is most successful when you already have some experience or familiarity with the users' culture.

A remote task analysis can also be very useful to supplement on-site sessions. If you only have the resources to visit one or two users, do so; and then supplement your data through remote sessions with other users.

42.3.2.4 International Task Analysis

As you collect data internationally, you should add two critical considerations to your repertoire: being culturally sensitive and being aware of elements that differ in different countries and cultures.

42.3.2.4.1 Being Culturally Sensitive

Research shows that methods based on the Western thought can lead to cultural conflict and misinterpretation of data, particularly in Asian cultures (Chavan 2005; Ann 2004).

For example, Chavan (2005) explains that, in India, users often hesitate to say that something is bad or to identify issues with a product. Even if an Indian user does not highlight any problems, you cannot assume that no problems exist for that user. Also, users in India may be more likely than users elsewhere to feel that they are being evaluated just because someone is observing them.

For another example, Ann (2004) says that, in China, relationships are very important. Friendship is a prerequisite to dealing in business or finance. This may make it difficult to recruit participants unless they come from friends' referrals. If you are not connected via a friend, users may not want you in their homes. Even if you are able to enter a home without such a connection, you may not hear the users' true feelings, as they may take great care not to offend you. If you do not continue the friendship after the study, Chinese participants may feel used and decline to participate in future studies. Furthermore, a Western researcher and participant relationship would not be well received in China. The Western approach in which you ask questions in a very scientific manner and re-ask them in different ways to probe deeper may lead to distrust rather than to useful information. Less intrusive styles may be more appropriate.

Therefore, choosing a culturally sensitive approach to task analysis for the location you will be visiting is critical. This is where local consultants or people in your company at that location can be invaluable. Whether you actually conduct the study or have them do it, they can be extremely valuable in helping you refine your approach so that the experience is pleasant and comfortable for the users and so that you collect valuable and accurate data.

42.3.2.4.2 Being Aware of Elements That Differ in Different Countries and Cultures

As Siegel and Dray (2005) recommend, you should be aware of the many elements that change from country to country and culture to culture so that you can collect data on whichever of these are relevant to your product. The following are just a few of the elements to consider:

- Purchasing dynamics and financial transactions—for example, forms of payment, willingness to disclose financial information to others or online
- Social structure and service expectations—for example, society classes, willingness to "do it yourself"
- Mental models of geography—for example, address formats, maps
- Use of physical space—for example, size of workspaces
- Climate and environmental conditions—for example, how environmental conditions impact the user of the product

42.3.3 Analyzing and Presenting the Data

Once you have collected the data, of course, you must analyze it and present it. Data is of no value if you do not communicate what you have learned to the people who need the information. To make the data useful, you must bring the data together, think about what you have learned, and draw out implications.

42.3.3.1 Analyzing the Data

Consider the following four principles as you plan to analyze the data.

42.3.3.1.1 Involve the Design Team

Making the effort to involve the rest of team pays off handsomely. Involving other team members ensures that they have a stake in the results. It also allows them to work with the raw data, which helps them internalize the "work of the user" more completely, even if they did not get to participate in the site visits. When you involve the team in the analysis, you build a shared understanding of what was seen and heard at the customer or user sites.

It also ensures that the questions the team has get answered. Often teams refine and redirect their thinking as they go through an analysis. They may drill down more deeply into the data. They may completely change the questions they have of the data. They may change their thinking about the direction they had planned for the product.

Working as a team can also help you generate actionable items that result from the study. You can work together to prioritize the findings. This is ideal to do as a team because you can discuss limitations, such as time, and determine what is truly feasible.

42.3.3.1.2 Make It Traceable

Any analysis should include references back to the raw data. There are many advantages. First and foremost, keeping the link ensures the integrity of the analysis. It is important to be able to say to those who were not involved in collecting and analyzing the data that all conclusions are traceable back to statements by users or direct observation of their behavior. Second, as we noted in discussing the first principle, interpretations may change as analysis progresses. During that process, it is important to be able to revisit the data and recall the context of the behavior or the comments. If you set up ways of tracking the data through analysis, the extra time and effort need not be substantial.

42.3.3.1.3 Make It Visible and Accessible

The analysis may be complex and detailed, but a report laden with text will almost certainly go unread. There is not time in the rush of a project for people to read. Therefore, many teams choose to display their analysis on a wall or in a "war room"; where team members can review and add comments to the display. (See, e.g., Simpson [1998].)

An alternative is a hyperlinked document in which higher level conclusions are linked to more specific analyses. Often the analysis is graphical so that designers can stand back and "see" patterns in the data. Some people create multilevel documents with a one-page summary, supported by a three-page overview, which in turn is supported by a 50-page report.

42.3.3.1.4 Match the Form to the Questions, the Stage, and the Team's Needs

The cardinal rule of all documentation is to give users what they need in the form they need it when they need it. That is why most technical communicators have moved from writing extensive tomes that people do not open to helping teams bring communication into the interface.

The same principle applies to the internal working of any project team. The best form in which to represent the data depends on many factors, including the questions that were asked, the stage in the project's lifecycle (that is, how the information will be used), the time in which the information is needed, and the team and company culture.

Keep in mind the essential purpose of any analysis. Analysis provides an anchor from which designs can be generated and against which they can be evaluated. The analysis is not an end in itself. You must keep the design team engaged with the analysis and with the representations of the analysis. In the Section 42.3.3.2, we describe a few of the possible representations.

42.3.3.2 Presenting the Data

The following are 13 ways to present task analysis data. (Also see Hackos and Redish [1998], especially Chapter 11. Courage and Baxter [2004] describe data analysis for a variety of task analysis techniques. Miles and Huberman [1994] also describe the rich variety of ways to organize qualitative data for interpretation.)

42.3.3.2.1 Affinity Diagrams

Affinity diagrams are hierarchical pictures of user data. They are produced inductively by grouping similar data elements together into categories and then grouping the categories together.

Affinity diagrams derive much of their value from the process that produces them, that is, a deep engagement with the data combined with recurring reflections on the generalization that best captures a number of data elements. Also, teams often produce "collateral" elements while creating an affinity, such as design ideas and additional questions that are captured and then used in design or further data gathering.

42.3.3.2.2 Artifacts

Some types of tasks are deeply intertwined with their artifacts. For example, the task of making appointments is necessarily interwoven with calendars that show dates and times. As a result, it is often best to begin with existing artifacts (e.g., Ellen's appointment book) and to organize data around that representation.

42.3.3.2.3 Flow Diagrams

Flow diagrams answer questions about how information or artifacts flow through a system (process analysis). They illustrate the dependency between system elements or states of the system and what needs to be transferred or moved from one part to another. They also show how roles are divided within an organization as data moves from one person or department to another or between the organization and outsiders.

42.3.3.2.4 Personas

Personas are composite archetypes who represent the primary and secondary users of the product. (Pruitt and Adlin 2005; Mulder and Yaar 2007; Courage, Redish, and Wixon 2007; Pruitt and Adlin 2010). A persona description often includes the user's activities, knowledge, and tasks in some depth. Some people, in fact, also include information about the persona's environments (physical, social, cultural, technological), thus capturing all the triangulated data that we discussed at the beginning of the chapter.

Rich persona descriptions that encompass user, task, and environment information are particularly useful for commercial products, which often begin with market segmentation that classifies and describes potential customers. The task analysis builds on this data by characterizing these users more precisely (Lee and Mikkelson 2000).

Because personas instantiate users as actual people, they tend to be memorable. You can ask "How would Julie do her work if we design the product this way?" (See Cooper [1999].) Personas can come to team meetings as life-sized cardboard figures (Butler and Tahir 1996), on posters or on placemats. They can become part of the product team's e-mail group with someone in charge of representing them (see Chapter 46 in this handbook).

42.3.3.2.5 Scenarios

A scenario is a short story of a specific situation that is real and relevant to a user. A scenario gives the team the user's goal and specific needs. It often also gives the team the user's names for objects and attributes of those objects. It may give the team information on what the user values. (e.g., Is price more important than choice in renting a car.)

Each situation that you observe on a site visit is a scenario. You can also collect scenarios by interviewing users through the critical incident technique (Flanagan 1954) in which you ask users to recall a specific incident and then to tell you about it.

You can elaborate a scenario with the sequence diagram (flowchart) of the procedure the user went through to accomplish the scenario. If accomplishing the scenario is difficult, and the scenario is important, creating a more efficient procedure could become a requirement for the new product. (See also using stories from task analysis and, indeed, throughout design and evaluation, Quesenbery and Brooks [2010].)

42.3.3.2.6 Sequence Diagrams

Flow diagrams track work through a system or across people. Sequence diagrams use time to track the actions and decisions that a user takes. Sequence diagrams (procedural analysis) show what users do and when and how they do it. This type and level of information is critical for interface architecture and design because it gives us the functions, objects, and attributes of a system (e.g., menu items and dialog box design) and the navigation for a website.

By laying out the sequence diagram that represents what users do today, you can often see ways to make the product help users be more efficient and effective. Thus, the sequence diagram of the reality of what you find in predesign observations is often elaborate and messy. It may be important for the team to see that reality as they work toward a more useful product.

42.3.3.2.7 Tables

Tables are an excellent way to show comparisons and so are useful for presenting many types of analysis. Technical communicators, for example, have traditionally used a user/task matrix to understand which tasks are done by which types of users. The user/task matrix becomes a major input to a communication plan—to answer the question of what tasks to include in documentation for people in different roles (e.g., system administrators, end users). Tables can be used to show the relationships between any two (or more) classes of data. See Table 42.1 for an example of a table with three classes of data.

42.3.3.2.8 User Needs Tables

Kujala, Kauppinen, and Rekola (2001) developed what they call a "user needs table" as a way to present a current task sequence along with the problems and possibilities that the designers should think about for each step in the sequence. They hypothesized that it would be easier to use findings about users' needs in design if the findings were connected to the task sequence that forms the basis of use cases. In their studies, designers found this type of presentation very useful in moving from data to requirements. They also found that writing use cases from this type of presentation keeps the use case in the user's language and keeps the use case focused on the user's point of view. Figure 42.1 shows an example of a user needs table.

42.3.3.2.9 Mood Boards for Quick Data Dissemination

Mood boards (Foucault 2005) are an ideal way to present preliminary research results when your team is under a tight timeline and you want to get them some data quickly or when you want to keep the momentum from the study going.

Mood boards are a collection of raw data and artifacts presented with the goal of inspiring the product team early in the development cycle. They often take the form of a large poster showing photographs, sketches, screenshots, participant quotes, and artifacts from the field, such as forms, printouts, and post-it notes. You can use mood boards to highlight some of the interesting or unexpected findings from the study.

You can put together a mood board quickly because the date is not yet refined or synthesized. Mood boards can also be ideal for international studies because they can convey differences between cultures and can give designers a feeling for the aesthetics of the other culture. Figure 42.2 is an example of a mood board from a study that was part of a project to develop technology for older adults in the United States. Mood boards were created for areas where there were product possibilities. These included older adults in the city, fitness for older adults, and fraud against older adults.

TABLE 42.1
Matrix for Weighing Market Size, Users' Tasks, and Potential Product Functions

Users	Relative Market Size High—3 Medium—2 Low—1	High-Level Task	Task Relative Importance High—3 Medium—2 Low—1	Tool Bar Customization	Better Drag and Drop	Progress Meters	Interruption Protection Recovery	Total (Sum of Products, How Well Market Is Served by These Features)
Techno Bob	1	Customize my screen	3	2	1	0	0	9
		Download information	3	0	0	1	2	9
Newbie Ed	1	Customize my screen	1	–1	2	0	0	1
		Download information	3	0	2	3	0	12
Practical Sue	3	Customize my screen	2	2	2	1	0	36
		Download information	2	0	2	1	2	30
Sum				17	35	27	18	

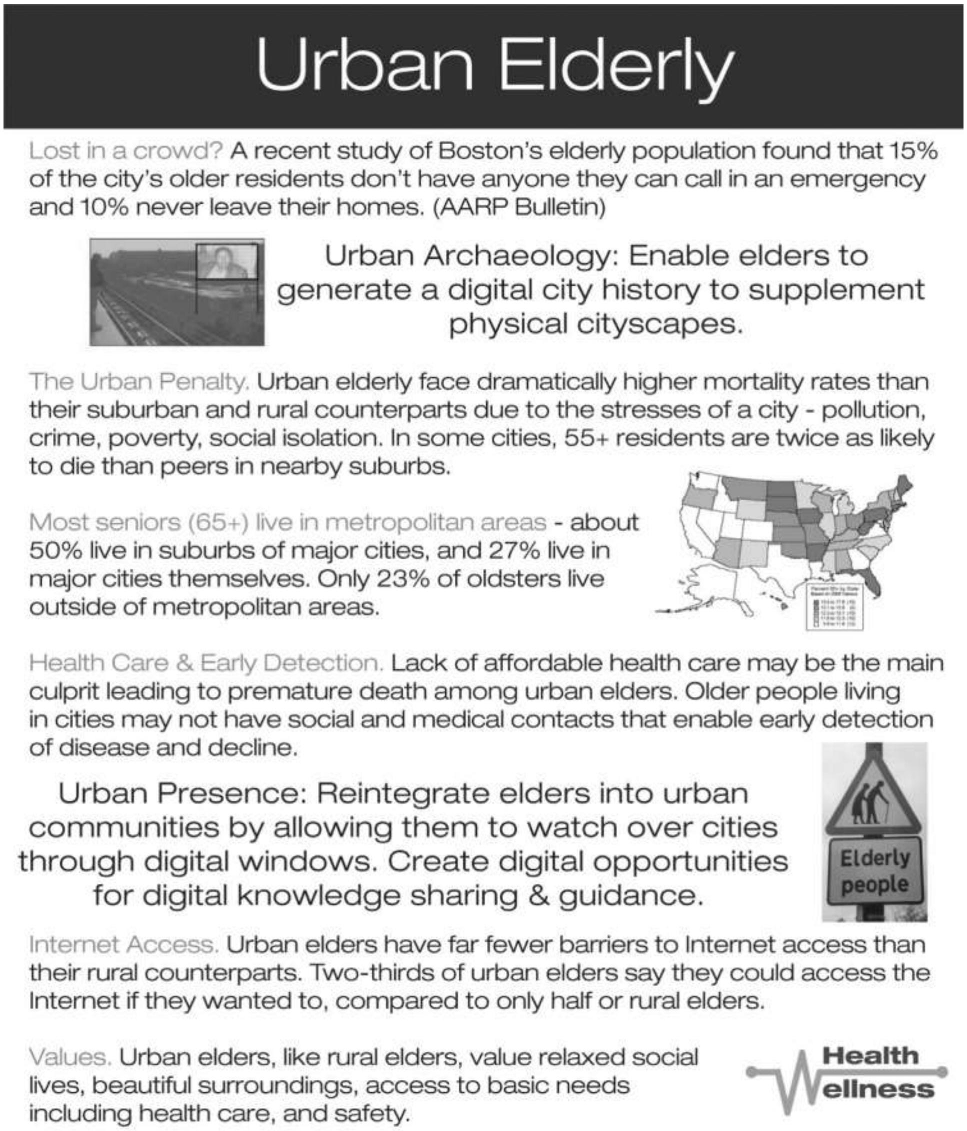
–1—will confuse users
0—users will not use it
1—users mildly positive
2—users strongly positive

Task Sequence	Problems and Possibilities
Step 1: When trapped in an elevator, passenger makes an emergency alarm.	• Passengers want to get out of the elevator as soon as possible. • All kinds of passengers must be able to make an alarm call (blind, foreigners, etc.). • Sometimes passengers may make false alarms unintentionally. • Passengers may be in panic. • Passengers need instant confirmation that they have created a connection to the service center operator and that they are going to get help.
Step 2: Unoccupied service center operator receives the emergency alarm call and asks for information (description of the failure).	• Different versions and types of remote monitoring systems. • Passenger is the only information source. • Service center operator does not notice the emergency alarm call.
Step 3: Service center operator completes transmission of information to the system and sends it to the area serviceman.	• Laborious phase for the service center operator. • Simultaneous calls must be differentiated. • Serviceman cannot see all information. • Inadequate information from a site system. • Possibility: Instructions as to how to operate the system. • Possibility: Possibility to open phone line from call center to the elevator.
Step 4: Service center operator calls the serviceman and reads the description of the failure.	• Extra work for the service center operator.

FIGURE 42.1 An example of a user needs table. (From Kujala, S., M. Kauppinen, and S. Rekola. 2001. Bridging the gap between user needs and user requirements. In *Proceedings of PC-HCI 2001 Conference*, Patras, Greece. With permission.)

42.3.3.2.10 Live from the Field: Another Technique for Quick Data Dissemination

Another very effective rapid communication method is to send information back to the team from the field in real time (Lovejoy and Steele 2005). This method is particularly useful for international studies where the product team is often quite curious and excited about the study. Also, if you are going to be traveling for an extended period, you can get some data to the team so they do not have to wait for weeks to hear what you are learning. Photos, stories, snippets of data, and insights can help the team to feel a part of the study.



Urban Elderly

Lost in a crowd? A recent study of Boston's elderly population found that 15% of the city's older residents don't have anyone they can call in an emergency and 10% never leave their homes. (AARP Bulletin)

Urban Archaeology: Enable elders to generate a digital city history to supplement physical cityscapes.

The Urban Penalty. Urban elderly face dramatically higher mortality rates than their suburban and rural counterparts due to the stresses of a city - pollution, crime, poverty, social isolation. In some cities, 55+ residents are twice as likely to die than peers in nearby suburbs.

Most seniors (65+) live in metropolitan areas - about 50% live in suburbs of major cities, and 27% live in major cities themselves. Only 23% of oldsters live outside of metropolitan areas.

Health Care & Early Detection. Lack of affordable health care may be the main culprit leading to premature death among urban elders. Older people living in cities may not have social and medical contacts that enable early detection of disease and decline.

Urban Presence: Reintegrate elders into urban communities by allowing them to watch over cities through digital windows. Create digital opportunities for digital knowledge sharing & guidance.

Internet Access. Urban elders have far fewer barriers to Internet access than their rural counterparts. Two-thirds of urban elders say they could access the Internet if they wanted to, compared to only half or rural elders.

Values. Urban elders, like rural elders, value relaxed social lives, beautiful surroundings, access to basic needs including health care, and safety.

FIGURE 42.2 An example of a mood board representing urban elderly. (Courtesy of Intel.)

Lovejoy and Steele (2005), for example, collected photos and narrated the photos with data to create what they call photo stories. Other useful ways to communicate findings quickly include blogs, e-mails, and websites.

42.3.3.2.11 Culture Cards

The last three data presentation methods focus on conveying the culture of your study participants. These techniques were developed by Intuit (Foucault 2005) to convey observations from a task analysis study.

Culture cards are a deck of 20–30 physical cards that are used to communicate key findings and images from different cultures. Information such as photographs, brief research findings, user descriptions, or users' needs are printed on materials of cultural significance, such as greeting cards, textbook paper, or handmade paper from the area. Figures 42.3 and 42.4 are examples of culture cards created for a project on pregnancy and parenting.

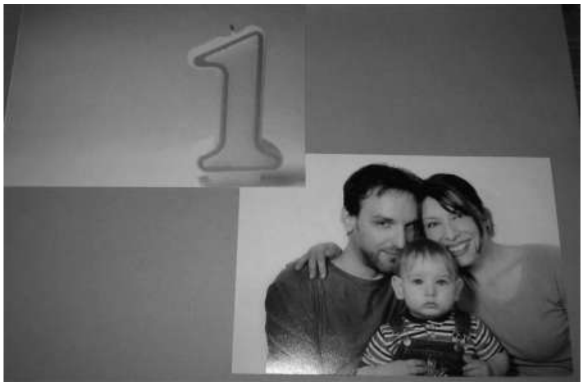


FIGURE 42.3 Images displayed on the front of the culture cards.

The intent is to be motivational: to inspire the product team to create culturally sensitive and appropriate design solutions. Culture cards can provide a useful overview of key findings and serve as a launch pad for brainstorming

and design sessions. Two key advantages are that they break the data into digestible chunks and they cue the designer to appropriate aesthetics for each culture.

42.3.3.2.12 Culture Scapes

When communicating results from an observational study, it is challenging to convey the true feelings and sensations generated by the environment. Smells, sounds, textures, and flavors are all important aspects of the users' environment, but they can be difficult to relay to the team (Foucault 2005). Images and words are often not enough. Figure 42.5 is an example of a culture scape.

Culture scapes are designed to allow the team to richly experience the culture by engaging multiple senses. Foucault (2005) successfully used culture scapes when relaying findings from a mobile technology study in Singapore. During the study the observers were struck by the intense heat and humidity and how it related to their observations. To convey these environmental realities, they presented their findings in a room that was 90 degrees Fahrenheit with 85% humidity. As a result of the simulated environment, team members "got" the importance of these environmental factors and their critical impact on design. If you plan to use culture scapes, it is important while you are in the field to consider what sensory experiences are most important and how you will convey them when you return.

42.3.3.2.13 Culture Capsules

Culture capsules showcase unfamiliar elements of a culture by physically re-creating a space from the observed environment (Foucault, Russell, and Bell 2004). This presentation method is of particular importance when space is the primary consideration in design. Photographs taken in the field guide these re-creations, which may also include artifacts from the physical environment being re-created. For example, Foucault, Russell, and Bell (2004) used this technique to highlight the space constraints in a typical Chinese home so the team would understand the limited space available in a typical home office in China. By replicating the physical spaces they had seen, the researchers made the necessary information about space constraints obvious to the product team. The space also served well as a brainstorming area and a project showcase.

DAN SZUC'S INSIGHTS ON TASK ANALYSIS AND USING TASK ANALYSIS

"Let's All Take a Step Back ... for Just a Moment Please"

Over many years I have been fortunate to be able to be exposed to different projects, roles, people, domains, products, teams and user research approaches. A key component of all this work is the ability to not just do the research but to take the learnings and do something with them. We have also learned the need to make the results come alive and move them out of reports and PowerPoint decks into something real and tangible for product teams.

You Don't Work in a Research Bubble

One of the challenging parts of analysis from field studies, interviews, testing, and so on is taking everything you have learned and bridge it into the design. It's nice on projects to be given the time to do some up-front user research, to have the space needed to analyze the data, both mentally and in physical space, to look for insights and think about how this can be communicated through design. Often we get lost in the methods themselves and we forget the journey we are on, the goals of the research and the reason we are doing the research in the first place. It's important not to treat user research as a silo-ed or singular activity independent of other research or insights that may exist to inform design and product strategy going forward. An important part of your role as a UX'er is to go out, question, and talk to other parts of an organization who can provide data to help, for example, market research, best practice, previous usability studies, expert opinion, focus groups, and so on. The more knowledge you can gather, the richer the story to tell people.

Choose the Right Method

Sometimes, we are far too protective over our toolset and we have seen practitioners try and pick the perfect method or process for a problem. Before starting the research, it's important to stand back and take the time to listen. Understand the questions that need answers and feel free to mix and match methods to get the answers. Also appreciate there WILL be gaps and you will not be able to answer all the questions with one round of research. "Rolling research" is key and to plan for constant insights should be just as important as the design, development and marketing efforts—it should form part of the business planning and product proposition. How do we know where we are today and the changes we need to make as we go forward? How do the insights help us get ahead that little bit more against the competition?

Slow Down and Speed Up and Slow Down Again

Product teams are moving faster to deliver and don't always take the time to stop and stand back to look at how they are delivering against past product lines or the competition. User research provides a reality check on the direction the product team is going in. It does not and should not provide all the answers. As researchers, we need to be very careful over promising the results of any research activity.

The Value of Asking Why

We should be questioning the value of what we make and its benefit to both the business and the people using the products and services. Often we see teams spending energies on proving the value of their own contributions (which is normal) instead of questioning the value of "the thing" itself. Some of the insights around value come from people's previous experiences, gut instincts, personal opinion, by speaking with other teams, and so on, but much of this can be informed through going out into the field to speak with users.

Dig Deeper and Then Dig Deeper Again

We should be able to look at a rich dataset from field research and squeeze all the goodness out of it to find the insight to bridge into design. For example: what are the takeaways for this workflow, screen, function, widget, copy, and so on? How does it help the users move forward in his or her journey towards completing a goal in both efficient and delightful ways?

Putting It All Together: The Bank

Recently we worked on a project for a bank to help them move from their existing website design to the next iteration of the design. The primary objective was to inform the new design with insights we were collecting through user research including usability reviews, competitor analysis, business and user discovery, design workshops and usability testing. It was really important to sit with the client up-front to understand what they were trying to achieve with the redesign effort and how we could compliment this in and around their timings. They were keen to show huge improvements from the current approach. Scope plays an important part of any research planning and you should also get a feel for the "research receptiveness" of the client as you plan the research beyond the first piece of work. What will work in Phase 1 and how does this inform Phase 2 and onwards?

Data Challenges

One of the challenges is how to take all the data you collect from the various research activities and make sense of it all. Also how you can take the team on the journey with you around their other work priorities so they feel they own the work instead of feeling like it's data being thrown over the fence with no place to go and no home.

Sell the Need

Sometimes we use terms for methods that our buyers do not understand, for example, Cognitive Task Analysis, GOMS, Hierarchical Task Analysis, Activity Theory, PARI (prediction, actions, results, interpretation), Syntactic Analysis, and so on. This is not to diminish the importance and value of the tasks, but the energy required to explain these can take away from the efforts required to better understand the need and then the approach we need to take.

"Talk Throughs"

One approach we have tried is "talk through."

So what are talk throughs?

During the user interviews, we would ask people to tell us a story on how they go about completing a task. We used the talk throughs to take into the design workshops as task flows to help drive the designs. The challenge was to get people to step outside of their domain (in this case "banking") and their own jargon and simply talk through a task, for example, "paying a bill." We would ask people do to this in both English and Chinese to listen to the steps they take and also the language or keywords they use. We also needed to be aware of creating an environment where people feel comfortable to tell a story that can lead to other stories and more insights. We took screen shots from competitors to overlay and see how it plays out next to the talk throughs, for example, What are the order of fields? What language is being used? What terminology can be simplified? What can be removed? What are we forcing users to do because of platform restrictions? What is the wish list to improve the experience? What are the gaps in our knowledge? Do we need to involve more users or more specialists to inform the design? For example, in one workshop we did not have a clear idea about the questions people have when buying and selling a specific investment product. So we quickly got on the phone and called a person who speaks directly to customers, is on the front line and sells products directly.

We also used the data from business discovery and user interviews to reduce our "guesswork" and to better understand:

- Product interaction: How users truly interact with the product, how much of the product they use, and what other software is used in the process
- Language: How users describe "products and services" to customers and the language they use
- Issues: Issues they face when using the software
- Tools: Other tools used to develop a customer solution. This can include brochures, fact sheets, pen and paper, and so on.
- Available time: How much available time the user has to deal with a task

Facilitating Design Workshops

Facilitating design workshops can be challenging at the best of times but especially so when the people attending do not speak English as a first language. It's important that you are comfortable with this as a facilitator and ensure you give the flexibility for people to speak in both languages (in this case English and Chinese). You should have someone in the room who can take over discussions in other languages and allow people to express their opinions, needs, issues and positives. A fluid discussion amongst different roles, skills, backgrounds and languages can build team spirit and push through improvements on the product. As trust builds, it's also key to allow for healthy arguments as the team continues on a journey towards something better.

Taking the "Talk Throughs" Forward into the Design

Talk throughs are simple flow diagrams drawn onto flip chart paper or a whiteboard to ground people back into what users want to achieve when completing a task. They navigate the team back to the core or essence of the task itself. This is important as discussions move forward and more layers of complexity are introduced including technology, politics, and visual design.

Takeaways

There is no substitute for immersing together with users to collect rich data to see how people use products and the issues they face to help drive the workflow of a new product design. Remember the following:

- Don't do user research for the sake of research—understand what you want to find out.
- Engineer your research to help bridge insights back into design.
- Respect other cultures, locales and language—allow people to express themselves in their language of choice.
- Don't reinvent the wheel—if you can inform design without doing in depth research, do it, but always question where research can help you dig deeper.
- Facilitate towards a goal—take what you have learned from research and facilitate it.

42.4 CASE STUDIES OF INNOVATIVE APPROACHES TO TASK ANALYSIS

42.4.1 Perspective Probe Case Study by Marianne Berkovich (Google)

Certain topics are considered taboo for polite conversation—sex, politics, money, and religion. But what if your team needs to understand one of these topics? We developed and used the Perspective Probe method to understand the sensitive topic of money and investing when we worked with the Google Finance team. Perspective Probe is a nonthreatening and whimsical way to get people's opinions on sensitive topics without asking them directly.

Think of the Perspective Probe as a way to co-prepare a delicious multicourse meal with your participants. You will provide the recipes, they will cook the dishes, and you will both enjoy them together. No one course is the "be all and end all" of the meal. It is even okay if one of the dishes does not turn out well. But taken together, it is quite a satisfying meal.

The Perspective Probe method consists of the following steps:

1. Creating activities targeted for what you want to learn, and then sending them to the participants
2. Having the participants complete the activities and send them back to the researcher
3. Conducting a debrief interview with each participant about the activities
4. Analyzing the results from all the participants and sharing the findings with the team

This case study describes how we went through these steps for the Google Finance project. The study was conducted over 5 weeks in the spring of 2008 with 11 participants in the United States.

42.4.1.1 Creating the Activities

The Google Finance team wanted to better understand how people think about investing, how they use their online portfolios as part of their other investment tools, so they could find opportunities to improve Google Finance. We first made a list of all the research questions that we had on the topic areas, then grouped and prioritized the questions. The pared down set of questions were the following:

- What items comprise participants' financial lives? What tools do they use?
- What are participants' financial goals?
- What is included and excluded from their portfolios?
- How do they currently use their online portfolios?
- What categories are important in their investments?
- How do they evaluate their portfolios?
- What else is important?

We decided that each research question would map to one activity that would be included in the Perspective Probe packet. Each activity would then shed light on one part of their perspective on investing. All the activities together would represent a complete picture of their standpoint.

As we brainstormed appropriate activities, we developed a set of guidelines to evaluate how well the activities fit our intended goal. The guidelines were the following:

1. *Simple*: Because we would not be there to explain the activity more fully than the instruction card provided with the activity, the activity had to be nearly self-explanatory.
2. *Open to interpretation*: We wanted to give the participants freedom to address the subtopic in the activity in a way that made the most sense to them, so we wanted the activity to leave room for their interpretation.
3. *Stand-alone*: So the activities could be done in any order.
4. *Different from each other*: To keep the participants interested and make sure they completed all the activities, each activity had to introduce something new.
5. *Fun and whimsical*: We were asking more time and effort from the participants than a usual study, so we wanted to make sure the experience was fun.

We piloted the activities with several Google employees to assess whether the instructions made sense and how long it would take participants to complete the activities. We then sent out the packets and asked participants to return the packets about a week after they received it.

42.4.1.2 Having the Participants Complete the Activities and Send Them Back to the Researcher

We recruited 16 participants across the United States who indicated that they used an online portfolio to manage their investments. Eleven participants ultimately completed the packet and the debrief interview. Each participant received a Perspective Probe packet containing a welcome letter, the activities, explanation cards with each activity, an inexpensive digital camera, and postage to mail the packet back.

The participants had about 1 week to complete the activities and mail back the packets. They generated 185 artifacts and photos.

42.4.1.3 Conducting Debrief Interview with Each Participant about the Activities

The following table lists the activity, research question it aimed to answer, and a brief description of what the participant was asked to do. (The numbers correspond to the question we listed earlier.)

Some participants responded with creativity to these activities. For example, one participant added her own twist and her own symbols in the "Draw Your Financial Life" activity. She drew each of her assets (such as 401k, life insurance, personal checking account, and her Volvo) as a hot air balloon lifting her up and each liability (such as children's education, household expenses, and consumer debt) as a stake tethering her to the ground. Another participant made simple collages instead of taking photos for the "Photo Checklist." During the interview, many participants said that they had fun working on the activities (Figure 42.6).

Activity	Description
1. Draw Your Financial Life	Participants were given an 11 × 17 piece of paper and instructed to draw the important items, tools, and flows that make up their financial lives.
2. Letter from the Future	Participants were asked to write a letter to their present selves from their future selves who had accomplished their financial goals, telling them what they have achieved and how they got there.
3. Portfolio Definition	Participants completed a dictionary definition based on their own view of what a portfolio was. We wanted to understand what was included and excluded from their portfolio.
4. Guided Tour of Your Portfolio	Participants filled a museum tour booklet of their portfolio and took photos of highlights on the tour. They covered private information with the provided sticky notes.
5. Teams of Investments	Participants completed a booklet of "teams" (groups) of investments that they had in their portfolios. They named each team and listed its members.
6. Portfolio Report Card	Participants listed "subjects" on which to evaluate their portfolios and then graded it.
7. Photo Checklist	Participants were given a checklist of open ended items to take pictures of to show their environments—such as where they keep track of investments, good sources of information about investing, and so on.

FIGURE 42.6 Activities and instruction cards in the Perspective Probe.

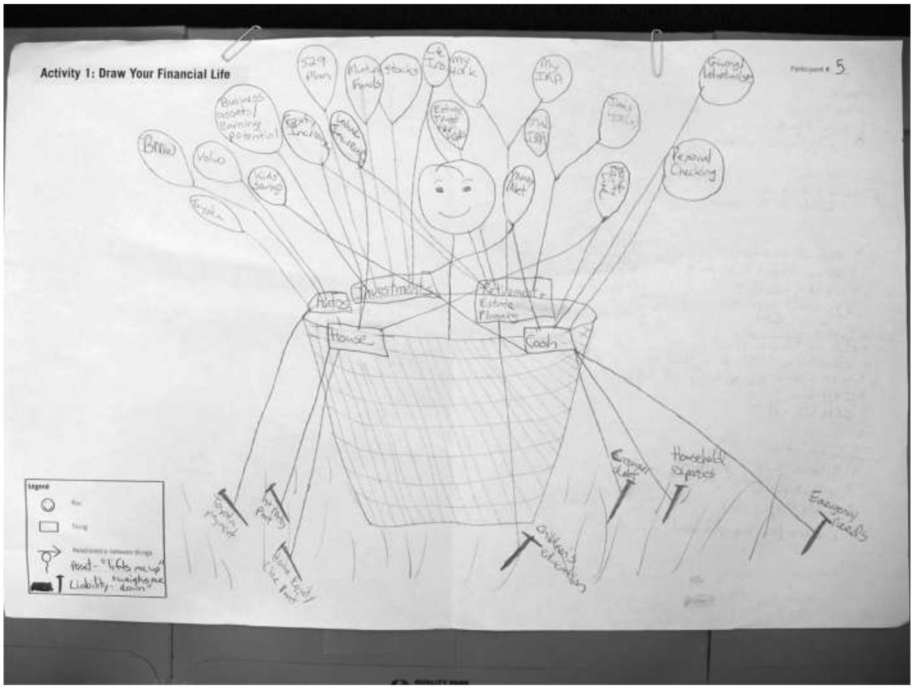

FIGURE 42.7 One participant's completed "Draw Your Financial Life" activity.

We found that the "Portfolio Definition" activity flopped and did not produce any interesting insights from participants. But one of the strengths of the Perspective Probe is that no one activity is the keystone. An activity can fail but the set of activities still yields good data.

During the one-on-one phone interviews, we used screen sharing to look at the digitized versions of their completed activities and discussed what they did. The sending of the packets back and forth had established rapport between the participants and researchers, so we were able to quickly get to substantive detail during the phone call (Figure 42.7).

42.4.1.4 Analyzing the Results from All the Participants and Sharing the Findings with the Team

We wanted to involve the whole team for the analysis of the findings, so we held a half-day workshop with engineers, product managers, interaction designers, and customer support staff. Before the workshop, each attendee was given a participant's packet and transcript of the phone call and asked to complete a one-page summary from a template we had prepared. During the workshop, we shared the one-page summaries with one another and noted insights, facts, and ideas on sticky notes. We created an affinity diagram with the sticky notes of themes that emerged.

One theme that emerged was that, at a high level, participants' financial concerns were similar, but the specific way that each participant dealt with the concerns varied greatly. For example, concerns we heard repeated were not needing to worry about finances in the future, making sure the portfolio is growing, having enough money for retirement or a child's education, not reacting to market fluctuations, being aware of short-term/long-term capital gains, and not having debt. However, we heard a variety of strategies about how to accomplish these in terms of how often portfolios should be checked and managed, as well as different definitions of "diversification" and different comfort levels with how diversified their portfolios were. After the workshop, we turned these and other insights into design guidelines for the interaction designers to refer to.

The Perspective Probe method helped us to collaborate with the participants to uncover rich data about their views on the sensitive topic of investing.

42.4.2 Triangulating Qualitative and Quantitative Methods for New Product Development by Jhilmil Jain (HP Labs*)

42.4.2.1 Introduction

This case study shows how bringing together (triangulating) information from qualitative and quantitative methods of understanding users, their needs, their tasks, and their scenarios helped us create a successful new product for small businesses.

42.4.2.2 Why Did We Do This Project?

At HP Labs, we have built a number of successful tools for individuals to manage personal projects such as planning a trip, working on an educational report, researching a product, and so on. Based on feedback from business customers, we identified the market opportunity to extend

* This project was conducted when the author was working at HP Labs.

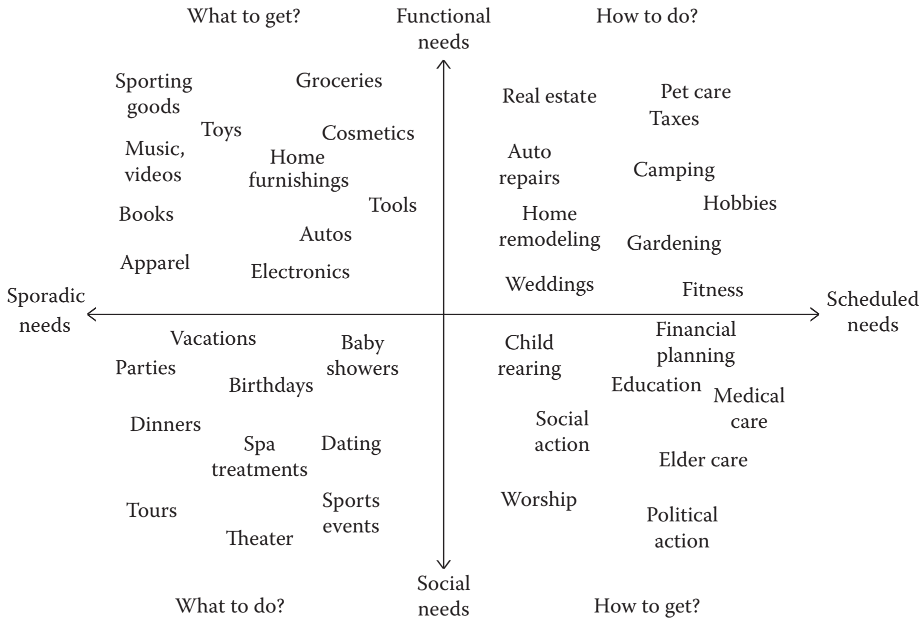

FIGURE 42.8 Project segmentation.

the "project-based" metaphor of these consumer-oriented tools to meet the needs of small companies that provide project-based services.

For many small business service industries (e.g., event planning, home remodeling, car customization, film production) managing vendor resources is a critical business function. Project managers and workgroups in these segments can be characterized by the following:

- Professional service businesses where project managers manage multiple complex projects simultaneously (e.g., a wedding planner plans several types of weddings and each could be in a different stage of planning).
- The majority of business activities involve sourcing* and managing a diverse set of interdependent vendors across 10+ different service and product categories (e.g., vendors such as caterers, florists, photographers, videographers, etc. need to often collaborate with the wedding planner).
- Projects require intensive collaborative client involvement to achieve highly customized solutions where clients have to make decisions with minimal expertise and time (e.g., the wedding planner works collaboratively with brides, grooms, and family members to plan the wedding).

The project managers/planners in these professional service industries are underserved by current vendor resource management software tools and platforms. The goal of our task analysis was to evaluate whether we could and should build a common cloud service-based platform† that provides a base level functionality to cater to multiple industries.

42.4.2.3 Which Task Analysis Methods Did We Use?

The first step was to identify specific industries to focus on in our task analysis. We conducted card-sorting as an internal-group exercise to identify relevant market segments that aligned well with HP's go-to market strategy for small businesses. (See Figure 42.8.) The x-axis of Figure 42.8 depicts projects across sporadic-scheduled needs, and the y-axis depicts projects across functional-social needs.

Based on our business goals and on the technologies that we wanted to incorporate in our new product, we identified industries that catered to the "scheduled and functional" needs of clients (top right quadrant), for example, event planning, home remodeling, video production, wedding planning, real estate, and so on.

First, we conducted 20 phone interviews with project planners and vendors and three focus groups with clients. These revealed the "day-in-the life-of" commonality across the various industries and we were able to generate a common experience map. (See Figure 42.9 for four domains such as event planning, wedding planning, video production, and home remodeling.) For example, in wedding planning, the project planner is the wedding planner, the client is the bride and groom, the vendors are people that provide products or services such as florists, caterers, photographers, and so on.

* Vendor sourcing consists of identifying customer needs, identifying vendors based on those needs, writing a request for proposal (RFP), soliciting input from vendors, analyzing results, creating contracts for the chosen vendors.

† Cloud platform services (also called "Platform as a Service [PaaS]") delivers a computing platform and/or solution as a service through the Internet. It makes it possible to use applications without the cost and complexity of buying and managing the underlying hardware and software. (See Cloud Computing Wikipedia [2010] for more details.)

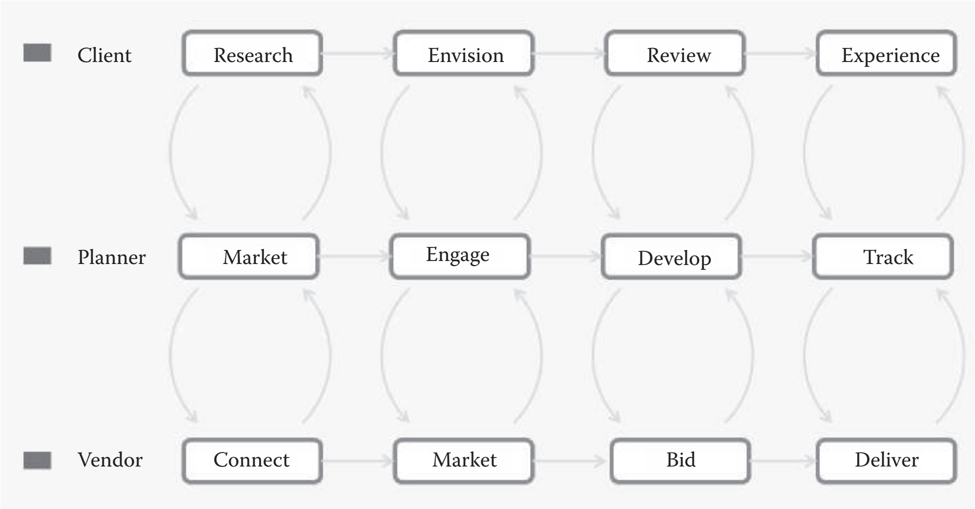

FIGURE 42.9 Experience map of three user types.

Second, we conducted five contextual observations (on-site office visits) to generate sequence and artifact models (see Figure 42.10) to depict the following:

- Detailed steps in the process flow for the planner to identify the workflow steps to be automated in the platform
- Digital versus physical artifacts used in each step such that we can identify the artifacts to be automated and tools to support in the automation; and also to identify the physical artifacts that are providing efficiencies and inefficiencies in the process
- Tools and software used such that we can evaluate which ones we need to integrate in the platform
- Stages where collaboration occurs with clients/vendors such that we can support this in the platform

Third, since we could not meet a number of planners, we designed and conducted two online surveys: to understand the needs of the planners and vendors. The survey was conducted using surveymonkey.com, where 56 wedding planners and 82 vendors took the survey and were given a $50 Starbucks gift card for their efforts. In the survey, we wanted to quantify the following:

- Service types/specialization offered
- Packages offered
- Fee structures for services and packages
- Marketing strategies and amount paid for them annually
- Software, physical artifacts, processed used for initial client engagement, project planning and management, finding and researching vendors, vendor proposals and estimates, contract management, client feedback and reviews
- Generic project planning software used (if any)
- Critical business pain points
- What are the roadblocks to business growth

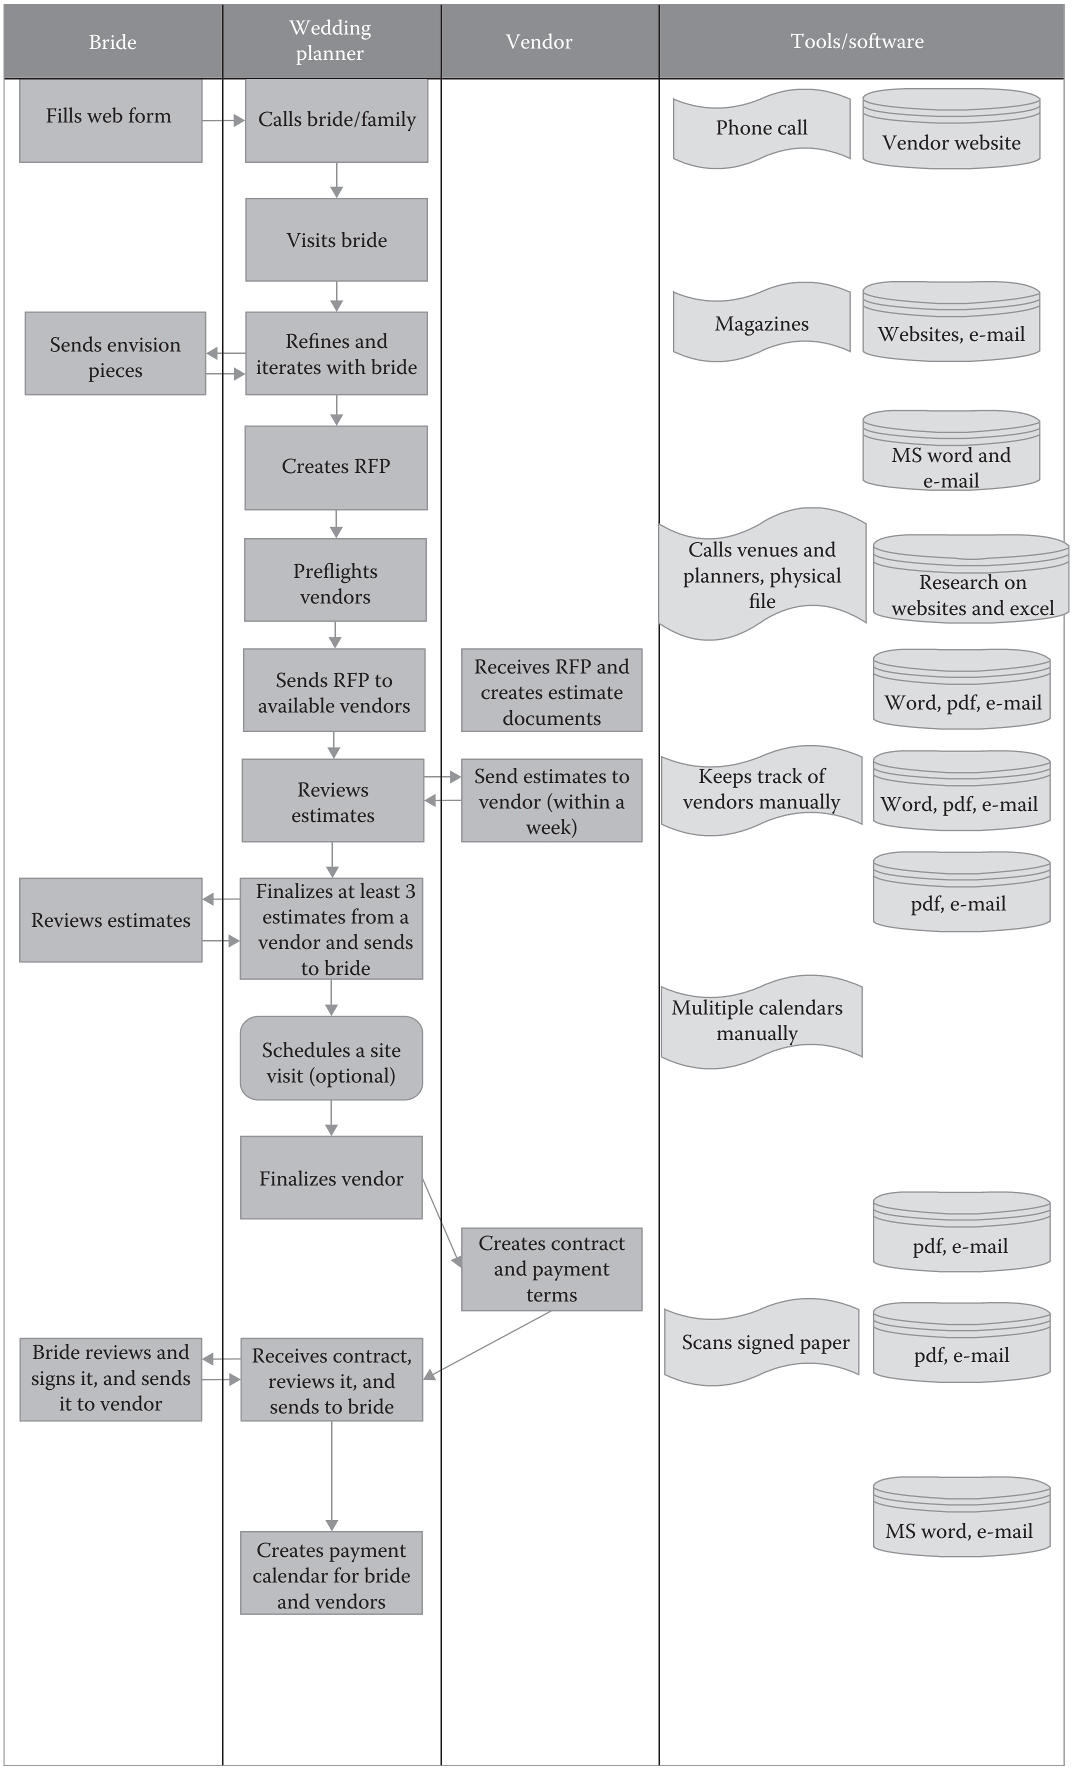
By triangulating data collected from interviews, contextual inquiry, and surveys, we identified pain points, innovation opportunities, and design implications for each of the following features:

- Lead generation (e.g., mobile solution for entering leads)
- Initial meeting with client (e.g., provide standard, but customizable, forms; scheduling calendar)
- Client communication (e.g., currently all manual, but need access anytime, anywhere; integrate with e-mail)
- Vendor management (e.g., customizable categories, need to record contact info, pictures, brochures)
- Vendor bidding, final selection (e.g., very iterative and involves lots of communication, but client has no visibility)
- Vendor contracts (e.g., allow form upload; automation will be difficult due to lack of standardization)
- Payment management (e.g., mostly by checks, no need to integrate bank account)
- Reviews/feedback (e.g., used for testimonials for marketing and also to shortlist vendors)

The above information was provided as a video diary that not only served as a design inspiration but also helped designers, developers, and product managers experience the users' pain points.

We also created 10 personas with even distribution across various industries and user types with two key framework dimensions: (1) size of business (e.g., number of events planned per month) and (2) technical expertise and appetite of users.

Both the video diary and the personas turned out to be highly successful deliverables because designers and developers were not yet assigned to the project when we collected and analyzed this data.



Bride
Wedding planner

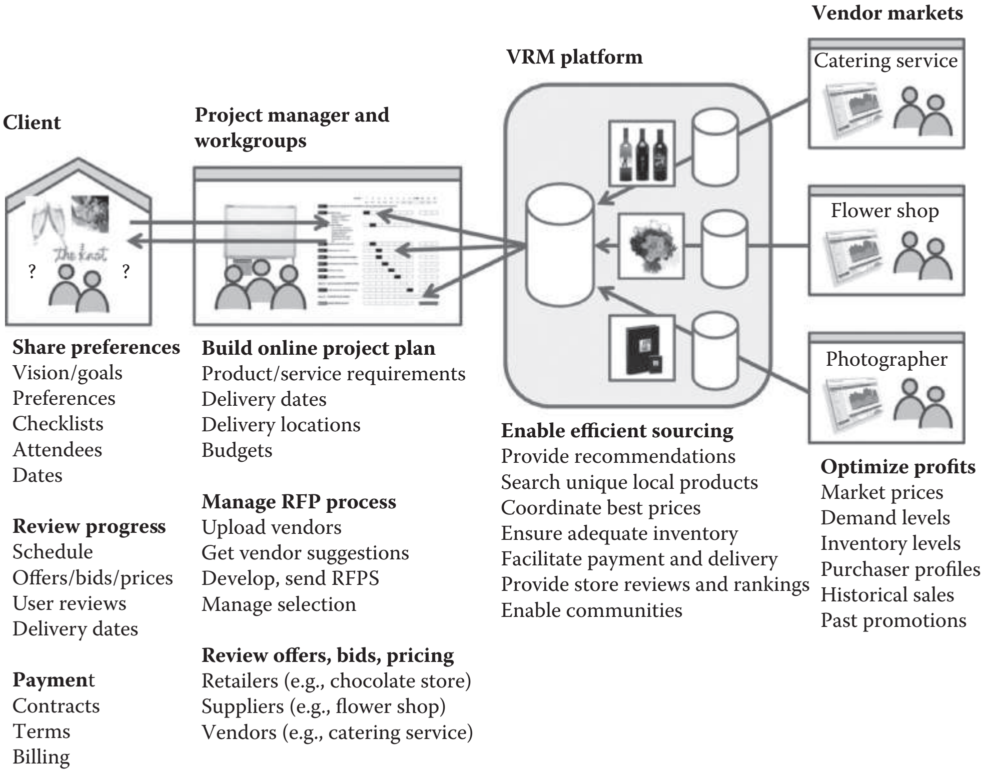

FIGURE 42.11 Overview of the Epicenter platform.

42.4.2.4 What Is Epicenter?

Based on the task analysis, we defined a brand new product called "Epicenter," which is a next-generation cloud service platform that connects small service companies with local suppliers/vendors and clients. (See Figure 42.11.)

- It is a web-based service that allows small service companies, such as wedding planners and interior architects, to more efficiently evaluate, source, and coordinate products and services required to implement their client's complex projects.
- It enables small suppliers and vendors to more efficiently market and supply products to local service companies by enabling them to have real-time visibility into the detailed project needs of small service companies and their clients.
- It enables clients to effectively create and communicate their requirements.

42.4.2.5 How Did We Handle the Need for Additional Task Analysis?

As we started designing each screen of Epicenter (see Figure 42.12), we realized that we needed to conduct additional task analysis for each stage in the workflow (requirement, RFP, proposal, contract, payment, feedback) for all three user types (planner, vendor, client) to help us identify the details of the process. Because we had limited resources at this stage, we chose to conduct rapid task analysis using the following steps:

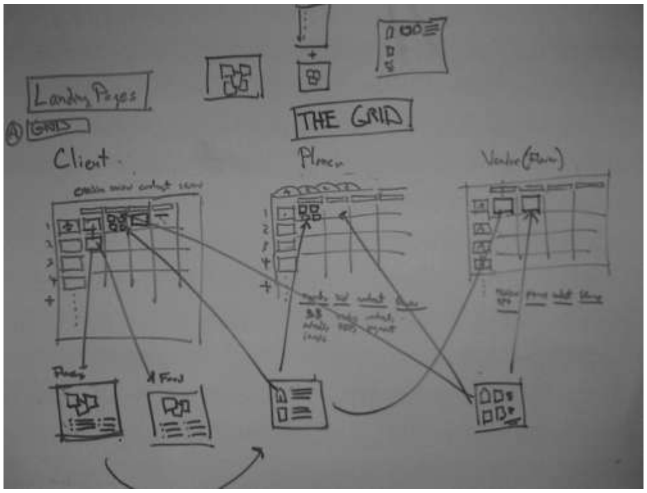

FIGURE 42.12 Initial Epicenter designs.

- We established a panel of three expert project managers (one each from event planning, video production, home remodeling) and we met with them every 2 weeks for a design review.
- We conducted scenario walkthroughs using low fidelity prototypes and focus groups with HP employees every month. (We were able to locate three women who were getting married/planning a wedding and a spouse who was a photographer.)

Additional task analysis not only helped us inform screen designs but also helped us prioritize features and functions.

42.4.3 Designing a Shared Media Experience: An Ethnographic Approach by Rama Vennelakanti (HP Labs)

42.4.3.1 Introduction

Unlike earlier times when television was an entertainment medium and the personal computer was a productivity device, the distinction and the boundaries are fuzzier today. Both are used to consume media as well as for productivity.

Today it is as familiar a sight to see a group of friends huddled around a laptop (or a desktop) checking out the latest posts on a photo sharing site or the latest episode of a popular soap as it is to see a group of friends or a family gathered in front of a TV to watch the World Cup or Wimbledon matches. A personal computer is used as much by a group to watch an online video as by an individual to produce an assignment; it moves between being a multiple-user device and a single-user device.

However what has not changed is the interaction mode—a single keyboard, a single mouse, a single remote. Both TVs and personal computers were designed for and have remained single user devices, at least as far as the interaction is concerned. So, what is otherwise a group experience/activity, such as watching videos or photos with friends, is often defined by the one person who has control of the interaction mode: the keyboard, mouse, and remote. This control over the interaction (or at least the desire for it) is often manifested in the tussle over the remote control. However, this single person interaction mode also ensures a sense of order by ensuring that the system receives just one command and control input at a time, thus avoiding chaos.

42.4.3.2 Case Study: What We Were Trying to Learn

The objective of the study was to identify patterns, if any, in the interactions that users have with media (and media devices) in an in-home group media-consumption scenario. Some of the questions we set out to answer were the following:

- What, if any, are the patterns of interactions?
- What are the factors that influence interactions with media?
- How do interactions change in a group situation?

42.4.3.3 How We Structured the Study

We recruited twelve users, across two cities, who met some basic criteria for ownership and use of media and media devices. They were given an incentive in the form of a gift or a gift coupon to participate in the study, apart from an occasional pizza for an activity with their friends or siblings.

As the focus was to identify parameters that influence interactions, we decided to study existing interaction behaviors, and to look for patterns in those behaviors. We were interested in users as they interacted with media individually and in groups, with media and media devices they are familiar with (their personal media and devices), with people they usually share these media with (family and friends), in surroundings they are familiar with (their homes), at times that were as close to usual for a particular media activity as possible.

42.4.3.4 Data: What We Collected and How We Collected It

Observation of interactions with each of these users was spread across 3–4 days depending on the media task. We spent a few hours on day 1 getting a profile of the user. We also took stock of the various devices in the user's home, specifications of those devices, and the user's familiarity and extent of use with those devices. We asked the users to categorize the devices based on ownership (even notional; i.e., the device was family owned or paid for by the parent but was used by the user), use, and media type among other parameters. We explored the user's media collections. We used a structured questionnaire method along with task flows to gather this data. (See Figure 42.13.)

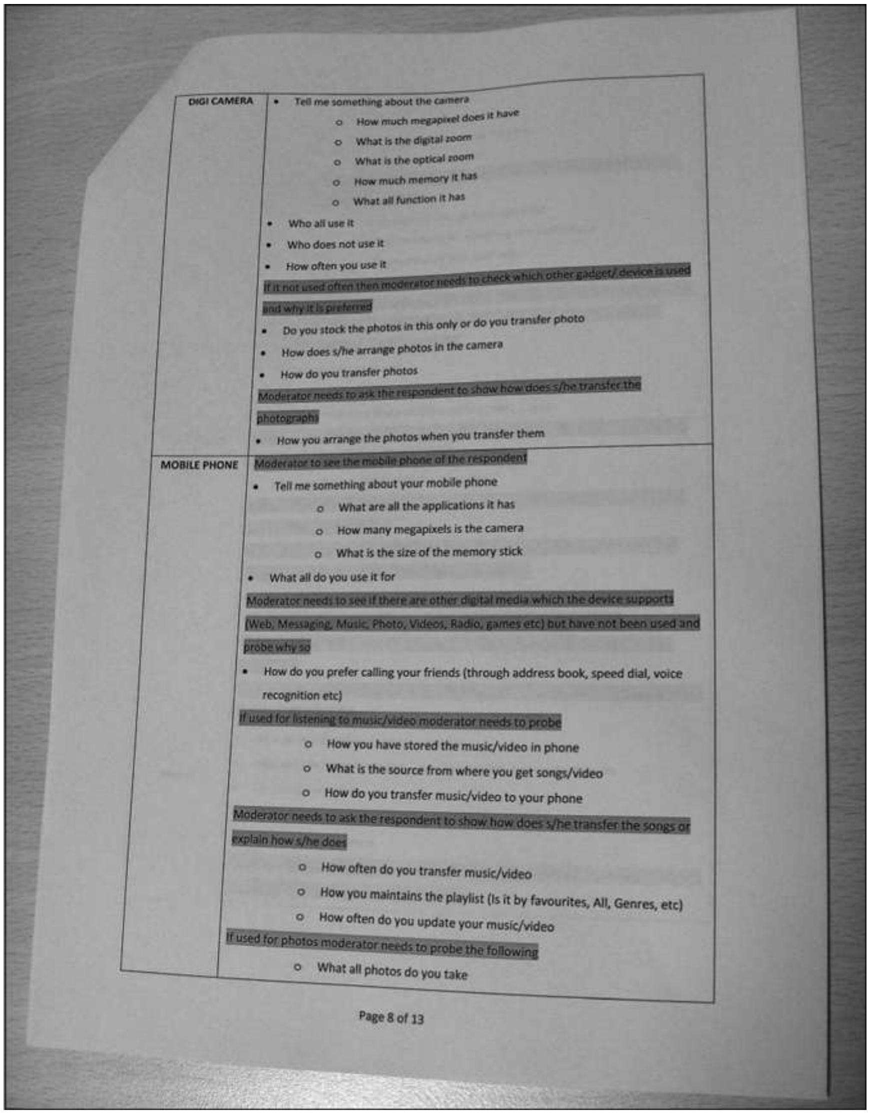
After this interaction on day 1, we set up specific activity slots, so that we could study the user's interactions with specific media types. The members for each activity (in a group activity) were decided by the user (as also the time of the day). We scheduled data collection at different times of the day at the convenience of the user. For single user activities, other members of the family—an inquisitive sibling or a parent joined in sometimes and this was allowed, as it provided us some natural interaction data.

We observed activities in various spaces in the home, where they normally happen. For example, if a family got together in a bedroom to watch a movie, then that became the observation scene. We observed the group activities passively; but single user activities were mostly interactive, with observations being followed by specific questioning to elicit information and understanding.

Some of the activities happened in their natural course and we observed them. For example, Sunday afternoon movie/video with the family was a regular happening, so we observed it as it happened. Some activities, such as a photo viewing session with friends, also happened in the natural course of events in the user's life. For example, some of the users had just returned from a trip and had arranged a photo viewing session before we got in touch with them; so we ended up observing this interaction. Some sessions were planned as part of the study where we asked the user to invite friends or cousins with whom they usually share a video game or watch the latest episode of "Heroes," and we observed the activity.

All activities were video recorded. We filled in observation sheets throughout the session. We had designed these observations sheets to capture information like seating pattern, the shape of the group (cluster), and so on, in drawings and notes. (See Figure 42.14.)

We took care to ensure that the video camera was unobtrusive. The observers always positioned themselves outside



DIGI CAMERA	• Tell me something about the camera ○ How much megapixel does it have ○ What is the digital zoom ○ What is the optical zoom ○ How much memory it has ○ What all function it has • Who all use it • Who does not use it • How often you use it If it not used often then moderator needs to check which other gadget/ device is used and why it is preferred • Do you stock the photos in this only or do you transfer photo • How does s/he arrange photos in the camera • How do you transfer photos Moderator needs to ask the respondent to show how does s/he transfer the photographs • How you arrange the photos when you transfer them
MOBILE PHONE	Moderator to see the mobile phone of the respondent • Tell me something about your mobile phone ○ What are all the applications it has ○ How many megapixels is the camera ○ What is the size of the memory stick • What all do you use it for Moderator needs to see if there are other digital media which the device supports (Web, Messaging, Music, Photo, Videos, Radio, games etc) but have not been used and probe why so • How do you prefer calling your friends (through address book, speed dial, voice recognition etc) If used for listening to music/video moderator needs to probe ○ How you have stored the music/video in phone ○ What is the source from where you get songs/video ○ How do you transfer music/video to your phone Moderator needs to ask the respondent to show how does s/he transfer the songs or explain how s/he does ○ How often do you transfer music/video ○ How you maintains the playlist (Is it by favourites, All, Genres, etc) ○ How often do you update your music/video If used for photos moderator needs to probe the following ○ What all photos do you take

the activity itself, but they had a good view of the activity and users. We took still pictures at various points in time to illustrate specific observations.

With younger users (especially female) other family members were allowed to sit in through the interview sessions for as long as they liked and were even encouraged to look at the video camera monitor. Once they were convinced that the video recording and the interviews were very functional, they often left us alone and did not intrude into the exercise.

42.4.3.5 How We Analyzed the Data

We analyzed the video, voice recordings of the interactions and observations, along with observation notes and photographs of interactions for individual media types and media devices to identify interactions and factors that impacted them. We compared across media types and media devices to identify factors that impact interactions and the interaction patterns. We analyzed the data more than once and sifted through the data many times. Each round of analysis uncovered insights which led to looking for more patterns and so on both across and within media types and media devices. It was a painstakingly meticulous and a handcrafted manual exercise. We viewed the video tapes over and over again to look for patterns and confirm insights. We still continue to mine the analysis for patterns as our understanding of the area deepens.

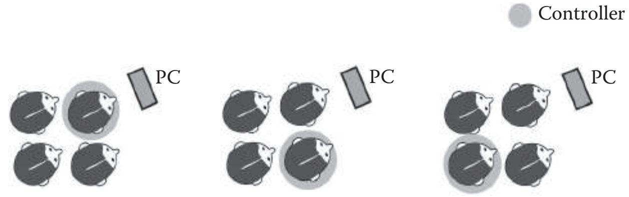
42.4.3.6 What We Learned

From our study, we found that various factors impact media interactions—media type, media device, the positioning/placement of the media device in the home, the members of the group and the power distance between them, the shape of the cluster formation of the group, time of day, media activity, role of the activity—primary (photo sharing), secondary (texting on the mobile phone while watching TV), or ambient (music while doing homework), and so on. (See Figure 42.15.)

All of these factors impact "control" of the media interactions (and the remote, mouse, and keyboard) and, therefore, the role of each person in the group. Control over the media and control over the media device meant control over interaction with the media.

42.4.3.7 Television

Control, in the context of interaction with the television, is driven by the remote control device. The remote is passed or taken/grabbed as a means of giving or taking control. This is done with ease.



Control with person close to computer

Control with person sitting next to computer

Control with person sitting behind

FIGURE 42.16 Shift of control among the group in the context of media consumption on a personal computer.

42.4.3.8 Computer

Possession of the keyboard and/or the mouse equals physical control over the interaction with the computer. Control over the keyboard and mouse tends to remain static through most of the activity, unlike the case of the television, where the remote can easily change hands and thus control can also change. Static control, as in the case of a personal computer, could be due to the fact that today using the computer is a sit-down activity. It is more difficult to dislodge a sitting user than to pass the remote to another person, as in case of the TV. However, at the computer, although the person carrying out an instruction or a command (that is, the person in possession of the keyboard/mouse) may not change, the person who is actually in control may. That is, the person who gives the command/instruction, and so controls the interactions, may be different from the person who controls the interaction devices. This brings forth another role a group member may play at the computer: the executor, the one who executes commands that are issued by someone else. Control itself (who decides what to do) may shift even if the executor (who uses the keyboard/mouse) does not. (See Figure 42.16.)

42.4.3.9 Challenges Our Insights Bring to Design

Existing behavior patterns provide us with significant insights into the research challenges that need to be addressed by technology research and user interface design to provide for a rich user experience. From our on-site observations and data collection and the insights from our data analysis, we can see the very interesting challenges that need to be addressed while designing intuitive interactions for accessory (keyboard, mouse, and remote) free group interactions in the context of media consumption.

Key design challenges include how to

- Pass and share control
- Allow interactions for all
- Develop rules for handling multiple and conflicting command and control inputs to the device to avoid chaos

Another key challenge is when and how much to actually "design" and when to let the social dynamics of the interactions take charge. Overdesigning may lead to a completely controlled experience which may shift focus of the experience from media consumption to control, which may end by being user unfriendly.

42.4.4 Making Task Analysis Tangible with Mental Models by Indi Young

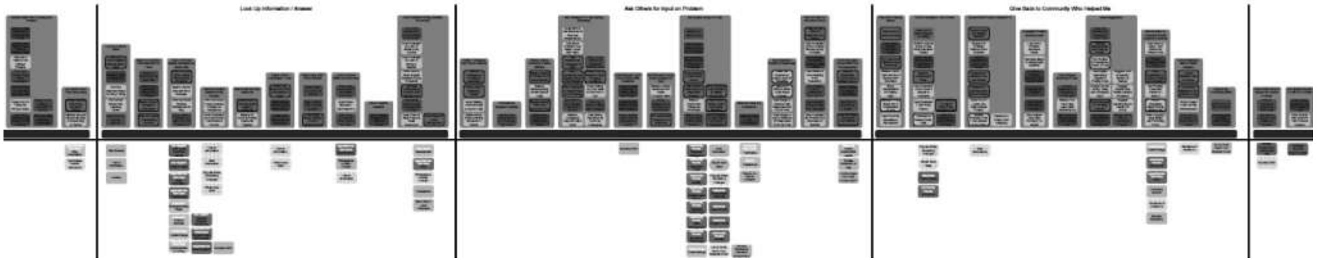
The mental models I develop are simple affinity diagrams. They are constructs that lay out the degree to which your organization is supporting what people want to accomplish. Mental models not only include the steps people go through, but also the philosophies people enact and the emotional reactions people experience during the process. A range of knowledge like this allows you to empathize with different groups and see things from their perspectives (Figure 42.17).

Aligned beneath the affinity groups of these steps, emotions and beliefs are the ways in which an organization enables people to understand, manipulate, achieve, or affect things. It also might show how an organization helps alleviate frustrations or removes workarounds. This alignment provides a foundation from which you can map out a path to improve what your organization does for people, whether that means improving services you already provide, redesigning artifacts, or brainstorming new approaches based on an empathic viewpoint.

In his book, *The Design of Everyday Things*, right after discussing his example of the refrigerator/freezer controls, Don Norman writes this definition of mental models: "the models people have of themselves, others, the environment, and the things with which they interact" (page 17 in the first Doubleday/Currency edition, 1990). The mental models I draw are not about things you interact with; they are about the "others" in this definition. They are diagrams your team uses to explore the behavior of certain audience segments. I could have called them "alignment diagrams" or "empathy models," but imagine how a business manager would react to spending budget on "empathy." "Don't we get empathy from all the demographic marketing surveys?" (Surveys are not conversations. http://www.rosenfeldmedia.com/books/mental-models/blog/oxymoron_scientific_survey/) I had to use a name like "mental models" that business leaders could get behind so that the needed information could get gathered.

Mental models do not change very quickly; therefore, they are helpful as long-range road maps for organizations. Imagine the mental model of how a person obtains ordinary groceries. Currently that model has to do with supermarkets, perhaps with farmers markets and veggie boxes thrown in. One hundred years ago, before the advent of supermarkets, that model would have consisted of relationships with specialty vendors, like the milkman and the corner produce shop. Five hundred years ago, depending on where on the globe you lived, the mental model probably revolved around a weekly town market. The philosophies and behaviors around getting groceries change slowly over the generations. Thus, an organization can rely on a mental model during its lifespan, focusing on supporting the behaviors in better ways, while also keeping an eye out for slowly drifting changes.

Mental models help your organization create relevant solutions for people. In a *Tea with Teresa* podcast (http://www.teawithteresa.com/podcasts), researcher Natash Alani talks about her research into nonliterate people in the Kutch region of India who use mobile phones. She discovered that the people she was talking to would not even use the keypad to enter digits, and the connection between the screen and the keypad was hazy in their minds. What was sharply in focus was their desire to hear their daughter's voice on the phone or to talk to their grandparents. In her research, Natasha found that when these people took public transit, they could not read bus schedules. To find out when the bus was arriving, they would ask a nearby fruit stand vendor if a bus had just passed through or not. This local behavior illustrates the importance of establishing relationships and communicating with associates around them. Later Natasha felt troubled that designers did not understand the situation well enough when she heard a suggestion for putting an electronic message marquis up to show times when the next bus would come. That solution would take away the opportunity for a person to talk



Look Up Information / Answer
Ask Others for Input on Problem
Give Back to Community Who Helped Me

FIGURE 42.17 An example mental model. Upper towers represent behaviors, philosophies, and reactions. Lower boxes aligned with towers show where your organization supports what people are doing.

to that fruit stand vendor. Instead, Natasha suggests, "Allow the fruit stand vendor to talk to the bus driver directly and find out if he is caught in traffic or will be arriving shortly." This action supports the known culture and empathizes with the way people place importance on the chance to chat with others around them. It is culturally relevant. And culturally relevant solutions are more effective—more *used*—and are more comfortable, learnable, and successful than solutions that ignore the behaviors of people in situ.

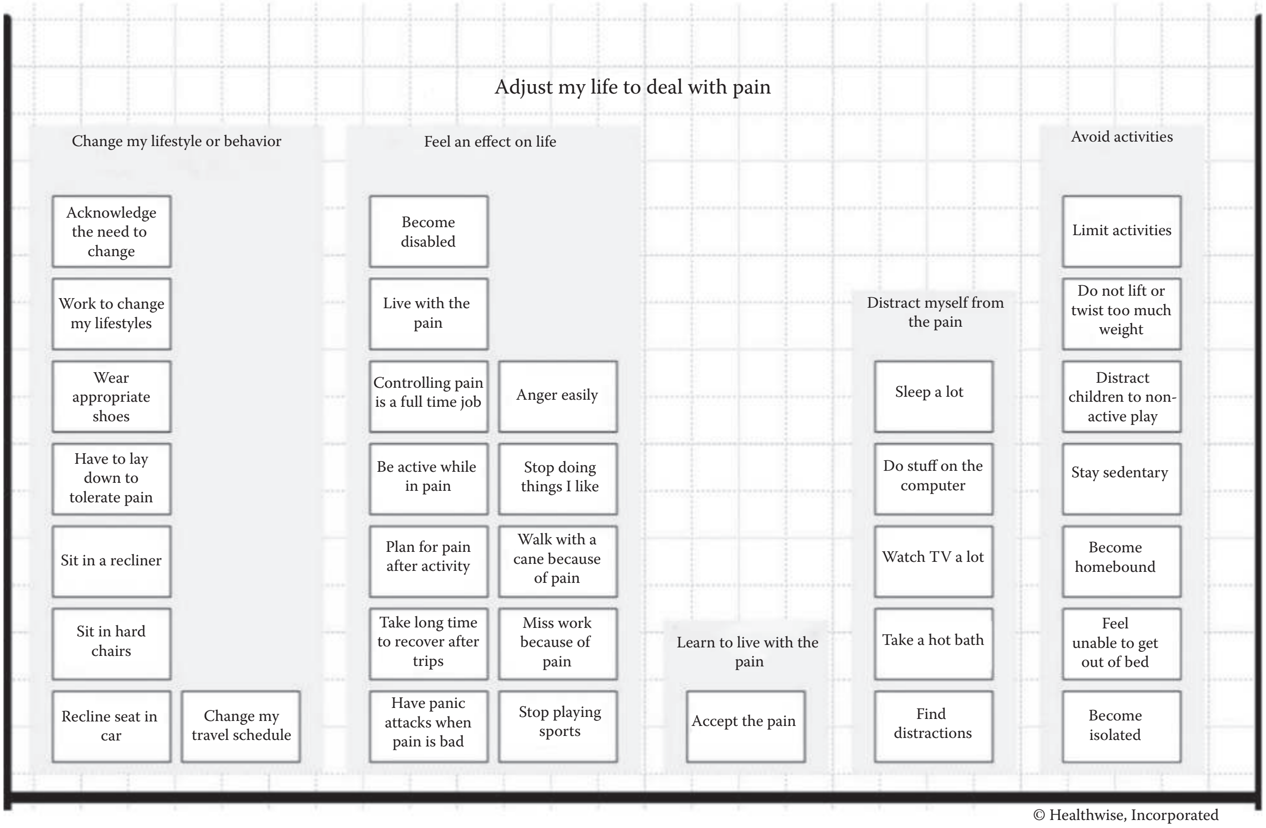
42.4.4.1 Case Study: Transforming Company Thinking

Healthwise (www.healthwise.org) is a nonprofit organization with a mission to help people make better health decisions. Healthwise works with health plans, hospitals, disease management companies, and health websites to provide the most current, scientific, evidence-based, consumer-friendly information to those who need it—encouraging patients to participate in decisions about their care, encouraging them to take action about their health, and offering support for the sometimes hurried and unclear synopsis doctors provide. The company began in 1975, offering printed decision-support and self-care materials. In the mid-1990s, Healthwise started creating an online resource of health information that would cover virtually all of medicine. Today the Healthwise® Knowledgebase includes more than 8000 in-depth topics and appears on many hundreds of websites.

Recently, Healthwise realized that the information it was providing could be more effective with improvements in search and browse functions. The user experience team within Healthwise spearheaded an initiative to improve information architecture for the knowledgebase and tools. But, with all the different ways of looking at the data, what was the best approach to create a single information architecture? At the same time, Healthwise wanted to expand its offerings. It wanted to offer more specific decision-support solutions for certain situations—but which situations? And what kind of support would be truly useful to the populace?

42.4.4.2 Starting with One Site

To answer these questions, Julie Cabinaw, Director of User Experience, decided to create a series of mental models to derive information architecture and to verify which of the many directions Healthwise had in mind to follow. However, first she wanted senior management to agree that this kind of research would be a good return on investment. She decided the most persuasive evidence would be a successful micro-site that incorporates knowledge found in the first mental model they would make. A micro-site is a site devoted to one health condition, like high blood pressure or diabetes, and does not expect the audience to identify itself—in other words, users remain anonymous. Her team spent one month creating a mental model about dealing with low back pain (Figure 42.18). The team learned some areas that were



Adjust my life to deal with pain
Change my lifestyle or behavior
Acknowledge the need to change
Work to change my lifestyles
Wear appropriate shoes
Have to lay down to tolerate pain
Sit in a recliner
Sit in hard chairs
Recline seat in car
Change my travel schedule
Feel an effect on life
Become disabled
Live with the pain
Controlling pain is a full time job
Anger easily
Be active while in pain
Stop doing things I like
Plan for pain after activity
Walk with a cane because of pain
Take long time to recover after trips
Miss work because of pain
Have panic attacks when pain is bad
Stop playing sports
Learn to live with the pain
Accept the pain
Distract myself from the pain
Sleep a lot
Do stuff on the computer
Watch TV a lot
Take a hot bath
Find distractions
Avoid activities
Limit activities
Do not lift or twist too much weight
Distract children to non-active play
Stay sedentary
Become homebound
Feel unable to get out of bed
Become isolated

FIGURE 42.18 Part of the low back pain mental model. Shows upper part of diagram where people talk about how they change the way they live because of this pain.

important to people with back pain where Healthwise could improve content, such as around how to deal with chronic back pain. They also learned that the use of alternative medical treatments, such as chiropractic or acupuncture, was very important to many people with low back pain. Through the mental model, they also uncovered how important having support—through family, friends and caregivers—was to people with low back pain, and how difficult it was for people in pain to ask for the help they need. These new insights proved the value of this kind of research.

To build the mental model, the team went through a few phases: they set the scope for their research, recruited participants for the research, conducted interviews, analyzed the data, and then built the mental model. In order to ensure contextual and appropriate information, the team set a simple but defined scope for the interviews, which was "to gain insight into how people understand and manage their back pain." The next step was to carefully recruit participants for the interviews to ensure a mix of people dealing with different back pain situations, across a variety of demographic backgrounds, such as age, gender, race, education and income levels. The team conducted nondirected interviews in which the interviewer lets the interviewee guide the conversation, picking up on clues provided to dive deeper into all possible ways that the person may think about the subject. Curiosity is the key to these interviews. From these interviews, the team analyzed the data to understand people's tasks, philosophies and feelings about dealing with back pain. They used spreadsheets to organize and group themes and patterns based on verbs, from which they built out the mental model. Finally, the team used the mental model about low back pain to understand the major arenas of people's thinking. They found mental spaces such as *understand cause of my back pain*, *treat my back pain* and *adjust my life to deal with the pain*. Since the hierarchical design of the model lends itself neatly to information architecture, the user experience team was able to create naturally understandable navigation for the Healthwise information and tools, such as Symptoms & Causes, Treatment, and Living & Coping.

The micro-site content derived from this mental model has delivered on expectations. Users visiting the pilot site at a major health plan are finding the content they need and rating the content they review as valuable to them in managing their condition. The mental model diagram allowed Healthwise to see where they could support people better and where there were new areas that conventional thinking about low back pain health care did not cover (Figure 42.19).

42.4.4.3 Expanding to the Rest of the Company

Mental models have spread to the rest of the company. Healthwise sales folks explain the mental model process when they present the company's solutions, so that clients understand that the information architecture comes from real people and real stories. Executives have been open to expanding the ways to support one of the core philosophies that has guided the company, evidence-based information, because of what mental model research has uncovered. Not all information and tools that the layperson is after are based on traditional medicine. For example, the mental model about low back pain revealed the importance of chiropractors and acupuncture. In response, the Chief Medical Officer and his team expanded relationships with experts in these areas to help validate and improve the quality of information for complementary and alternative medicine, such as chiropractic and acupuncture, to people suffering back pain.

> Mental models are emphatically part of the DNA of Healthwise now," says Julie. Her user experience team has created mental models about wellness, coping with a health condition, and pregnancy. Healthwise plans to create products supporting people with these health interests. Julie notes, "Now product managers come to me asking us to create a mental model for a product. Two years ago, that wasn't even in our company vocabulary.

For more on the Mental Models approach to task analysis, see Young (2008).

42.5 CONCLUSION

Many usability practitioners do task analysis in one form or another, although often they do not recognize it as such, much as Moliere's character found the fact that he had been speaking prose all his life a revelation.

Some may hesitate to plan for task analysis because they think of it as too complex and time consuming to apply in real-world situations where time is always too short. In this chapter, we have tried to show that task analysis is a family of flexible and scalable processes that can fit well in almost any development environment.

Some may have thought of task analysis only in terms of highly structured ways of capturing minute details of specific procedures relevant to evaluating already created designs or developing training or documentation for already determined systems. In this chapter, we have tried to show that while such uses of task analysis continue, the more common use today is in developing a very broad understanding of users' work and is of great use from the earliest strategic planning stages through all the phases of predesign. Task analysis as laid out in this chapter continues to be useful throughout the process, being used at later stages to develop scenarios for user-oriented evaluations as well as in inspection methods.

Task analysis is a way to involve the entire team in understanding users. It provides ways to organize the mountain of unstructured data that often comes from field studies or site visits. It is an essential part of the process of creating any product (software, hardware, website, document) because products are tools for users to accomplish goals; products are all about doing tasks.

43 Contextual Design

Karen Holtzblatt

CONTENTS

43.1 INTRODUCTION

Contextual Design (CD) is a user-centered design process that takes a cross-functional team from collecting data about users in the field, through interpretation and consolidation of that data, to the design of product concepts and a tested product structure. CD has been used in companies and taught in universities all over the world, along with other user-centered design processes. This chapter introduces the steps of CD; for a full description, see *Contextual Design*[1] and *Rapid Contextual Design*.[2]

Over the last 20 years or more, the high-tech industry has moved from using an engineering-driven requirements and design process to more user-centered processes. It has moved away from tail-end usability testing of products conceived by collecting features from customers, users, internal stakeholders, and enhancement databases. Although, not all companies practice user-centered design, most know that achieving best-in-class solutions depends on designing from a deep understanding of what people do, so that products enhance the activities of daily life to make it more efficient and delightful. And in the last 20 years, product managers and designers alike have come to understand that a "deep understanding" of what customers or users do means collecting and working with field data.

Engineering-driven design can be summarized succinctly as, "putting 10 smart guys in a room to decide what might be 'cool' technology to ship." The ultimate challenge for organizations is that understanding the customer is hard, takes time, and challenges entering assumptions and job activities. The alternatives—talking to each other rather than users, building internal organizational buy-in for the next release, looking at surveys, analyzing bug and enhancement databases, and creating rapid high-fidelity prototypes, and showing the ideas to people in a focus group or on the web—feel easier and seem like a valid way to gather requirements. They also do not challenge people who are used to interact with tools to do social science type requirements work.

But as platforms evolved and evolved more, and as we moved from natural-language command line interfaces to WYSIWYG to VisiCalc to the web to the iPhone, "regular" people became the real customers. And like it or not, engineers, product managers, and user experience designers are not regular people. They love technology too much. Their instincts are not in sync with the lives of real people. Their willingness to mess with technology is not in sync with real people. So, if teams are going to design successful products for real people, they need to get exposed to and use reliable data about the lives of the people they design for.

Field data with a process to use it for design is even more important today than in the past. Why? Technology is filtering into every nook and cranny of people's lives. Twenty years ago, we were only just introducing the idea of understanding the lives of real people to companies making productivity software and tools for a market. Then, enterprise software companies became aware of the power of field data for driving new concepts for their products and ensuring their products really worked for people. Recently, companies making hardware/software products like mobile phones, medical devices, and measuring instruments have also started to become aware of the need for field data. All of these companies make products for sale. They need to pay attention to their customers or their products will not be bought. They are motivated to find ways to ensure that what they make will enhance and delight customers to be successful—and they need to deliver on time within an engineering process.

The value of field data for getting any technology system right has been discovered over and over by industry after industry. Recently, IT and businesses have started to recognize the power of field data. There are some early adopters, but only this year analysts are starting to talk about a user-centered model for business systems.[3] These same companies earlier recognized that they need data for their customer-facing websites, but that is not the same as using powerful data to help drive the internal systems that support the business itself.

Today, technology has infiltrated every aspect of the work of employees and the process redesign implies simultaneous process and technology redesign. More companies are realizing that understanding the employees as user is also a part of choosing and customizing third party systems. At the same time, these businesses are challenged by the changing expectations that employees bring from their personal life—web surfing, social networking, blogging, and lightning-fast finding that produces the right information. Figuring out what systems should be like for these workers is a big challenge requiring a deep understanding of both the business needs and the practices of the people.

On the consumer side we are in the middle of a serious business revolution. Technology is becoming a part of our cars and our homes. Utility companies want to reach into our houses to turn down our thermostats. Technology is challenging many traditional industries to look for new business models and products: publishing, music, retail, banking, and a myriad of other services. These companies are not used to designing their products as software products or web-based services. These companies do not have established organizational practices to help them understand how to translate their existing products and services into those supported by technology—that also produce revenue. And these existing companies are challenged by new start-ups who begin with the web and iPhone as their platform of reference, rather than the store or book.

As technology evolves across all these industries we need to acknowledge that the people who make the products are less and less like the people who use them. We cannot rely on the intuition of the builders guided by their inner sense of what works to produce things that work for people. Their personal experience is not reflective of the experience of the real users and the customers. This is the same challenge that software companies faced years ago when CD was developed. The users were not the developers and the customers took no pleasure in figuring out how the software worked. We moved from creating tools for developers to editors for regular people. We moved from computers that calculated, presented forms, and offered command line interfaces to WYSIWYG drag and drop, and the web. Product development came to be about developing for the average everyday worker and the person at home, at school, and at play. This challenge simply continues in industry after industry as more technology is integrated into that industry. The product managers, business managers, analysts, user experience experts, designers, coders, IT administrators, and all others who pride themselves on understanding and using technology are not the users, but they are the builders. And so, as organizations, we need to bridge the gap between the users of the products and the makers of the products. Thus, the CD was designed. CD is a process for understanding people and driving that understanding into the design of products and systems.

43.2 CONTEXTUAL DESIGN OVERVIEW

CD is a step-by-step process for helping a team collect field data and use it for the purpose of defining and designing products, systems, websites, mobile devices, consumer electronics, and so on. It takes a team from understanding the customer through analysis of that data to build a coherent view of the practices and experiences of the customer/user. Using that consolidated data, CD helps the team to interact with the data to produce a high-level product or solution concept. This constitutes the first phase of CD: requirements and high-level solutions. This first phase of CD is useful for any kind of requirements and concept generation where understanding the day-to-day behavior of people is necessary. So, for example, medical device companies may use only this phase of CD because innovations and solutions are a matter of science, not software. Or, when a company wants to characterize a market to see if it is a reasonable area to expand into, the team may use only this first phase of CD. A "no" answer in this case is as valuable as a "yes"—it saves money and ends arguments.

If a product that can be materialized and prototyped as the solution (such as a software, or a hardware device), the second phase of CD is appropriate. These steps help a team to work out the details of the design and validate the product/solution direction while gathering low-level requirements and finalizing the user interaction design. Validation of the high-level solution concept is critical to ensuring success; iterative design has long been recognized[4] as critical for determining the detailed design. Because the initial concept is generated from understanding the user—rather than just collecting a list of desired features—it is more likely to be the kind of product or system that resonates as valuable with people. But in all product development the devil is in the details—so this second phase of CD works out those lower level details in a collaborative process with the user.

CD is a front-end design process that can fit with any corporate methodology. Today, many user experience teams are challenged to work within the agile development process. CD for Agile is a variant of CD that works with agile methods. (See Section 43.4.5.) But CD can also be an integral part of process reengineering, providing methods to validate process storyboards with stakeholders and users. It can support internal development where phase 1 might be done within the business but phase 2 within IT. Of course, CD works with more traditional development processes as well.

One cornerstone of CD is that it acts as a framework or scaffolding for putting structure into a part of the engineering process that is typically unclear: how to get to the most important requirements to drive the next version of a product or system. It helps teams step through an organized process to collect data and generate solutions, all the while involving stakeholders and team members. Section 43.3 is a description of key techniques and some issues.

43.3 PHASE 1: REQUIREMENTS AND HIGH-LEVEL CONCEPT

43.3.1 Contextual Interview—Getting the Right Data

In order to design a product that meets users' real needs, designers must understand the users and their practices.* But as we have discussed, designers are not usually familiar with or experienced in the user activities they are supporting. If they operate from their gut feelings, they rely on their own experiences as users. Generally, designers are more tolerant of technology than average users, so they are not representative of end users.

On the other hand, requirements gathering is not simply a matter of gathering requirements by asking people what they need in a system, like gathering pebbles from a beach. A product is always a part of a larger practice. It is used in the context of other tools and manual processes. Product design is fundamentally about the redesign of work or life practice, given technological possibility. In addition, practice cannot be designed well if it is not understood in detail.

You cannot simply ask people for design requirements, in part because they do not understand what technology is capable of, but more because they are not aware of what they really do. Because the everyday things people do become habitual and unconscious, people are usually unable to articulate their practices. People are conscious of general directions, such as identifying critical problems, and they can say what makes them angry at the systems they use. However, they cannot provide day-to-day details about what they are doing. This low-level detail of everyday practice is critical to ground designers in what is needed before they invent how technology might augment the process.

The challenge of getting this design data is designing a technique to get at the data that is unconscious and tacit. The first step of CD is Contextual Inquiry, our field data gathering technique that allows designers to go out into the field and talk with people about their work or lives while they are observing them. If designers watch people while they work, the people do not have to articulate their practices. If they do blow-by-blow retrospective accounts of things that happened in the recent past, people can stick with the details of cases using artifacts and reenactments to remind them of what happened. Contextual Inquiry overcomes the difficulties of discovering tacit information.

In CD, the cross-functional design team conducts one-on-one field interviews with users in their workplaces (or life spaces), focusing on the aspects of the practice that matter for the project scope. The Contextual Interview lasts about 2 hours and is based on the following four principles that guide how to run the interview:

- Context—While people work, gather data in the workplace and focus on the activities they are doing.
- Partnership—Collaborate with users to understand their work; let them lead the interview by doing their work. Do not come with planned questions.
- Interpretation—Determine the meaning of the user's words and actions together by sharing your interpretations and letting them tune your meaning. When immersed in their real lives and real works, people will not let you misconstrue their lives.
- Focus—Steer the conversation to meaningful topics by paying attention to what falls within the project scope and ignoring things that are outside of it. Let users know the focus so they can steer, too.

The Contextual Interview starts like a conventional interview, but after a brief overview of the practice, it transitions to ongoing observation and discussion with the user about that part of the practice that is relevant to the design focus. The interviewer watches the user for overt actions, verbal clues, and body language. By sharing surprises and understandings with users in the moment, users and designers can enter into a conversation about what is happening and why it is happening, and the implications for any supporting system. As much as possible, the interviewer keeps the user grounded in current activity, but can also use artifacts to trigger memories of recent activities.

The fundamental intent of the Contextual Interview is to help designers get design data: low level, detailed data about

* Some products, systems, and websites support the way people work, keep businesses running, or help users find needed information. Other products, systems, and websites address games, other entertainment, or consumer information to support life decisions. To gather data for these consumer products we have to look at people's life practice. To simplify language, this chapter will use practice to mean both work and life practice.

the structure of the practice and the use of technology within that practice. Contextual Inquiry, which is based on observing people in the context of their practices while they do their normal activities, has become standard in the industry as the best way to get this necessary design data.

43.3.1.1 Challenge: What Is the Field?

Collecting data in the field allows us to see the whole context of the users' practice: where they do their activities, how they do them, the tools they use, people they interact with, interruptions, breaks, and organizational props. Being in their own environment also ensures that the work we observe and discuss is real to them. It is not an artificial task in which they have little motivation. Being in the field also ensures that we can see them using not only the target product but related products; not only the target activities but related activities. As a result, field data lets us see adjacencies and constraints as well as the details of the actual practice. Adjacencies are key when looking for places for product expansion.

Today we know that a conference room, a usability lab, or a coffee shop is *not* the field—unless they happen to be where the real work is done. These locations engender out-of-context discussion and opinion ungrounded in real experience; or they impose artificial tasks that do not have the real load, context, or motivation of real life. Clearly a structured questionnaire or a conventional interview (directed by the interviewer) is not the same as following the work as it unfolds with the user. Only in that context will we see unarticulated and tacit experience.

But budgets are tight and today we have remote meeting software. What about a virtual field visit—is not that still the field? I heard of one company that conducts such "visits" with all the developers sitting behind the one person conducting the "field interview"—just like they used to sit behind the one-way mirror of a usability lab. We know that developers resist traveling, and that it is expensive. But a group experience like this does not engender the intimacy needed for genuine human connection and valid data between the interviewer and the interviewee. And this setting feels much more like the one-way mirror of the usability lab or focus group. Users know they are being watched—they feel that they are on stage.

Even if we maintain the one-on-one interviewing relationship, we lose the larger physical, social, and work context. Yet "traveling overseas" without the cost of travel is seductive. So this is our rule of thumb: *if* the scope of the project is small so that all the work/activity is performed online and in a tool, and *if* you have already done most of your field interviews in the field (60%), then adding on a few remote interviews to extend your reach can make sense. In the end, engineering is always a trade-off. We think this is the best way to make this one.

43.3.1.2 Choosing Customers Depends on Project Scope

The number of people that should be interviewed is directly related to the project scope. The wider the scope, the more people need to be interviewed to cover that scope. Our rule of thumb for a small scope, such as top 10 problems, usability improvement, next product release, or checking a planned design, is six to ten users from three to five businesses covering one or two roles. The more roles you need to cover and the more contexts (type of business, characteristic of person, and geographic location), the more people you need to interview.

When analyzing the project, first identify the job titles or roles targeted and the people that support the activities to be studied. Remember, the work or life practice that users engage in is what counts—if one person is called a system administrator and the other a database administrator, but they do the same work as it relates to the project, it does not matter that their job titles are different. We interview a minimum of three individuals per role; four is better.

If the product is to support people across different contexts (e.g., different industries) what matters is whether the contexts imply a different practice. In real estate, for example, the work is structured differently within the industry: a group of small, distributed agencies, a large corporate real estate company, and an in-house real estate representative. In each situation, the communication, sharing, and work management is likely to differ, creating three different practice patterns. To cover real estate, you need to collect data in all three contexts. We try to interview at least two businesses or independent set of people per practice pattern.

If, for your industries, there are no changes to practice patterns, then simply touch multiple industries without worrying about overlap. In this case, wide diversity is best.

The goal in selecting users to interview is to get enough repetition in the practice so that each role and contextual variable has three or four interviews that represent it, remembering that any one person may represent several of the contextual variables. As long as you have overlap, you will be able to find the common structure and key variations in the practice. Remember, paper prototype interviews later will expand the number of contexts and roles represented in the whole project.

43.3.2 Interpretation Sessions—Creating a Shared Understanding

Contextual Interviews produce large amounts of customer data, all of which must be shared among the core design team and with the larger, cross-functional team of user interface (UI) designers, engineers, documentation people, internal business users, and marketers. Traditional methods of sharing through presentations, reports, by e-mail do not allow people to truly process the information or bring their perspectives into a shared understanding. CD overcomes this by involving the team in interactive sessions to review, analyze, and manipulate the customer data. We recommend a cross-functional team of two to six individuals composed of, for example, a user researcher or business analyst, an interaction designer, a product manager, a developer, and so on. At least two team members should be full time on the project—but others can participate less often.

The interpretation session is a 2-hour commitment which should occur within 48 hours of the field interviews. The team gathers in the design room, where the interviewer tells the story of the interview from handwritten notes and memory. Plan to have at least three individuals in an interpretation session for each interview.

Team members ask questions about the interview, drawing out the details of this retrospective account. One person is the recorder, typing notes online. The team member who did the interview retells the story being captured. Any additional participants listen and point out the key issues to be captured. Each team member brings a different perspective to the data, whereas open discussion enables the team to arrive at a shared understanding. Participants ask questions, triggering the interviewer's memory and eliciting more data than would be available from a designer working alone. When the discussion sparks design ideas, they are captured in the notes.

The notes are displayed on a monitor or computer projector so that everyone can see them. These notes capture the key practice issues, cultural observations, breakdowns, successes, task patterns, design ideas, and any other interpretation or issue that has relevance to the project scope. Later these notes are transferred to sticky notes and used to build the affinity diagram.

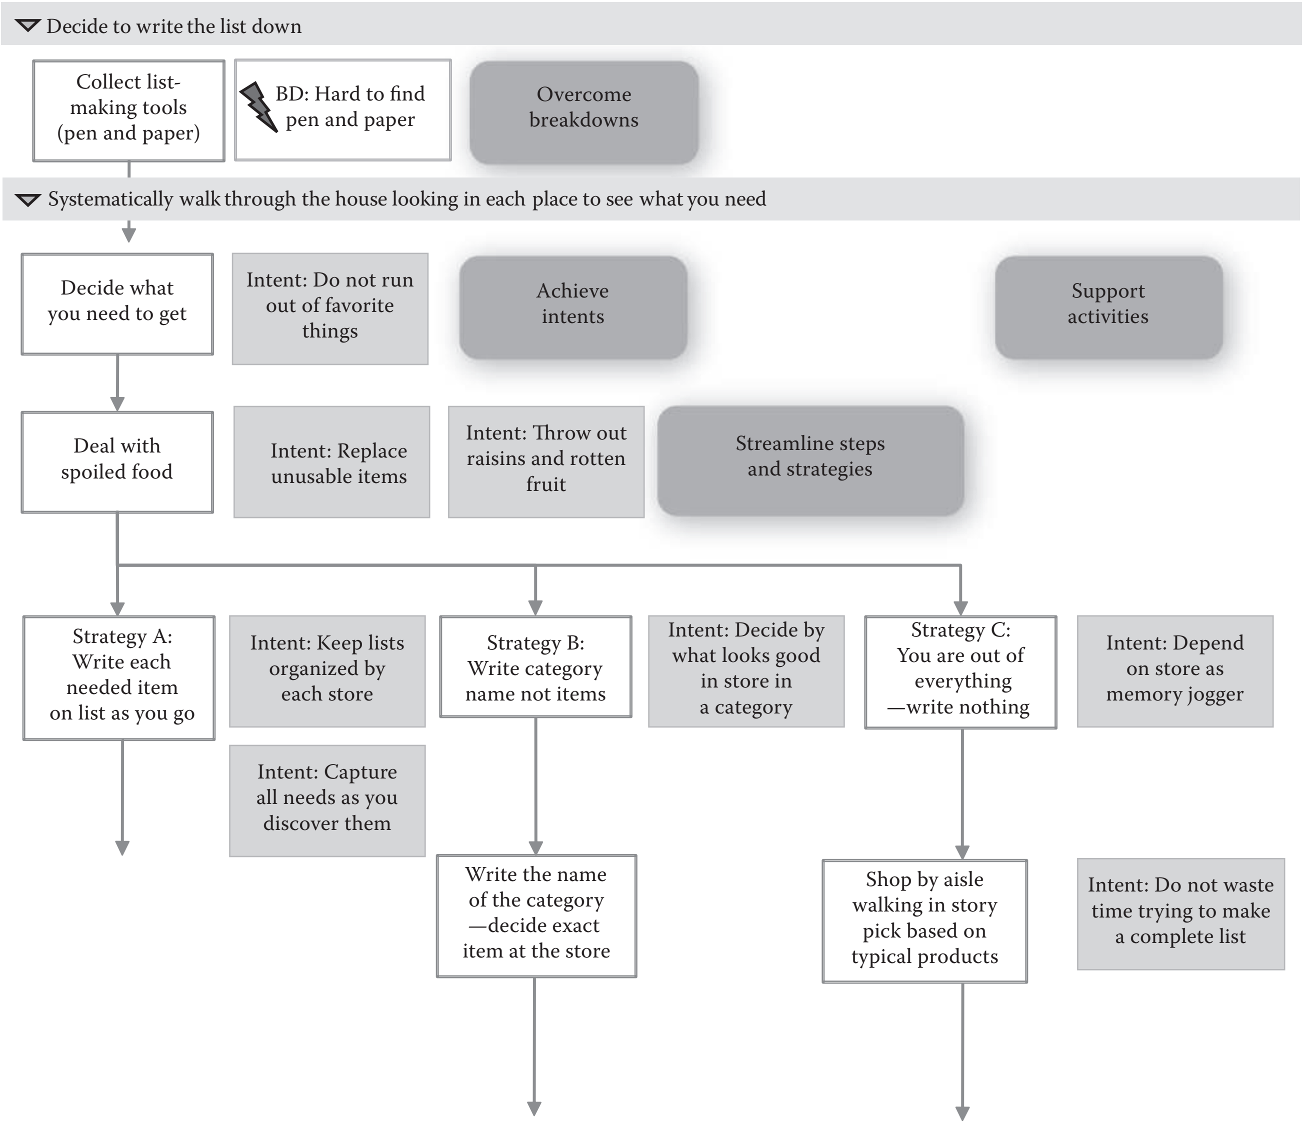
While we audio record interviews for backup; we do not transcribe the recordings or do videotape analysis. Both transcription and video analysis take too long, and video analysis limits the perspective to one person. Since videotape and photos are so easy with new technology, teams may choose to capture specific images and a recording for a later highlight tape to be shared with key stakeholders to give them a flavor of the users. But we believe that the return on investment (ROI) on tape analysis is simply not worth the time and effort—and slows down the process. Interpreting within 48 hours produces the detail that is needed by a design team and creates another context for sharing the experiences. You can include one additional stakeholder in each interpretation session as a way to share data as it unfolds.

43.3.3 Work Modeling—Revealing the Structure of the Practice

Work models capture the practice of people in diagrams. Work models reveal the structure of the practice from different points of view. Each point of view helps the team understand what is going on in the world of the user from that aspect of the practice. Practice taken in as a whole can be overwhelming; each work model abstracts out a different aspect of the practice to reveal what people do and care about from that point of view only. The team can discuss and invent for that part of the practice without getting overwhelmed. Different work models are important for different kinds of projects; part of project planning is to pick the correct models to use.

Work models are captured by modelers during the interpretation session. Relevant data is recorded in each diagram as it is revealed during the retelling of the interviewing story. Models are in addition to capturing the key issues, as described above.

- The *sequence model* (see Figure 43.1) is equivalent to a task analysis. It shows each step required to perform a task in order. A sequence model represents the activities of someone who will use the system. The sequence model also shows the breakdowns in the practice (as do all the models). The consolidated sequence models become the basis for redesigning the steps of the activities. This is the most basic work model and is used in nearly every project.
- The *flow model* (see Figures 43.2 and 43.3) depicts people's responsibilities and the communication and coordination required to support the work. The flow model reveals the actual human process used by a workgroup or individuals within an organization irrespective of time or order. When consolidated, the flow model is the key model for finding the core workgroups to support and for redesigning processes—both formal and informal. The flow model is important any time when a product or system is trying to support a formal or informal business process like selling, bill paying, buying, or collaborating as a team.
- The *cultural model* (see Figure 43.4) reveals the influences on a person, a group, or an organization, whether external to the company (such as law) or internal company policies (standards). It reveals the cultural milieu in which the product will have to succeed. When consolidated the cultural model is the key model for identifying the value proposition for the system and revealing influences on buying behavior. The cultural model is important any time when a project is focused on decision making such as buying, or is concerned about cultural values conflicting across populations.
- The *physical model* (see Figure 43.5) shows the physical layout of the work or home environment and the constraints it imposes on the design. The physical model captures the footsteps between places, the role of distance, and the use of space. It shows the way people physically structure their work environment and work space. The physical model captures the structure and flow of work as it is manifest in space. When consolidated, the physical model can reveal both how to redesign work within the space and also how to support work online that was previously manual. The physical model is always helpful—along with pictures—for helping the team get a flavor for the physical environment of the user. But it is particularly important for the design of kiosks or other technology that will reside in space.
- The *artifact model* (see Figure 43.6) shows how artifacts are structured and used during the performance of tasks. The artifact model is a key when a team is trying to take a paper artifact, like a medical



Decide to write the list down
Collect list-making tools (pen and paper)
BD: Hard to find pen and paper
Overcome breakdowns
Systematically walk through the house looking in each place to see what you need
Decide what you need to get
Intent: Do not run out of favorite things
Achieve intents
Support activities
Deal with spoiled food
Intent: Replace unusable items
Intent: Throw out raisins and rotten fruit
Streamline steps and strategies
Strategy A: Write each needed item on list as you go
Intent: Keep lists organized by each store
Strategy B: Write category name not items
Intent: Decide by what looks good in store in a category
Strategy C: You are out of everything —write nothing
Intent: Depend on store as memory jogger
Intent: Capture all needs as you discover them
Write the name of the category —decide exact item at the store
Shop by aisle walking in story pick based on typical products
Intent: Do not waste time trying to make a complete list

FIGURE 43.1 A sequence model showing the steps and strategies for a task.

record, and put it online. Analysis of existing artifacts identifies their intent, usage, structure, and information. Artifact models merge with physical models for designs for automobiles or technologies in the home. Space and usage of physical things reveal what is happening with the use of a complex product in space. The consolidated artifact model brings all the variations across users into one model so that they can be considered together for the redesign.

43.3.3.1 Challenge: Working as a Distributed Team

More and more companies are depending on distributed teams. Distributed teams have the advantage that data can be collected from different locations with less travel, which saves time and cost. However, any distributed team that has to be more organized is dependent on the latest collaborative technology, and needs to work harder to develop a shared understanding.

The interpretation sessions are easy to do in a distributed fashion. If you have collaboration or virtual meeting software, you can use that to run a distributed meeting. Simply display your word processor in a collaboration space so all can see the notes as they are typed. Get everyone on the phone and start the session as usual. As the interviewer tells the story, the recorder captures the issues and others can call out design ideas and ask questions to get at the details of what happened.

If you are capturing sequence models, capture those online in a word processor, switching the shared display from the interpretation notes to the sequence model as needed. Capture other models on paper, and periodically stop to check for correctness using video. If that is not possible, have them reviewed later by the other team.

The key to success is keeping everyone engaged. Be sure that everyone has a role and is actively participating. If someone has been quiet for a period, check in with him or her. Consider having both sides of the phone responsible for some type of data capture to ensure involvement.

Each bubble in the flow model represents a role. A job title plays multiple roles. Behind each role is a list of responsibilities the role plays. This flow model shows a process with the key work groups coordinating at each step in the process. Both formal and informal activity is depicted.

Finally, do not start distributed. Do your first interviews on the road together or in one location. Work out your process and your initial understanding of the users' activities, issues, and practices together. This becomes the bedrock of your shared understanding. After that, the distributed session works very well.

43.3.4 Consolidation—Creating One Picture of the Customer

Consolidating the notes and the work models creates a coherent representation of a market's or a user population's needs and activities. Then the design can address a whole population, not just one individual. The most fundamental goal of CD is to get the team to design from data instead of from the "I." If you walk in the hall and listen to designers talk, you will hear comments such as "I like this feature" or "I think the interface will work best this way." It is rare to hear, "Our user data says that the work is structured like this, so we need this function." It is natural for people who design to make a system hang together in a way that makes sense to them. But they are not the users, and increasingly, they are not in any way doing the activities of the people for whom they are designing. Getting designers, marketers, and business analysts out to the field and into interpretation sessions moves them away from design from personal preference. However, we do not want them to become attached to their users to the exclusion of the rest.

Product and system design must address a whole market or user population. It must take into consideration the issues of the population as a whole, the structure of work, and the variations natural to that work. The core intent of data consolidation is to find the issues and the activity structure and create a coherent way to see it and talk about it.

In CD, we consolidate the notes from the interpretation session into the affinity diagram and then consolidate each work model separately.

FIGURE 43.7 The affinity diagram.

The affinity diagram (see Figure 43.7) brings issues and insights across all users together into a wall-sized hierarchical diagram. The team prints the notes captured in the interpretation session onto sticky notes. The team then organizes all this data into groups, finding common underlying themes that cross the customer population. The process exposes and makes concrete common issues, distinctions, practice patterns, and needs without losing individual variation. Walking the affinity diagram allows designers to respond with design ideas that extend and transform the work. They write these on sticky notes and stick them right to the data that stimulated the idea. This encourages a culture of design from data over a focus on cool ideas generated from the "I."

The affinity is built from the bottom up, which allows the individual notes that come together to suggest groupings instead of trying to force them into predefined categories. Groups are labeled using the voice of the customer—saying what they do and how they think. A team of four can build an affinity diagram in 1–3 days. This is the place that we recommend using helpers—a one-day commitment can speed the process and expose stakeholders to the raw data building buy into the process and the data.

The consolidated work models show the detailed activity structure that the system will support or replace. For example, the sequence model shows each step, triggers for the steps, intents, different strategies for achieving each intent, and breakdowns in the ongoing work. Work practice redesign is ultimately about redesigning the steps in the sequences or the processes and practices represented by the different models. Whether the redesign eliminates or changes the steps or process, knowing the as-is process keeps the team honest, ensuring that any redesign does not forget the basic intents, collaborations, or activities that currently need to be performed. More often than not, technology introduces new problems into the practice by failing to consider the fundamental intents that people are trying to achieve. Redesign will better support the practice if it accounts for the existing practice—changing it consciously with consideration.

Every model helps the team think differently about the practice but the consolidated sequence is critical for nearly every system and acts as a guide for storyboarding or for streamlining any business processes. As such, it is nearly always used on a project. (See *Contextual Design* for guidance in consolidation.)

43.3.4.1 Personas Built with Contextual Data Reliably Focus the Solution

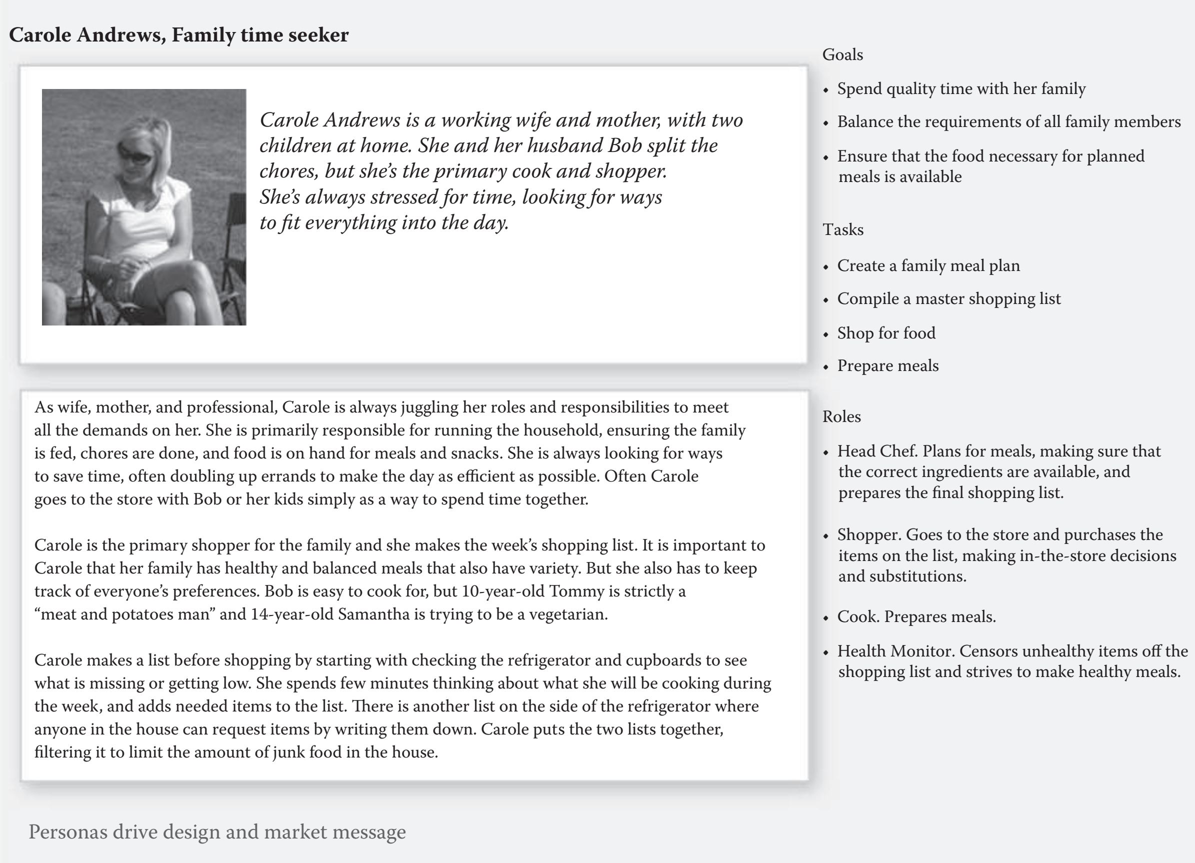
When your cross-functional team has worked together to gather, interpret, and consolidate customer data, you have developed a shared understanding of the users and their issues. You have not just built the data—you have experienced it in a way that others have not. Therefore, you may find the consolidated models and affinity to be evocative representations of the customer data you experienced, but others do not share that experience and cannot assimilate these models as easily.

Most teams need to communicate their understandings of user needs and their design plans to stakeholders—management, customer organizations, product groups, and so forth. These stakeholders, with no background in CD and no experience with the data, do not embody the memories of the real users from the field interviews. When they walk the data they can see the issues, needs, and breakdowns, but the power of knowing the users and their issues personally is not as poignant or personal.

Personas can help bring users alive and focus the stakeholders on the relevant issues, when they are built from rich contextual data. Popularized by Cooper,[5] a persona describes typical users of the proposed system as though they were real people. Their use is becoming more widespread, though with mixed success. According to Manning's research,[6] "A persona that is not backed by rich contextual data is not valid, which accounts for much of the mixed success." However, he goes on to say that, when backed by rich contextual data, they can help developers and designers not involved in the data collection focus on the needs and characteristics of their users. Anyone, trained in CD or not, can read this vignette and gain a sense of the typical user they are trying to support.

We build personas from the data collected and consolidated with CD to help focus on the characters we will vision about in the next step, to help stakeholders segment their market according to practice instead of typical demographics, to clarify branding and prioritization, and to bring the users and their needs to life for developers.

To build a persona, (see Figure 43.8) the team looks for core practice characters among the users, each characterizing a different way of doing the work. Expect anywhere from six to eight of these in a typical project. For each core character, find the base user: the user who most exemplifies this character. Then look at others who also manifest this character and borrow other relevant tasks, values, and life story elements to create your archetypical persona. This collection of exemplary facts then becomes the basis for your story of the named persona. With the rich user data in the affinity already grouped into issues, it is easy to harvest the data for the key elements that differentiate the different personae. Write a paragraph about the persona's



Carole Andrews, Family time seeker

Carole Andrews is a working wife and mother, with two children at home. She and her husband Bob split the chores, but she's the primary cook and shopper. She's always stressed for time, looking for ways to fit everything into the day.

As wife, mother, and professional, Carole is always juggling her roles and responsibilities to meet all the demands on her. She is primarily responsible for running the household, ensuring the family is fed, chores are done, and food is on hand for meals and snacks. She is always looking for ways to save time, often doubling up errands to make the day as efficient as possible. Often Carole goes to the store with Bob or her kids simply as a way to spend time together.

Carole is the primary shopper for the family and she makes the week's shopping list. It is important to Carole that her family has healthy and balanced meals that also have variety. But she also has to keep track of everyone's preferences. Bob is easy to cook for, but 10-year-old Tommy is strictly a "meat and potatoes man" and 14-year-old Samantha is trying to be a vegetarian.

Carole makes a list before shopping by starting with checking the refrigerator and cupboards to see what is missing or getting low. She spends few minutes thinking about what she will be cooking during the week, and adds needed items to the list. There is another list on the side of the refrigerator where anyone in the house can request items by writing them down. Carole puts the two lists together, filtering it to limit the amount of junk food in the house.

Goals

- Spend quality time with her family
- Balance the requirements of all family members
- Ensure that the food necessary for planned meals is available

Tasks

- Create a family meal plan
- Compile a master shopping list
- Shop for food
- Prepare meals

Roles

- Head Chef. Plans for meals, making sure that the correct ingredients are available, and prepares the final shopping list.
- Shopper. Goes to the store and purchases the items on the list, making in-the-store decisions and substitutions.
- Cook. Prepares meals.
- Health Monitor. Censors unhealthy items off the shopping list and strives to make healthy meals.

Personas drive design and market message

FIGURE 43.8 A persona built from Contextual Design data.

project-related life; get a representative picture; list the typical tasks, roles, goals, and other practice characteristics relevant to your project focus, and you have built a persona based on reliable customer data that you know represents your user population.

43.3.5 Visioning a New Work Practice

Visioning is about invention. However, design of technology is first design of the story showing how manual practices, human interactions, and other tools come together with your product or system to better support the whole practice. Visioning is the CD technique to help teams tell that story. Visioning is a vehicle to identify needed function in the context of the larger practice. Visioning ensures that teams put off lower-level decisions about implementation, platform, and UI until they have a clear picture of how their solution will fit into the whole of the practice. Teams commonly focus too much on low-level details instead of the full human-technical system. This is one reason systems often break the way users perform activities and fail to deliver something the market wants. Therefore, the primary intent of visioning is to redesign the practice, not to design a UI. Because a visioning session is a group activity, it fosters a shared understanding among team members and helps them use their different points of view to push creativity.

In CD, the core team visions a solution, but this is another time for bringing in stakeholders and helpers. A good visioning session has four to six participants. If helpers have been involved in the interpretation session and affinity building, they may want to participate in the visioning session. Again, this is about a 2-day commitment, which allows a wider team to participate in creating the solution direction.

The first step to a visioning session is to walk each consolidated work model in turn, immersing the team in customer data so their inventions will be grounded in the users' work. During the walk, team members compare ideas and begin to get a shared idea of how to respond to the data. Our rule is that no one gets to vision unless he or she has participated in walking the data. Without this rule, the process is no longer data-driven; anyone can walk in and offer their pet design ideas. Simply walking the customer data naturally selects and tailors preexisting ideas to fit the needs of the population. Since we will evaluate the visions based in part on fit to the data, knowing the data is important.

During the visioning session, the team will pick a starting point and build a story of the new practice. One person is assigned to be the pen. That person draws the story on a flip chart, fitting ideas called out by the team members into the story as it unfolds. The story describes the new practice, showing people, roles, systems, and anything else the vision requires. The team does not worry about practicality at this point; all ideas are included. Creating several visions allows the team to consider alternative solutions.

After a set of visions is created, the team evaluates each vision in turn, listing both the positive and negative points of the vision from the point of view of customer value, engineering effort, technical possibility, and corporate value. The negative points are not thrown out but used to stimulate creative design ideas to overcome objections. When complete, the best parts of each vision and the solutions to objections are brought together into one, named as synthesized practice redesign solution (see Figure 43.9).

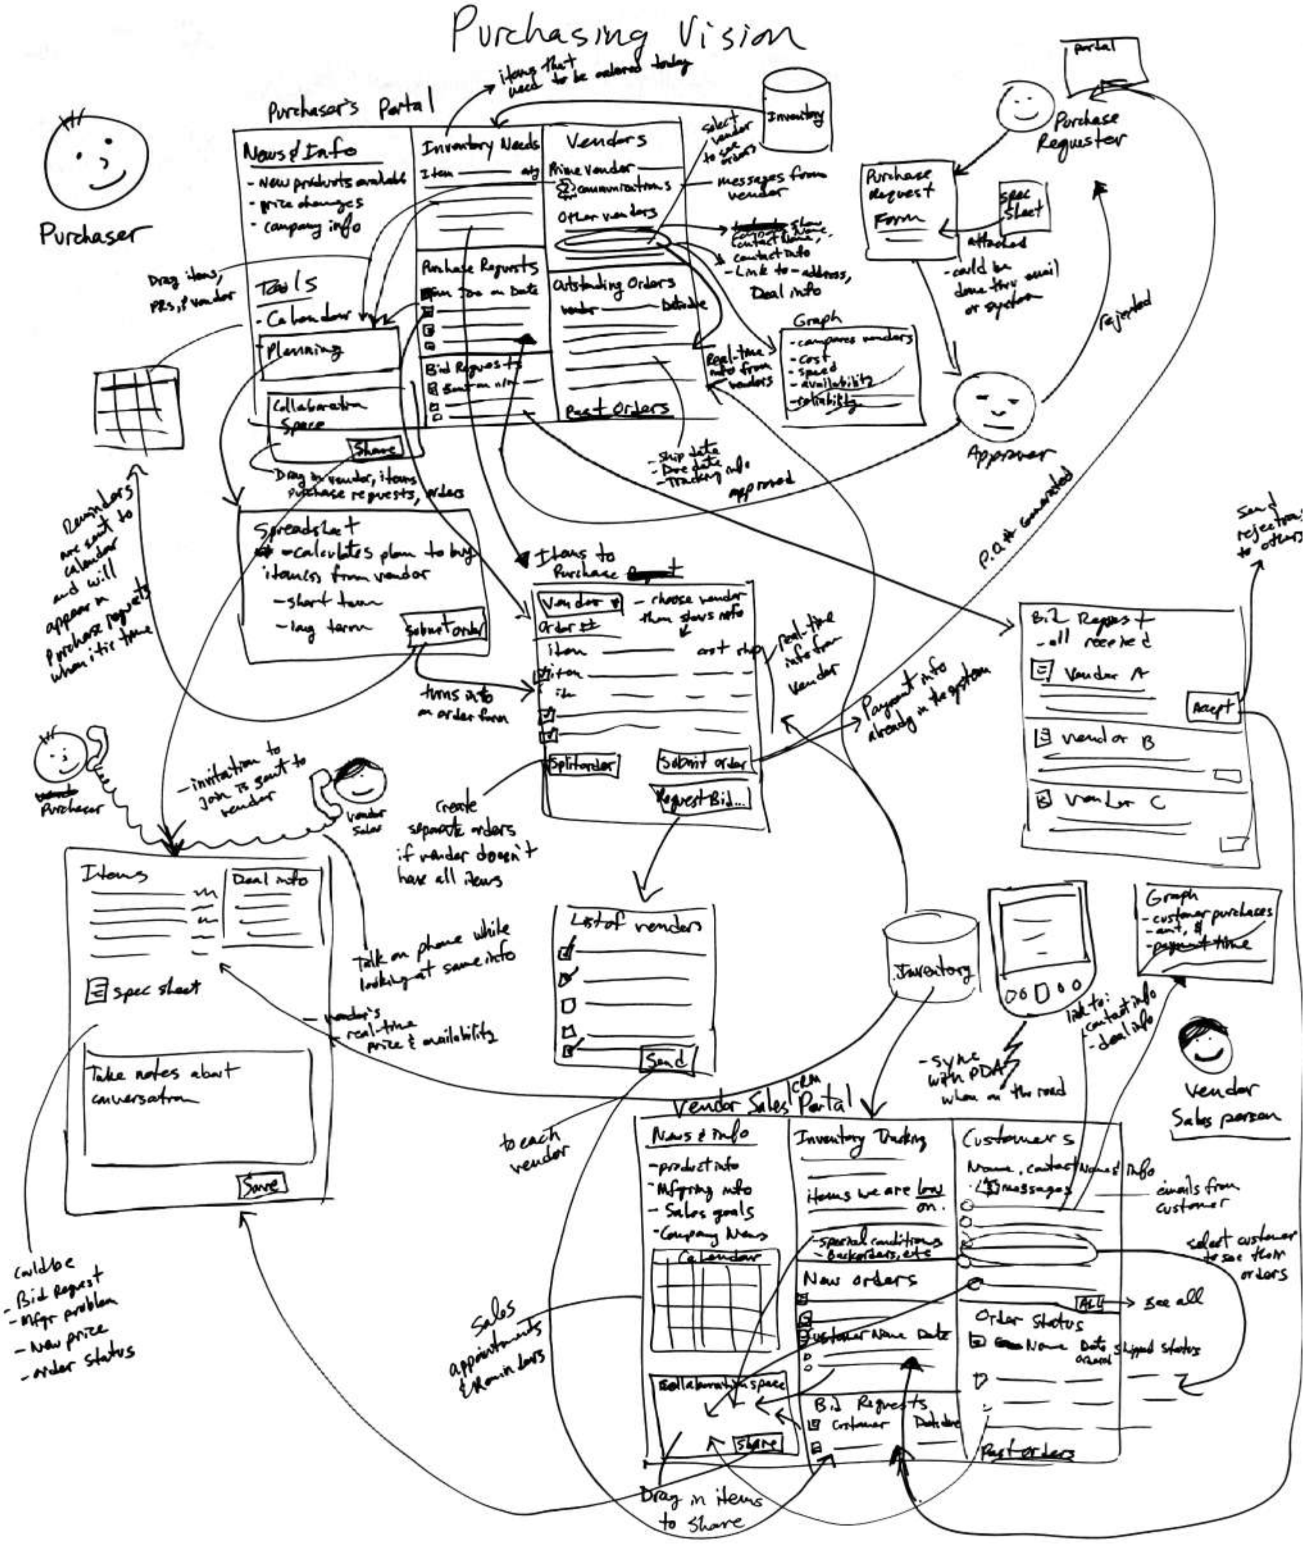


FIGURE 43.9 A complete, synthesized vision.

43.3.5.1 Challenge: You Cannot Invent from Customer Data

Every team we work with raises this claim. Customer data tells you what it is, not what it could be. How can you see the future by looking at the past? Here is what we say.

Every invention supports a real need—otherwise, why would anyone want it? Invention is a response to some life or work practice by a designer or technologist who, on seeing a need and knowing the technology, imagines a new possibility. Edison did not invent the idea of light; he saw candles and gas and electricity and invented light bulbs. Bricklin did not invent spreadsheets; he saw how paper spreadsheets are used and knew what technology could do.[7] The developers of WordPerfect worked in the basement below a secretarial pool. Nobody invents entirely new things that fulfill no need and contribute in no way to human practice; they invent new ways to fill existing needs and overcome existing limitations. As people incorporate these products and new ways of working into their lives, they reinvent it by adopting and adapting the new way of working. If designers are out there, seeing people living their lives with, without, and in spite of technology, they can see future directions for technology.

A vision is only as good as the team's combined skill. Customer data is the context that stimulates the direction of invention. However, no invention is possible without understanding the materials of invention: technology, design, and practice patterns. The visioning team needs to include people who understand the possibilities and constraints of the technology. If the team is supposed to design web pages and none of them has ever designed a web page, they will not be able to use web technology to design. When the people who always designed for mainframes were told to design windowing interfaces, they replicated the mainframe interface in windows. This is why we recommend that design teams include people with diverse backgrounds representing all the materials of design and the different functions of the organization. Only then will an innovative design, right for the business to ship, emerge.

We do not ask customers what to make; we understand what they do. Customers are not aware of the details of their practices, do not know the latest technologies, and do not know what your business is capable of—so they cannot tell you what to invent. We do not ask them. Instead, we understand what they are doing and capture it systematically. We immerse a design team—who does understand technology, the practice, and the business—in that data and let them vision. However, we are not done. The vision has to be right for people, so we take it out and test it. We let people test-drive the future in our paper mockups and let their tacit knowledge of their lives shape and direct our vision.

43.3.6 Scoping the Project—The Half-Way Point in CD

The vision, produced by a cross-functional team immersed in customer data, is the jumping off point for concurrent design:

- Interaction design: The vision guides the detailed design to produce the overall user experience architecture and final interaction design.
- Engineering: The vision contains implementation assumptions and challenges that must be looked at for viability before the company can commit to the vision.
- Marketing: The vision is the story of the new practice—the basis for communication to customers. Sales and marketing are always based on storytelling: how the new product will benefit the customer. Sharing the story in user groups, focus groups, and individual conversations is a good way to gauge sales point (the excitement that the new product will generate).
- Business planning: The vision can be used to drive marketing surveys and investigations to flesh out the business case.
- Business (or enterprise) process design: The data itself reveals the root causes of problems and suggests which processes to study more and measure. It also provides a representation of the as-is process to drive process mapping and as-is use for case development. The vision represents the new human-technical system that could be put in place to streamline the process. Rather than starting by improving the processes and then designing the system to support it, the vision redesigns the process and the technology as one integrated whole.
- Testing: The consolidated models drive test case development.
- Documentation: The vision communicates what the product or system is so they can start the introduction to the user's manual.

Because the vision is the center of the design, revealing direction for a system or product based on real user data, some companies may wish to transition to their existing processes after this step. But whatever the team does at this point they must pick the part of the vision that they will carry forward into detailed design and validation. A vision produces more than can be developed by any team in a reasonable amount of time. Many teams take 3–5 years to fully develop the ideas produced in their vision. In an agile or rapid CD project, the scope is constrained in the beginning—but even then a vision may produce design direction for several releases.

43.4 PHASE 2: DETAILED DESIGN

43.4.1 Storyboarding—Working Out the Details

Too often when people design, they break the existing practice because they jump from their big ideas to low-level UI and implementation design. As soon as designers start focusing on technology, technology and its problems become their central design concerns. How technology supports the practice is subordinated.

The steps and strategies of a practice, being tacit, are easy to overlook. If we are out in the field watching them, we can see them. This is what is captured in the sequence and other models. Storyboarding keeps the team honest and the design clean. Guided by the affinity diagram and consolidated models, the vision is made real in storyboards. Storyboards ensure that the team does not overlook any intents and steps that are critical to the practice. Even if the practice is changed, we have to think through the details of how it will be changed to ensure that adoption is easy.

Storyboards are like freeze-frame movies of the new practice (see Figure 43.10). Like storyboarding in film, the team draws step-by-step pictures of how people will perform activities in the new world of the vision. Storyboards include manual steps, rough UI components, system activity and automation, and even documentation use.

Because they focus on practice redesign, storyboards prevent the design team from prematurely delving into too much detail. They are guided by customer data, and after each task has been thought through and sketched, the team reviews it to ensure that it remains true to the customer data. This does not mean that no invention happens, but the team must account for the steps and other data elements of the affinity. They must look at them and make a conscious decision about how to handle them. They might change all the steps and even eliminate whole sequences; as long as people can still achieve their fundamental intents, the change will work. When teams forget or ignore the user's intent, the design is in trouble.

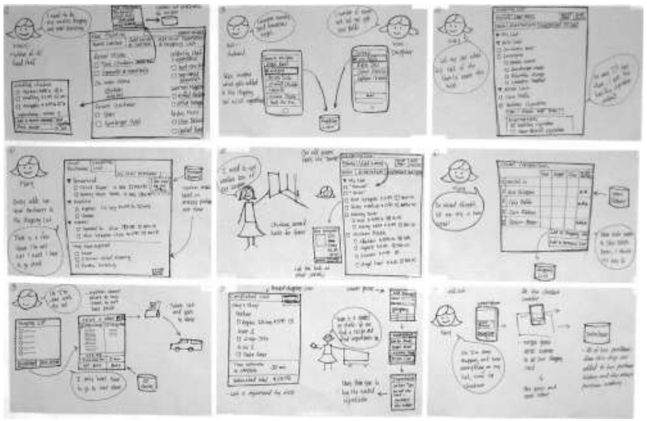

FIGURE 43.10 Storyboards are like freeze-frame movies.

43.4.2 User Environment Design

A good product, system, mobile device, or web page must have the appropriate function and structure to support a natural workflow within it. System design really has three layers. At the top, the visual design presents and provides access to the function, structure, and workflow provided by the system. At the bottom, the implementation makes that function, structure, and flow happen. But the core of a product is the layer in between: the design of the behavior of the system to support the user's redesigned work. Just as architects draw floor plans to see the structure and flow of a house, designers need to see the floor plan of their new systems.

Hidden within the storyboards are the implications for the system floor plan—the User Environment Design (UED) (see Figure 43.11). The UED formalism represents a set of focus areas or places in the system that provides support for coherent activities. A place might be a window, web page, dialog box, or pane. The UED shows each part of the system—how it supports the customer's work, exactly what function is available in that part, and how the customer gets to and from other parts of the system—without tying this structure to any particular UI or implementation design. The function defined in the UED drives functional specification and

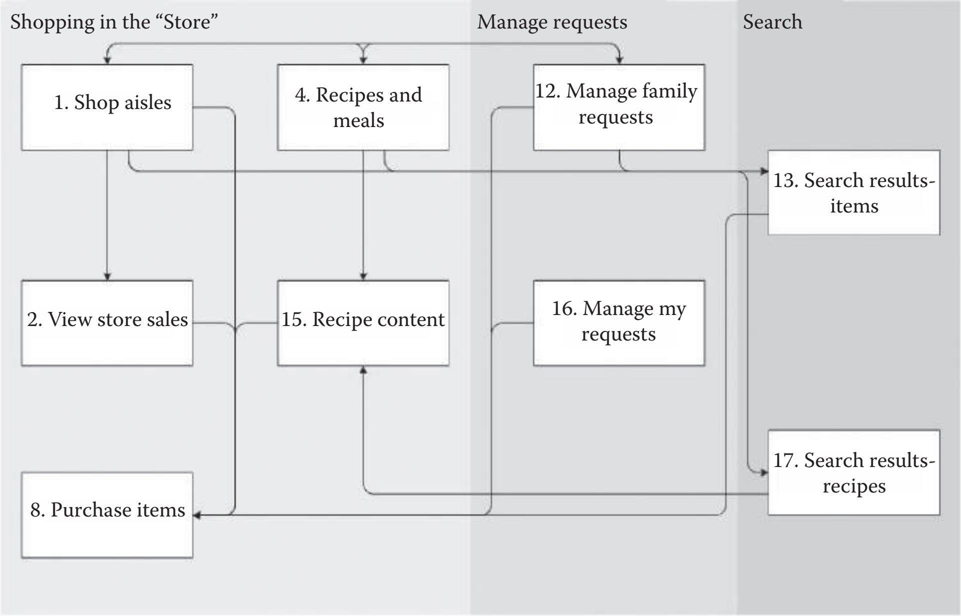

FIGURE 43.11 The User Environment Design.

implementation level use cases. The function in each focus area becomes the specification for the part of the UI that will support that function.

In creating a UED, the team walks the storyboards and derives the implications of what the system needs to provide. As the implications of storyboard after storyboard are rolled into the UED, the team starts to see the best way to structure the system. This system structure now represents the system that, if built, will actualize the vision as it has been worked out in the storyboards. Whether this system will be valued by the users has yet to be tested. Any design team can anticipate needed function only up to a point. Therefore, after working out the preliminary UED, the team mocks up each focus area in paper and tests it in mock-up interviews. Through iteration with the users, the UED stabilizes, the UI paradigm stabilizes, and the lower-level requirements are solidified.

43.4.3 User Interface Design and Mockup

After visioning, the team will work out their first cut at how to present their ideas in a UI. The team defines how to lay out the needed function and information represented in the UED into a set of rough screens representing the core places in the system. These places in the UI may augment an existing interface, add new places and features implied by the vision, or represent the changes that were worked out in more detail within the storyboards.

However, this function and initial layout is yet untested with users. To ensure that you have the right solution, testing and iteration is essential. To test your design concepts and clarify your functions, we recommend constructing a paper prototype and testing it with your user population in paper prototype field interviews. Users do not understand models or even storyboards when presented with them. However, users can talk UI talk, or form factor talk for physical products. So to test ideas, we move quickly through initial storyboarding and system structure to a rough UI to get back to the users with our ideas represented as UIs.

Many people have talked about paper prototype testing and its value, including Snyder.[8] Build the paper prototype using normal stationery supplies (see Figure 43.12). Card stock provides a stable background to simulate the screen. Post-its effectively simulate anything that might be moved during an interview, such as pull-down menus or buttons. Sample content should be put on a removable sheet so that users can replace it with their own real content during the

FIGURE 43.12 Examples of paper prototypes.

interview. Web content should be laid out, for example, products or content types to provide a context for discussing the structure of the content and its layout. For hardware designs, use other kinds of props to simulate the hardware. The final prototype is rough and hand drawn, but it represents both the system's structure and its behavior.

Mock-up interviews help designers understand why design elements work or fail and help to identify new function. These interviews are based on the principles of Contextual Inquiry given earlier. We test the paper prototype with users in their contexts to keep them grounded in their real practices. Users interact with the prototype by writing in their own content and manipulating and modifying the prototype. The partnership is one of co-design. As the user works with the prototype, following a task they need to do or did in the recent past, the user and designer uncover problems and adjust the prototype to fix them. Together the user and interviewer interpret what is going on in the usage and come up with alternative designs.

After the design has been tested with four to six users (depending on the scope of the project), we redesign to reflect the feedback. Multiple rounds of interviews and iterations allow testing in increasing levels of detail, first addressing structural issues, then UI theme and layout issues, and finally detailed user interaction issues.

We find that three rounds of testing result in a product or system that is valued by the users and has finalized the structure of the product, the user interaction design, the content type and tone, any navigation structure or information architecture, and clarified business rules. However, if you are moving into an agile process and additional testing will occur within the sprints, two rounds may be sufficient. You may also choose to put the third round online and use remote interviews to test the overall look in a more realistic environment. After two rounds of face-to-face testing in paper, a third round of remote online interviews can work well.

43.4.3.1 Challenge: Paper Versus Online Testing

Designers like tools. We are so often asked why we use paper mockups instead of online prototypes. We create mockups in paper because they are fast to assemble and they allow the user and interviewer to make changes to the interface in the moment. Hand-drawn paper prototypes make it clear to the user that icons, layout, and other interface details are not central to the purpose of the interviews; it keeps the user focused on testing structure and function. The rougher the mockup, the easier it is to test structure and function.

As the interface is tested, it starts to stabilize. At round three of the mock-up interviews, we begin to solidify the interaction design and build our mockups in wire frames. However, we still print and cut the wire frames up to allow for real co-design with the user and quick changes in the moment.

Toward the end of the prototype rounds, we use running prototypes to test low-level usability function that simply cannot be tested on paper.

How are mock-up interviews different from demos, rapid prototyping, or usability tests? The primary issue in answering this question is, where did the design being tested come from? Any time you iterate an existing design, you can expect not more than a 15%–20% change to the structure that is being presented. People will have an opinion about what you are showing them; it is much harder to find out that what you are showing them is not fundamentally valued. The question is what kind of data you can get in each context:

- Demonstrations at a user conference or in a focus group assume that people are aware of their practices, that out of the context of real use they can predict and project what they would need or want, and that their knowledge of their activities is not tacit but known such that they can bring it to bear in a discussion. We do not find this to be true. Demos and focus group discussions are better tests of sales point than function. They measure excitement with the product and clarity of the sales story.
- Rapid prototyping allows users' tacit knowledge to shape and tune a system that is being presented. Since the context of the discussion is to try to tune and shape what is already designed, the fundamental structure of the system and its value is rarely challenged. Some designers or technologists decided that the presented function was needed and should be structured in a particular way. CD does rapid prototyping, but only after systematically using customer data to produce the basic design to be tested. In this way, customer data shapes the whole of the design, not just the final testing.
- Usability testing can be another kind of rapid prototyping and as such suffers from the same challenges if the tested system is not originally designed from customer data. This is why usability professionals are at the forefront of pushing processes like CD into their organizations. They know that usability has to be built into the product during definition phase, not left to the end of the process. At some point, paper mock-up interviews are no longer good enough to test fine interaction with a tool. It may be possible to take a running prototype to the user on a laptop. If not, testing in the usability lab is an alternative. Even when testing a running prototype we recommend using Contextual Inquiry techniques: re-creating the user's own work tasks, discussing issues as they occur, and proposing design solutions.

43.4.4 Integrating Contextual Techniques into Standard Processes

Some companies have software methodologies within which any user-centered design process must fit. In general, CD can fit into any software or system development methodology. Most methodologies define a series of stages, each with deliverables and milestones. Few define specific ways of gathering requirements, so CD can easily be fit within the requirements step of these methodologies. Methodologies differ in the deliverables they require for their milestones. However, the natural data and design artifacts of CD can be used easily as inputs into any methodology's format.

Corporate methodologies typically follow a set of steps such as

- Business case. Define the marketing or work improvement rationale for building a new or revised product or system. Use phase 1 of CD to characterize an external market and generate product concepts that can then be further investigated and validated with focus groups, surveys, and other market intelligence. Or use phase 1 to understand the current business work practice—including the informal steps that are documented nowhere—and design business process and support system improvements. Use the vision with stakeholders to show the business value of the new direction.
- Requirements gathering. Gather user needs and overall business needs to guide building the product or system. Phase 1 of CD will also get the detailed data on issues and tasks needed to develop a product/system and phase 2 will result in system requirements at the level of the UI and core function. Some companies would be satisfied with requirements extracted from untested storyboards. Paper prototyping tests the requirements as well as the user interaction, so we recommend that you finalize your requirements after you define and test your UI.
- Design. Detailed design of the product or system, both the UI and underlying technology, making sure it can be implemented. Phase 2 of CD also results in the high-level design of the final layout and structure of the system and the function as it is presented to the users. Following multiple rounds of iteration and redesign you will need to scope the actual deliverable. Then specification and final design can be completed for the shipped product/system.
- Implementation. Code and test the UI and the overall system. Here you test the running system first with running prototypes and then during Alpha and Beta field tests using Contextual Inquiry to gather low-level and tactical changes.

All organizations have some sort of method or process that user-centered design must fit into. The challenge is how to communicate to the organization in a language they understand, and how to ensure enough time is budgeted for field research. Once you understand the methodology of your company, different steps of CD may occur at different points—but if you do them all (or a reasonable variant) you can ensure that your product/system will work for people.

Any methodology can use the consolidated customer data to drive brainstorming of recommendations, or the visioning process to generate a more systemic response to the data. Visioning is close enough to brainstorming, a known technique in any company, that it should be able to be easily adopted.

Similarly, paper prototyping is widely accepted as a means of testing design ideas and refining them. We recommend doing it in the field, with real user cases and not the canned test scenarios of some usability testing. This kind of prototyping is great for getting feedback from users and working out the details of a particular design. Sometimes this is the best first step in getting user data into a design and letting developers and designers alike see how their systems are being received.

CD can also become the basis for the development of personae to augment the design process. Usability testing is built into the process such that good user experience is a natural outcome of any CD project. If you just want to get started infusing user data into their processes, you can just do Contextual Inquiry interviews and build an affinity. In only a few weeks, you can begin to understand your market or user population and generate solution concepts.

43.4.5 Challenge: Agile Development and UX

Agile development is a relatively new approach to producing software. In contrast to the traditional approaches that emphasize requirements analysis, design, and implementation as distinct phases, agile methods seek to minimize upfront planning in favor of producing working base levels quickly and often. Feedback from these base levels is used to ensure that the resulting product is useful. Scrum[9] and XP[10] (Extreme Programming) are two popular agile approaches.

Agile techniques were initially promoted by the development community to protect themselves from changing demands. From their point of view, requirements constantly change and are unreliable anyway—providing the system as defined by the requirements offers no confidence that the system will be acceptable to users. So huge amounts of effort are poured into creating very large requirements documents which are unreliable and which change over time anyway. Then years go into developing the system—and by the time the system is delivered, requirements have already changed and the system is obsolete.

Accordingly, agile methods favor face-to-face interactions over formal documentation. Rather than writing the requirements down, agile teams seek to have the customer or product owner tell them directly about a needed function, right before coding on that function starts. To organize development, functions are written as "user stories"—simple index cards that describe one requirement at a high level. All the details of the design of that user story are worked out in conversation with the customer.

The customer role in an agile team is critical to its success. This role defines what needs to be done, prioritizes tasks, and works closely with the developers to work out each detail of the system. However, most agile teams are unable to put a real customer on the team—and when building for a user population or market, a single user's feedback is not enough. Consequently, they usually have a customer surrogate instead, who has all the difficulties we have discussed above in representing the real users. Scrum teams work with a product owner instead, who is given authority to make final decisions—but this product owner is not a real user either.

Agile methods organize development around short sprints, from 1 to 4 weeks in length. At the beginning of the sprint, the user stories to be implemented are selected. At the end, the resulting code is tested and the team reflects on their process. In theory, the project is re-evaluated at each sprint and could change direction completely. In practice, there is generally a strong expectation that the stories defined at the beginning of the project are the ones that will be implemented (just as they would have been in traditional development) and there is little time to rework stories that users aren't happy with.

Because agile teams distrust up-front design, they are impatient with user research. They would rather build something, test it, and change it instead of getting bogged down in a long design process. But it is very hard to develop a coherent UI within the constraints of short development sprints—and being developer-driven, agile methods do not provide for systemic design. Fortunately, agile teams in the industry have started to discover how difficult it is to produce a coherent product without doing some design work.

Agile development dovetails very nicely with user-centered design. Although there are some cultural clashes, the problems agile teams face are very much the ones user-centered design knows how to solve: how to have a reliable customer voice on the team; how to produce a systemic design to drive development; how to test and iterate that design with customers; how to do detailed UI design and testing in the middle of development sprints. We see CD integrated with agile as follows:

- Phase 0. We recommend starting an agile project with what many call a 'phase 0' or 'sprint 0'. This should last for 4 to 10 weeks, depending on the scope of the project and the number of roles to be supported. (Any single agile team can really only expect to implement for 2–3 roles, which limits the overall length of this phase.) At this time, the UX team can do Contextual Inquiry interviews with key roles, build an affinity and consolidate sequence models, vision with stakeholders, and do 0–2 rounds of paper prototype testing and iteration. The more rounds of testing they do the more stable the design; the fewer rounds they do the more they will need to test and iterate the low-level designs during sprints.
- Release planning. Development starts with a release planning session, in which the initial set of stories to be implemented is selected. The UX team participates in writing and prioritizing user stories. Each story describes an element of the vision developed in phase 0. The story does not have any of the design detail in it—"as a system manager I need to see what systems are down or offline at a glance"—might be the whole of a user story. These stories are prioritized into sprints, seeking to put the most important stories first and to produce a minimally useful system as quickly as possible.
- Sprint planning. Each sprint starts with a sprint planning session. User stories are selected for implementation in the next sprint, choosing only as many stories as the team thinks it can implement in the time. The team then plans tasks to complete the story. Some of these tasks should be for the UX designers—to work out the detailed UI design, consult with developers on system look and behavior, and test out any implementation. If multiple rounds of testing were done in phase 0, the story may need just low-level visual design and a sanity check with users; if few or no rounds were done, and then expect to need a few rounds of paper prototyping during the sprint or across multiple sprints to get the design right. Often, the UX work will take longer than the time of a sprint allows. In that case, expect to do the UX design work a sprint before actual implementation starts.
- Sprint execution. During the sprint itself, the UX designers perform their different roles. They go to users with prototype designs in paper or online. They communicate completed designs to developers who are starting work on stories. And they test completed code with users to ensure that the design as implemented meets users' needs.

43.5 CONCLUSION

The core of CD is getting customer data into the minds of product managers, designers, and developers. It provides the data that is needed to guide business decisions, prioritize requirements, identify how to streamline work, be clear on what will be of value to the user, and produce a high-quality user experience. Becoming user-centered is accessible today to any company that really wants to be user-centered. In these times when nontechnical products and services are becoming technical—when technology is becoming integrated into almost every aspect of life—design for people is even more important than it was 20 years ago. And as industries like publishing, banking, and retail are being challenged to create new ways to provide their services online, understanding the role of technology in people's lives and how to support them through products and services may be the difference between success and lost business.

44 Grounded Theory Method in Human–Computer Interaction and Computer-Supported Cooperative Work

Michael J. Muller and Sandra Kogan

CONTENTS

44.1 INTRODUCTION

Grounded Theory Methods (GTM) are a set of practices for exploring a new domain, or a domain without an organizing theory (Glaser and Strauss 1967). The practices are strongly *grounded in the data* and the theory is said to *emerge from the data*. These practices provide intellectual rigor for organizing an inquiry (Corbin and Strauss 2008; Charmaz 2006a, 2009; Gasson 2004). Most GTM inquiries in human–computer

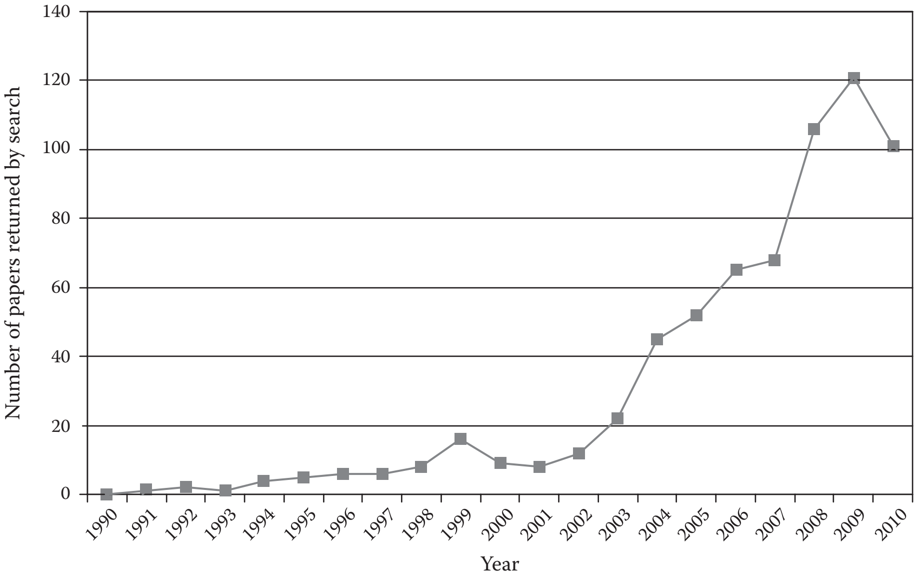

FIGURE 44.1 Grounded theory references in the Association for Computing Machinery Digital Library (2010 is an estimate based on data through May 2010).

interaction (HCI) and computer-supported cooperative work (CSCW) are based on qualitative data, but the same rigor can be applied to exploratory studies that use quantitative data, or a combination of qualitative and quantitative data (e.g., see contributions in Bryant and Charmaz [2007]; Morse et al. [2009]).

Grounded theory has been growing in importance. Hood (2007) reports figures from the Social Science Citation Index, in which grounded theory was mentioned in 101 journal articles during the 1970s, more than twice that number (296), in the 1980s, and six times that number (605) between 2000 and 2006. At the time of writing, the Association for Computing Machinery Digital Library lists 645 entries for the search “grounded theory,” with 180 articles on that topic during January 2009 to May 2010 (Figure 44.1).

44.1.1 Grounded Theory Addresses Human–Computer Interaction and Computer-Supported Cooperative Work Topics

In recent examples from the Association for Computing Machinery (ACM) Digital Library, grounded theory has been used in papers on software engineering, including developers’ orientation to new projects (Dagenais et al. 2010), metrics (Umarji and Seaman 2008), software testing and quality processes (Taipale and Smolander 2006), bug tracking (Bertram et al. 2010), and a developers’ open source community (Ge, Dong, and Huang 2006). Developers’ views on user interface design issues and team cohesion were also explored (Ferreira, Noble, and Biddle 2007; Whitworth and Biddle 2007), as well as their use of forecasting visualizations (Asimakopoulos, Fildes, and Dix 2009; see also Faisal et al. [2008] for end-user experiences with visualizations), along with developers’ social relations (Williams et al. 2007), their relationship to marketers (Jantunen and Smolander 2006), and the differences between their views and the views of their managers (Umarji and Seaman 2009). Managers’ views of software development were also explored (Adolph, Hall, and Kruchten 2008; Lee, DeLone, and Espinosa 2006; Morgan and Finnegan 2010).

In a more traditionally sociological framework, grounded theory has been used in the study of organizations (Sousa and Hendriks 2006), virtual teams (Sarker 2006; Sarker et al. 2001), and management of information systems methodologies (Goede and de Villiers 2003). In the organizational context, grounded theory has also been used to understand the transfer of training (Fincher and Teneberg 2007) and individual self-interruptions (Jin and Dabbish 2009).

Outside of the strict workplace context, grounded theory has helped to understand social phenomena in families (Dalsgaard et al. 2006), the needs of families managing collections of music (Sease and McDonald 2009), and viewing the contents of videos related to smartphones (see also Blythe and Cairns [2009]; Swallow, Blythe, and Wright [2005]). Accessibility needs have also been addressed (Kane et al. 2009; Savago and Blat 2009). In more personal domains, grounded theory has been used to study people’s formative experiences with computers (Schulte and Knobelsdorft 2007), impression management during disease (Mamykina et al. 2010), and value issues in games software (Barr et al. 2006).

Finally, in a more reflective way, grounded theory has been used to explore the needs of scholars in media studies (Kierkegaard and Borlund 2008) and for an examination of HCI methods (Nørgaard and Hornbæk 2006).

44.1.2 Grounded Theory Is a *Conceptual* Method

The “methods” in GTM are *not* a series of step-by-step procedures that are to be carried out with participants, or that are to be applied to data. Rather, the methods relate to *ways of thinking* about data (Glaser and Strauss 1967), and especially ways of making sense of the data (Charmaz 2006a,b), gradually and iteratively developing a theory to describe the data and the phenomena that are manifested through the data. Ideas, understandings, and new possibilities are recorded in a series of memos, which then form part of the structure of the report of the work. In the process of GTM, the theory is rigorously tested, again and again, by constant comparison with the data, and the series of tests both strengthens the theory and leads to new insights (Chiovitti and Piran 2003; Haig 2005; Stern 2007; Suddaby 2006). This combination of open-minded exploration and rigor is the hallmark of GTM (Bowen 2006; Stern 2007). It is also a perplexing paradox, and we will spend considerable effort in this chapter to make sense of that paradox.

44.1.2.1 Uses of Grounded Theory Method in Human–Computer Interaction and Computer-Supported Cooperative Work

Grounded theory originated in sociology (see Section 44.1.2.1.1), and has become a key methodology in certain fields such as nursing. In those fields, it is often used as the major organizing principle for an entire large project (see examples in Bryant and Charmaz [2006a, 2008]; Morse et al. [2009]). Within HCI and CSCW, GTM has also been used as a method for data analysis within a larger project, which is then integrated with more formal theories in the broader research literature. There are two major ways that researchers have applied GTM in HCI and CSCW.

44.1.2.1.1 Analyzing Data That Have Already Been Collected

Perhaps the most common usage in HCI and CSCW is to make sense of data that have already been collected. For example, a researcher might conduct a series of open-ended interviews with a predetermined sampling strategy. Once the interviews have been transcribed, the researcher could use GTM to discover the major themes that emerge from the interviews, and then develop a sense of conceptual categories among those themes, perhaps with high confidence about how several subthemes contribute to the same category. Then the researcher would set each category in relation to the other categories, finally producing a detailed analysis of the conceptual structure of how the informants described their experiences.

In this way, GTM is used to analyze data that have been collected in a relatively familiar HCI research program. In this structure of work, the domain is known; the type of data to be collected is known; the sampling strategy is known; and the number of informants has been predetermined. Most of the readers of this chapter have conducted research in this relatively familiar and straightforward manner.

44.1.2.1.2 Organizing an Exploratory Study

The second usage of GTM in HCI and CSCW is different, and is closer to the original intentions and claims of the methodology (Glaser and Strauss 1967). In this second usage, the researcher has only a general sense of the domain. The researcher collects an initial small sample of data, and then *immediately begins to construct a theory* of the domain. The researcher knows that the theory is based on insufficient data, and that therefore *the theory will be wrong in some respects*. The researcher analyzes his or her incomplete theory and determines its weakest point—a research strategy known as abduction (see also Peirce [1865/1982]; Reichertz [2007]). That weakest point becomes the focus for the next small sample of data. The researcher tests the theory with the intent of *learning how it fails* at its weakest point, and of making a stronger theory based on that failure.

The stronger theory is, of course, also incomplete, and shows the way to its own weakest attribute. Abductive testing continues with iterations of small data samples and further theorizing, that is, the researcher continues to try to make the theory fail. Each failure leads to more knowledge, and the theory becomes stronger, more detailed, and broader with each iteration. Finally, the researcher discovers that he or she is no longer learning anything new from each iteration, and the theory is ready to share with others.

This way of constructing theory follows a different form of scientific reasoning from the conventional paradigm of hypothesis testing (e.g., Popper 1968; Sanderson 2003; for discussion, see also Dodig-Crnkkovic [2002]; Greenberg and Thimbleby [1992]; Jaccard and Jacoby [2010]; Mackay and Fayard [1997]). Where hypothesis testing is often called *deductive* or *confirmatory*, GTM follows a form of *inductive* or *emergent* theory development (Glaser and Strauss 1967; Goulding 1998; Jaccard and Jacoby 2010). There is a large scientific and philosophical basis for inductive theorizing (e.g., Awbrey and Awbrey 1995; Dewey 1986; Eiter and Gottlob 1995; Menzies 1996; Patokorpi 2009; Peirce 1865/1982; Yu 1994), but it may be less familiar to many readers of this chapter. There is also a 400-year tradition of abductive reasoning, which is a core component—and a key differentiator—of grounded theory (Reichertz 2007).*

More controversially, there is a disagreement about whether grounded theory follows an objectivist research agenda (i.e., sensing the world *as it is*) or whether grounded theory is part of a post-objectivist, constructivist agenda that recognizes all scientific descriptions and theories as being contextualized in a particular culture, and potentially in the biography of a particular researcher (see Charmaz [2007, 2008]; more generally in HCI, see Kaptelinin et al. [2003]). The reader is entitled to know that our own views tend toward the constructivist position. However, most of the methodology of grounded theory can be applied across both sides of this disagreement, and we have been careful to present the material that is common to both perspectives in this chapter.

44.1.2.2 Strengths and Weaknesses of GTM: A Preview

Before we begin to provide details, it is fair to ask, *What is GTM good for in HCI and CSCW?* We provide some

* See also the International Research Group on Abductive Inference, http://user.uni-frankfurt.de/~wirth/.

quick answers here, and we will return to this question at the conclusion of the chapter:

- Grounded theory is useful to explore a new domain, or a domain without a dominant theory.
- Grounded theory is a useful method for *constructing* a theory of this new domain.
- Grounded theory is an excellent method for avoiding a premature conclusion about the domain. In medicine and forensics, we would say that GTM helps to avoid "confirmation bias," or the tendency to collect data that we expect to agree with our hunch (or our developing theory). The principle of abduction (Peirce 1865/1982; Reichertz 2007) is exactly opposed to confirmation bias, because it makes us avoid testing the theory at its strongest point, where we would expect it to succeed, and where the success will provide little new information. Rather, abduction teaches us to test the theory at its weakest point (Awbrey and Awbrey 1995), where we would expect it to fail, and where the failure will provide a large amount of information about how to improve the theory. Abduction helps us to be *surprised*, and surprise is often the gateway to new insights and the kind of "discovery" that is at the heart of the GTM (Reichertz 2007).
- Grounded theory is *not* a useful method for testing a hypothesis, or for trying to prove or disprove a theory (Suddaby 2006). The deductive, hypothesis testing methods are much better suited to that kind of problem.

We also think that GTM transforms a human weakness into strength. Most of us think about the data we are collecting. Most of us try to explain the data to ourselves and our colleagues, even while we are engaged in the early stages of a research project. In a conventional data collection discipline, this kind of informal theorizing is considered a problem. It can lead us to ask the wrong questions, or to bias the answers. It can cause us to make subtle changes in the way we analyze our data, or in the strategies we use for finding informants. We fear that we may unintentionally distort what was supposed to be a uniform process for collecting data in the same way from each informant. In conventional data collection, we try to avoid this kind of premature theorizing, and we try to discipline ourselves to prevent that theorizing from influencing how we collect data.

By contrast, GTM encourages us to theorize throughout the process of choosing where and how to sample, and throughout the period in which we collect and analyze our data. In GTM, we use our tendencies to think and to theorize as advantages. Rather than try to deny our thoughtfulness, we develop disciplines, such as abduction, to try to formalize our theorizing into a quality process that leads to new insights and new theories. As *thinking* scientists—as reasoners who are often passionate about our research—we can use the rigor of GTM to make us more fully human.

44.2 SYNOPSIS OF GROUNDED THEORY METHOD

Charmaz (2008) writes,

> Grounded theory methods consist of simultaneous data collection and analysis, with each informing and focusing the other throughout the research process. As grounded theorists, we begin our analysis early to help us focus further data collection. In turn, we use these focused data to refine our emerging analyses. Grounded theory entails developing increasingly abstract ideas about research participants' meanings, actions, and worlds and seeking specific data to fill out, refine, and check the emerging conceptual categories ...

Research using GTM usually begins with a broad, very shallow set of unorganized information (left side of the "Data" portion of Figure 44.2). Over time, through a series of disciplined procedures (Charmaz 2006a; Corbin and Strauss

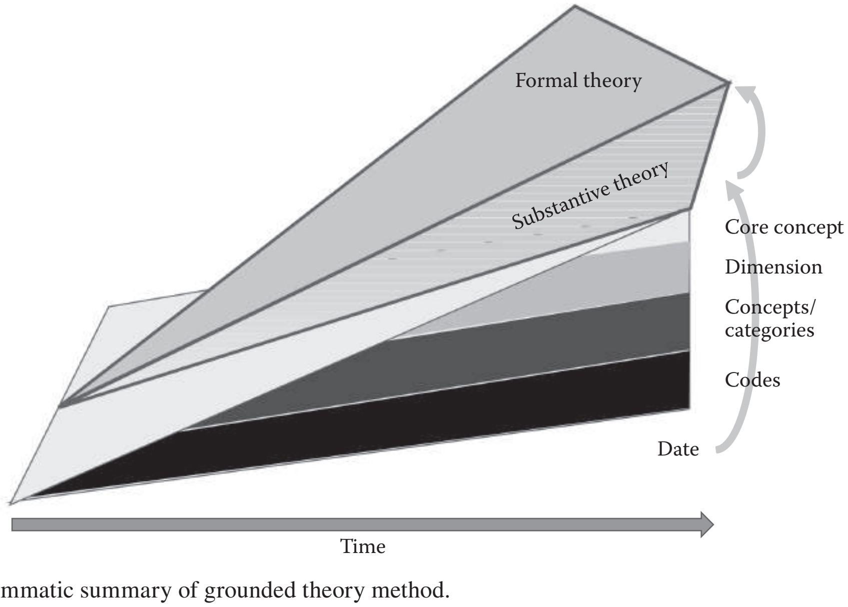

FIGURE 44.2 A diagrammatic summary of grounded theory method.

2008; Glaser 1978, 1992, 1998; Strauss 1987, 1993; Strauss and Corbin 1990, 1998), the information becomes more narrowly focused, and is understood in greater depth (i.e., moving from left to right in the "Data" portion of Figure 44.2) (Glaser and Strauss 1967). These disciplined procedures take the form of the following:

- *Coding* of the data in greater degrees of integration, breadth, and understanding (Star 2007), usually including
  - Open coding
  - Axial coding
  - Selective coding
- Development of *theory* through memo-writing (Charmaz 2006a,b; Dick 2005; Lempert 2007)
- *Theoretical sampling*
- *Constant comparison* of the developing theory with the data, always returning to the data (Glaser and Strauss 1967; Corbin and Strauss 2008)

Each of these concepts will be explained in the following sections.

As the data collection becomes more focused, the researcher begins to develop more and more powerful descriptions (theories) of the domain; in GTM, these are called "substantive theory" (Glaser and Strauss 1967) as shown in Figure 44.2. Finally, the substantive theory, which is developed from the data *internal* to the project, is brought into relationship with more formal theories from the research literature or from past investigations (Corbin and Strauss 2008; Lempert 2007). These more formal theories are *external* to the project, but are of course important in broader interpretations of the project, and in integrating the project's findings into the broader research literature.

44.3 BRIEF BUT NECESSARY HISTORY OF GTM

The history of Grounded Theory has been told many times (e.g., Bryant and Charmaz 2007; Charmaz 2006a,b, 2008; Locke 2001; Morse et al. 2009), and we will not rehearse it in detail here. However, it is helpful to know about a schism in the thinking of the two founders of the approach, and the "second generation" of grounded theorists (Morse et al. 2009) who have begun to heal that schism, and who are introducing new directions of their own (Figure 44.3).

Grounded theory was "discovered" during collaboration between Bernard Glaser and Anselm Strauss during the 1960s, and was first described as a methodology in their *Discovery of Grounded Theory* (1967). Glaser and Strauss had already worked together on topics of death and grieving (Glaser and Strauss 1965), and they continued their collaboration into the next decade (Glaser and Strauss 1968; Strauss and Glaser 1970).

In the logical positivist atmosphere of the 1960s in the United States, their insights were a revelation. Star (2007) described the impact of Glaser's and Strauss's early work as "a manifesto for freedom from the sterile methods that permeated social sciences at the time." Others were similarly moved; students gathered, and this new form of inquiry developed an enthusiastic and increasingly influential set of students, who in time went on to teach their own students about grounded theory.

44.3.1 Divergence

Subsequently, Glaser and Strauss proposed different types of procedures. Strauss favored a formalized set of methods, published in a series of theoretical works (Strauss 1987, 1993). With Juliet Corbin, Strauss provided and repeatedly revised a set of core procedural descriptions of methods (most recently

published as Corbin and Strauss 2008)—a work that has sometimes been called "the cookbook" by Strauss's students and *their* students. Strauss's work in methods—especially the series of methods revisions with Corbin—has been extremely influential, and has allowed researchers with no direct ties to Strauss or his students to become competent practitioners of GTM.

Glaser considered these finely detailed methods to be a form of interference between the researcher and the data, and critiqued the Straussian procedures as "forcing" the data into a straitjacket imposed by arbitrary procedures (summarized in Glaser 1992). Glaser's perspective focused intensely on matters of "sensitivity" and "emergence" (Glaser 1978, 1998). A researcher who had attained theoretical sensitivity (Glaser 1978) would learn to attend to the data, and the theory would "emerge" from the data directly to the researcher, without being "forced" through unnecessary Straussian procedures (Glaser 1992).

These differences of emphasis led to increasingly divergent practices. Strauss developed detailed coding strategies and a vocabulary of coding methods and even of the kinds of notes that researchers keep about their data (see Section 44.5.2), as well as recommendations about how to fit a grounded theory analysis into the prior research literature. By contrast, Glaser's emphasis on working *only* from the data until the theory *emerges* from the data, led to a strong rejection of specific steps or procedures, and an insistence that the research literature should be avoided during the early stages of a project, as more of a source of distortion than of clarity. Table 44.1 summarizes these and other differences between the two approaches.

Students of Strauss, and students of Glaser, learned two increasingly divergent sets of concepts and methods, while leaders of each school continued to claim that it was the correct form of Grounded Theory. Understanding and resolving the differences in perspectives became, for some, a critical problem (e.g., Kelle 2005, 2007; van Niekerk and Roode 2009). In their analysis, van Niekerk and Roode (2009) suggested that the two versions of GTM could look very similar to a novice researcher. Focusing on the difficult process of *conceptualizing theory*, they contrasted the procedural approach of Corbin and Strauss (2008) with a greater flexibility and creativity in the approach of Glaser (1978, 1992, 1998). In their view, flexibility and creativity are an advantage, but only for the experienced researcher. Unfortunately, mentors who follow Glaser's approach are few and far between (see also Simmons [1994]; Stern [1994]). The Corbin and Strauss approach (2008), and the syntheses of Charmaz (2006a) and of Clarke (2005), offer stronger guidance for people who need to use grounded theory in the absence of a mentor. For this *Handbook* chapter, we have relied more on those accounts than on Glaser's works, because Glaser wrote more as arguments to experts, or as supplements to a formal mentoring relationship (1978, 1992, 1998).

Some of the students made additional methodological refinements, and brought in additional philosophical

TABLE 44.1
Summary of Differences between Glaserian and Straussian Grounded Theory Method

Issue	Glaserian GTM	Straussian GTM
Who should try this?	Only researchers who have conceptual ability and theoretical sensitivity.	Anyone who is willing to learn the appropriate procedures.
Research question	None or very general. Learn from the data.	Begin with a question, and refine it through data and theorizing.
Use of the literature	After ground theory analysis is complete.	Before, during, and after analysis, as appropriate.
Theoretical sensitivity	Comes from immersion in the data.	Use and learn from appropriate methods and tools.
Questioning	Focus is always on the data.	Use the data to pose questions, and answer the questions through constant comparison with other data and new data.
Coding	Substantive coding (also called open coding). Open coding ceases as soon as a core concept emerges. Codes are then refit and refined around the emerging core concept.	Simultaneous and constantly compared open coding, axial coding, and selective coding. Categories and dimensions are integrated with one another, leading to identification of core concept, leading to further coding compared with core concept.
Causative model	None.	In some versions of the "cookbook," a generalized causative model is recommended.
Theory attributes	Parsimony, scope, and modifiability.	Detailed and dense, with full description of process to refine theory.
Theoretical outcome	Abstract conceptualization.	Full description.
Memos and diagrams	Ideas about categories and their relationships. Diagrams used as needed.	Memos help to develop abstract thoughts (theory) about the data. Different types of memos are recommended for different types of coding issues (open, axial, selective, etc.). Diagrams help to clarify relationships among categories.

Note: Because Glaser and Strauss pursued different approaches to grounded theory, there has been some controversy. Even the comparisons of their two approaches are somewhat controversial. For this summary, we draw on work by Bryant (2002, 2003), Bryant and Charmaz 2007), Charmaz (2006a, 2009), Corbin and Strauss (2008), Gasson (2004), Glaser (1978, 1992, 1998, 2003, 2004), Heath and Cowley (2004), Kelle (2005, 2007), Morse et al. (2009), van Niekerk and Roode (2009), Strauss (1987, 1993), and Strauss and Corbin (1990, 1998).

and theoretical concepts. Stern (e.g., 2007, 2009) pursued Glaser's approach, while Corbin (2009; Corbin and Strauss 2008) pursued Strauss's approach. Others developed their own innovations, many of which are summarized in Bryant's and Charmaz's *Sage Handbook of Grounded Theory* (2007).

44.3.2 Steps toward a Unified Practice

A group of noted GTM students gathered together as a self-described "second generation" of ground theorists, and published a set of essays and method descriptions, along with transcripts of their discussions, as they attempted to bring the diverse strains of GTM back into a common discourse space: *Developing grounded theory: The second generation* (Morse et al. 2009). Among the "second generation," Charmaz's work on constructivist grounded theory (2006a,b, 2008, 2009) has become influential as both a source of procedural advice and a statement of the responsibility of the grounded theorist for the theory that he or she reports.

In Charmaz's constructivist synthesis of Glaser and of Strauss, the work of the grounded theorist goes beyond "forcing" and "emergence" to become a conscious *construction* of theory, always guided by data and disciplined by a set conceptual procedures that add rigor, credibility, and accountability of the theorist to the data at every step of the analysis (Charmaz 2006a, 2008; for a partially convergent perspectives, see Bryant [2002, 2003]; Clarke [2005, 2009]; Seale [1999]). The synthesis in our chapter is based primarily on the "cookbook" by Corbin and Strauss (2008) and the procedural descriptions of Charmaz (2006a), as well as pertinent observations by Glaser (1978, 1992, 1998), and illuminated by the work of other grounded theorists as appropriate.

44.4 WORKING WITH DATA IN GTM

There are three major aspects of GTM: working with data, working with theory, and structuring a GTM research project. In practice, a grounded theorist has to think about all three aspects in parallel. It is easier to write and read about the aspects separately, and we will therefore present each subtopic in its own section. We will integrate the three aspects as we go.

As outlined above, GTM is deeply concerned with data at every stage of the analysis. It seems fitting to begin with methods for working with the data. Corbin and Strauss (2008) and Charmaz (2006a,b) outline a similar set of practices for working with data. To make the concepts concrete we will illustrate them with examples from several different research programs (Allen 2003; Charmaz 2006), including some of our own (Muller, Millen, and Feinberg 2009; Thom-Santelli, Muller, and Millen 2008).

44.4.1 Describing the Data

The core work of grounded theory is to describe the data and the domain of the data through a series of descriptive *codes*. The descriptions are both highly detailed and specific to the domain, but also become more generalized and applicable to other domains as well (Figure 44.2). Star (2007) wrote, "A code sets up a relationship with your data, and with your respondents…. a matter of both attachment and separation…. Codes allow us to know about the field we study, and yet carry the abstraction of the new." Writing descriptions that are both accurately detailed and powerfully abstract is challenging. Kelle (2007) comments,

> Glaser and Strauss's initial idea that categories would emerge from the data if researchers with sufficient theoretical sensitivity would apply a technique of constant comparison was difficult to realize in practice. Consequently, this idea was modified and refined several times in the ongoing development of grounded theory leading to a variety of different, new, and complex concepts like *theoretical coding, coding families, axial coding, coding paradigm*, and many others that supplemented and sometimes displaced the concepts of constant comparison and theoretical sampling from the early days.

Influential accounts of GTM provide a four-step process to help to meet the challenge of how to get started in coding (Charmaz 2006a,b; Corbin and Strauss 2008; Dick 2005; Star 2007): open coding, axial coding, selective coding, and the designation of the core concept.

44.4.1.1 Open Coding

Coding of data begins with writing simple descriptive labels. This process is usually called "open coding." Initially, open coding is done by creating labels for the persons, objects, or concepts in each item of data (typically, an interview transcript, or a paragraph in an interview). Over time, certain codes (labels) begin to recur, and the researcher can begin to keep a list of recurring codes. A number of software applications are available to help with keeping a list of codes, and with applying codes directly from the list to the data.*

There has been much discussion on the granularity of coding. For example, in a study of configuration management, Allen (2003) attempted to follow the recommendations in the second edition of Strauss and Corbin (1998) for coding by "microanalysis which consists of analyzing data word-by-word…" (Figure 44.4). He found this level of analysis to be too time-consuming, and to lose the pattern of the data in too much irrelevant detail. Allen switched to a procedure he called "key-point coding," in which he first excerpted useful sentences or statements, and then applied codes against those large units of analysis (Figure 44.5).

Our own work has used open coding to identify topics of interest. In a study of employees who create named "collections" of files in a social file sharing system (Muller, Millen, and Feinberg 2009), we conducted interviews via instant messaging, and we coded the text that was recorded

* Because both authors work for a large company that provides software, we are ethically bound not to comment on other companies' software products. Therefore, with regret, we will not provide information about the available commercial tools that can be used to support grounded theory coding, or other aspects of GTM. Interested readers can use words from this chapter as search terms to begin to find these tools and to find blogs and articles that review these tools.

in the saved chat-session logs. The "Open Code" column of Figure 44.6 provides an excerpt of open coding from one of those logs. For our purposes, coding at the level of each interchange (pair of turns) in the chat session allowed sufficient granularity without making the coding task—or its outcome—overwhelming.*

Many other discussions could be cited here (e.g., Charmaz 2006a,b; Corbin and Strauss 2008; Locke 2001). The choice of the granularity depends in part on the sheer quantity of the data. Small sets of data can conveniently be analyzed in great detail, almost as if one were performing a close reading or an explication de texte. Larger sets of data will necessarily require a more macro-level focus.

Initially, the labels in open coding are not part of an organized body of concepts. Organizing the open codes into more complex conceptual structures occurs in the next several steps.

44.4.1.2 Axial Coding

In axial coding, the researcher begins to find relationships among the open codes (Charmaz 2006a,b; Corbin and Strauss 2008). Some of the relationships lead to clusters of codes. Often, it is possible to name each cluster. A named cluster is often called a "category," and much of early coding in GTM is a search for powerful categories. The right-most column of Figure 44.6 provides examples of axial coding, in which the open codes are organized into more abstract conceptual categories (axial codes).

In some cases, the codes that are organized into categories are simple, mutually exclusive alternatives, such as color names. In other cases, the codes can be arranged in a sequence or along a scale of some sort, such as the stressfulness of life events. In the latter case, the category is often termed a "dimension," and another goal of early coding in GTM is to discover these dimensions and to arrange the open codes along the dimensions—a process that is sometimes called "dimensionalizing the category." A dimension is a powerful concept for organizing the data, and is a step toward the "abstraction of the new" that Star wrote about (2007).

The relationship of axial codes to their constituent open codes can be described in several ways. Some grounded theorists prefer diagrams. In Allen's study of configuration management (Figures 44.4 and 44.5), he detailed the relationship of multiple open codes to a single axial code, as shown in Figure 44.7a and b (for reasons of space, we have presented only two of his axial codes, in summary form). Here, we can see a reuse of some of the open codes that were introduced in Figure 44.5, but now they have been renamed and organized in relation to one another. By contrast, we used *textual* representations, as shown in the right-most column of Figure 44.6 (Muller, Millen, and Feinberg 2009).

Several different forms of diagrams have been richly investigated by Clarke in her situational analysis revision of GTM (Clarke 2005, 2009), intended to be used after some basic coding has been done. Her *situational maps* (Figure 44.8) are

similar to the diagrams of axial codes presented earlier (e.g., Figure 44.7), insofar as they can present a number of concepts in relation to one another, usually in a superset-subset visual organization. Clarke works back and forth between "messy" and "ordered" situational maps, as illustrated (by excerpt) in Figure 44.8. In the language of the preceding discussion, we interpret that the "messy" situational map contains primarily the open codes, while the "ordered" situational map organizes the open codes under axial codes.

Once a category or a dimension has been determined, the researcher may need to return to the data and recode the data in terms of the emergent concept that is summarized in the category or the dimension. For example, in the study excerpted in Figure 44.6, we had anticipated coding in terms of *Self* versus *Other*, but we had to return to each chat transcript in order to rework those open codes into the axial code of "Audience," and to catch all of the different types of audiences. While this return to the data takes time, it is an essential step in knowing the data well. In the language of Glaser, the constant return to the data is part of developing sensitivity, and allows the emergence of the insights that become theory.

Most projects are complex, and contain multiple categories and/or dimensions. The process described above—clustering open codes via axial coding, followed by recoding—may have to be followed multiple times, once for each axial code.

44.4.1.3 Selective Coding

Eventually, the researcher determines that some axial codes are more important than others. The researcher can then begin to focus on those sets of codes, and can begin to ignore the other, less important codes. By selecting certain codes for further development (Glaser, 1978, 1992; Corbin and Strauss 2008), the researcher is making a decision about what topics to pursue. When Charmaz (2006a,b) writes about *constructing* grounded theory, she is noting the importance of the researcher's choice in deciding what to focus on.

According to the standard sources for GTM, there are several ways to make this decision (Charmaz 2006a,b; Corbin and Strauss 2008). One way is to see which codes occur more often, or with greater generality across many different informants or different situations (Figure 44.8c presents a good example, in which the concept of "Nurses" is a strong organizing principle). A second way to do this is to see which codes occur in some contrasting pattern, for example, certain codes occur primarily with informants from one situation or attribute, while other codes occur primarily with different informants from a second situation or attribute (our *self-versus/and-audience* category from Figure 44.6 is a good example). A third way to do this is to note more complex patterns, or to understand that a particular category or dimension has explanatory power across many different situations or attributes. Each researcher will develop her or his own additional heuristics for deciding what is important.

Another way to determine importance is to consider broader, more formal theories that are *external* to the research project. This strategy was discouraged in the initial presentations of GTM (e.g., Glaser and Strauss 1967), and is anathema to the strict Glaserian school of GTM (e.g., Glaser 1992, 1998). However, HCI and CSCW make distinct demands upon researchers and research reports, including the requirement to explicate relevance to other work in the field. In our disciplines, it may be appropriate to consider formal, external theories at an earlier point in the research than in the "pure" grounded theory methodology from sociology and nursing.

Yet another possible heuristic is to consider the organizational setting in which the researcher is working. Grounded theory was developed in an academic setting, where researchers are often able to choose their GTM research topics based primarily on the data. By contrast, a GTM research project in an organization (Locke 2001) may be expected to produce answers to certain questions. During selective coding, it may be appropriate to choose topics based on those organizational priorities (e.g., what does the researcher's organization need to learn?).

In Allen's study, configuration management began to appear as a recurrent theme, as shown in Figure 44.7c. The two axial codes (Figure 44.7a and b) pointed toward the overall area of configuration management. However, other open codes and axial codes could have led in a different direction. Perhaps in part because of organizational priorities, Allen chose to narrow his focus to configuration management.

In our study of "curators" in file sharing, we began to see several key categories—*self-versus-audience*, and *self-sourced-versus-added-by-others*. Those two concepts emerged from the data. In addition, our previous GTM research in social tagging had led to similar categories of *audience* and also *impression-management* (see also Thom-Santelli, Muller, and Millen [2008]; Thom-Santelli, Cosley, and Gay [2006]). Based on the strong *audience*-related theme that we found in the initial file sharing codes, we used the external information from the social tagging study as an additional way to search for open and axial codes in the file sharing study. This step also required some amount of reviewing and recoding. The themes were indeed present in many of the interviews, and so we began to code selectively on themes of *self-versus/and-audience*, *source-of-file*, and *impression-management* around the role of the collection creator.

44.4.1.4 Core Concept and Closure

Finally, toward the end of the coding process, the researcher has to ask himself or herself, "What is this data a study of?" (Glaser 1978; also Kaufman 1986). What is the topic of this research? Once determined, the focal topic is often referred to as the "core concept" of the project and its report, and the process of determining the core concept is referred to as "closure." The answer to this question is found in the codes that were revealed through the previous step of selective coding—including the contextual constraints that were discussed in the Subsection 44.4.1.3 (e.g., need for relevance to other theories; fulfillment of organizational responsibilities).

How does the researcher determine the core concept? Opinions vary. In Charmaz's approach to GTM (2006a,b), the construct of the core concept is exactly that—a *construct* that is created as a human choice by the researcher, who then bears the responsibility for that act of construction. In Clarke's situational analysis, the accountability is also on the researcher, including a responsibility to ask (and to design the study to ask) *whose voice is not being heard (and why)? Whose silence is significant (and why)?*

By contrast, Glaser would claim that there is a kind of *inevitability within the data* to determine the core concept—that the core concept "emerges" after the researcher has spent sufficient time working with the data (e.g., Glaser 1992). Corbin and Strauss have tended to present a broader analytic framework that conveys its own *inevitability through the analytic process* leading to the core concept; at least one version of this analytic framework was entitled "The Paradigm" in earlier editions of their procedural work (e.g., Strauss and Corbin 1990).

In Allen's study, the choice made in selective coding led directly to the core concept of configuration management (Allen 2003).

In our study of file sharing, several interviews provided a key additional insight into how the file collectors viewed their own role, as shown in Figure 44.9a. All three of these informants appear to be engaged in an ongoing process of selecting files for their collections, with an explicit concern about how other people would be able to use those files (*collecting for others/audience)*. In addition, these and other informants also thought about how to name and describe their collections for the easiest discovery and use by others (Figure 44.9b).

These insights came from five informants in five different countries, and in four distinct job roles. Following the GTM principles of *theoretical sampling* (see Section 44.5.1), we tentatively concluded that this curator/editor code was found broadly across our sample. We also thought that the axial codes we had discovered earlier—*self-versus/and-audience* and *source-of-file*—were convergent with the concept of curating/editing. In addition, we realized that many people in a role similar to curators or editors would want to be known for their work, and that therefore the axial code of *impression-management* was also relevant. We conducted a last review of open codes and axial codes, and we reread selected chat sessions, and finally decided to construct our report around the concept of "curators."

44.4.1.5 Issues in Choosing the Core Concept

Is a core concept really required? Heuristically, most grounded theorists have recommended choosing a single topic around which to base an analysis, and choosing that topic as early as possible in the project (e.g., Corbin and Strauss 2008; Glaser 1978, 1992; Glaser and Strauss 1967; Locke 2001; Morse et al. 2009; Stern 2007; Strauss 1987, 1993). It is usually helpful for

A. Collecting for others

"regular collections with manually selected/curated resources.... trying to help people (and myself!) make sense of the files that are available.... putting together a collection and deciding what goes into it… and if they are different from the ones I've seen before then I add them to my collection…"(I15, enterprise 2.0 evangelist, Canada)

"a kind of editor, you share you own and other useful info via collections" (I18, sales, Finland)

"put some structure around the content I collect/create around my topic… what is good for me is good for my readers" (I19, product manager, France, already quoted in Figure 5).

B. Making the collection findable and usable

"very short descriptions… the intent of the collection – so I can keep the collection name really short!" (I9, project management, UK)

"sometimes I used the [descriptive field] to link to other related content [cross] reference" (I19, product manager, France)

and "i asked everyone to use the naming convention, and I enforced it" (I22, sales, USA)

FIGURE 44.9 Excerpts from the study of curators in a file-sharing service. (a) Code: *collecting for others*. (b) Code: *making the collection findable and usable*.

readers and reviewers if they know (to repeat Glaser's question [1978]) "What is this data a study of?"

But is this focus a *requirement* of grounded theory methodology? Or is it just a heuristic, or a rhetorical move, to increase the likelihood of publication? In their revision of GTM called "dimensional analysis," Bowers and Schatzman (2009) recommend delaying the choice of the core concept, and possibly keeping multiple core concepts throughout the later phase of the project. This is a minority view among grounded theorists, but it is available as a framework for researchers with complex domains.

In our discussion of the "uses of GTM in HCI and CSCW" (Section 44.1.2.1), we noted that some HCI researchers use grounded theory primarily for data analysis, and not to organize an entire project. In this case, the grounded theory part of the analysis is encapsulated within the broader project, and the "outcomes" of the grounded theory analysis may be partially structured by the requirements of that encapsulating project. For example, in a study of online communities (unpublished), we conducted a series of quantitative analyses of the social dynamics of more than 8000 distinct communities, and we used GTM to understand the attributes of a smaller number of communities that we had selected for detailed study. The results of the grounded theory analysis were then interpreted in the context of the broader quantitative study. In this case, the overarching themes of the research came from the quantitative study as well as the organization's needs, and we entertained multiple "core-concept-equivalents" as we developed and reported our grounded theory analyses. Other research projects have made similar uses of GTM to understand user comments or interviews within the context of a broader, multiple-method research project.

44.5 WORKING WITH THEORY IN GTM

Section 44.4 discussed how to code data, once the data have been collected. We also wrote, in the Section 44.1.2.1.2, that GTM advises to collect a small amount of data, and immediately begin coding and theorizing from that small sample. How is this done?

44.5.1 Theoretical Sampling through Constant Comparison

Outside of GTM, the conventional experimental approach favors either (1) large samples with high internal homogeneity or (2) stratified samples in which a particular variable is systematically varied (e.g., income or gender). The goal is to have sufficient data be able to characterize *all* the members of the large, homogeneous group, or *all* the members of each of the "strata" that make up the stratified sample (e.g., a homogeneous subset of high-income people, a homogeneous subset of medium-income people, etc.). By contrast, the usual initial strategy in GTM is to *sample for diversity* (e.g., Corbin and Strauss 2008). The assumption is that most interesting phenomena will become visible in the different ways that they occur across the diversity of people and organizations. Our observation of those differences will lead us to the factors that cause the differences, or at least the factors that are associated with the differences. Each set of observations is kept deliberately small, to allow for sampling across a greater diversity of people and situations.

44.5.1.1 Initial Sample

Remembering that the goal is to sample for diversity, the immediate question is, *How to start?* To choose the first sample of data, the researcher may try to find the most "representative" case or situation. Alternatively, the researcher might begin at an extreme of the range of possible person attributes or situations. For example, in our study of file sharing, we began by interviewing people who had used the "collection" features more than most other users. This initial sampling strategy assured us that we would receive a lot of information about collecting, but it also postponed interviews with people who were less frequent users. We made this choice, assuming that we would sample from the mid-frequency users later on.

We wanted to avoid any other source of bias in our sample, so we structured our list of high-frequency users in frequency order, and then we selected the informants such that they spanned as broad a range of attributes as possible. We interviewed at most one person from each country, and we tried to choose informants from as many different organizations as possible. This approach had the added advantage of avoiding the researcher's tendency to study other researchers. Using our criterion of different organizations, we would interview fewer members of the research organization, despite the ease of finding and recruiting them.

44.5.1.2 Subsequent Samples

In GTM, the first sample leads to the first set of codes, and then the first theory. The first theory allows us to make a quick, informal hypothesis—often of the form that, *if the phenomenon occurs under these circumstances, then it should (or should not) occur under a predictable second set of circumstances.* This hypothesis tells us how to choose our next sample: The second sample should abductively test the initial hypothesis. If the phenomenon occurs according to the hypothesized pattern, then that outcome strengthens the initial theory. If the phenomenon does not occur as predicted, then that tells us a limit to the initial theory, or tells us to recast the initial theory, or to replace it with a very different hypothesis.

44.5.1.3 Theoretical Sampling

The selection of the second (and subsequent) samples is made on the basis of the developing theory. For this reason, grounded theorists speak of *theoretical sampling.* In each case, the goal is to provide the strongest test *against* the developing theory (abduction), to reveal its weaknesses early, and to broaden the range of situations and attributes over which the theory makes good predictions or descriptions. As Charmaz writes, "Consistent with the logic of grounded theory, theoretical sampling is emergent. Your developing ideas shape what you do and the questions you pose while theoretical sampling" (Charmaz 2006a,b).

44.5.1.4 Constant Comparison

Theoretical sampling is a process of creation and destruction. What survives is a stronger theory, and a more informative—more powerful—way of describing the data. To continue Star's statement (2007) that we quoted in "Describing the Data,"

> Codes allow us to know about the field we study, and yet carry the abstraction of the new… When this process is repeated, and constantly compared across spaces and across data… this is known as theoretical sampling… Theoretical sampling stretches the codes, forcing other sorts of knowledge of the object… taking a code and moving it through the data… fractur[ing] both code and data.

Another way to describe this process is to say that data are always at the heart of ground theory, and that theory grows only by being tested against the data. Theory emerges *from the data* that we already have, and the emerging theory provides guidance about where or how to collect *the next set of data*. In summary, theory is repeatedly compared with old and new data. And new data are repeatedly compared with old data. As Star wrote, this is the principle of *constant comparison*, and lies at the heart of the inference process in GTM.

44.5.2 Memo-Writing and Writing from Memos

In keeping with the incremental nature of theoretical sampling, most grounded theorists write their emergent theory incrementally as well. In GTM, this process is called memo-writing, and is the recorded manifestation of the inference process, answering questions such as "what do I think is going on here?" and "what are the next data that I need to collect to test my theory?" and "what have I learned from the new data, and how do I code what I have learned?" and "what do I need to do next?" In the language of Section 44.5.1.3, "Memos are excellent source of directions for theoretical sampling—they point out gaps in existing analyses and possible new related directions for the emerging theory" (Glaser 2004). Consequently, memo-writing is begun as soon as the first data are collected, and continues throughout the project (Corbin and Strauss 2008).

Memo-writing is considered to be a necessary component in conducting a GTM project:

> Theory articulation is facilitated through an extensive and systematic process of memoing that parallels the data analysis process in GT. Memos are theoretical notes about the data and the conceptual connections between categories. The writing of theoretical memos is the core stage in the process of generating theory.

(Glaser 2004). Corbin and Strauss (2008) concur: "[Memos] force the analyst to work with ideas instead of just raw data. Also, they enable analysts to use creativity and imagination, often stimulating new insights into data." Charmaz (2006a,b) agrees: "Memo-writing constitutes a crucial method in grounded theory because it prompts you to analyze your data and codes early in the research process…. [N]ote where you are on firm ground, and where you are making conjectures. Then go back to the field to check your conjectures."

Memo-writing goes on simultaneously with data collection and coding. In the memos, the researcher writes her or his justification for the codes, and makes a note of potential alternatives, hypotheses not yet tested, and implications (Glaser 2004). Stern writes (2007), "If data are the building blocks of the developing theory, [then] memos are the mortar." Charmaz adds (2006a,b), "You write memos throughout your research. Memos provide ways to compare data, to explore ideas about the codes, and to direct further data gathering. As you work with your data and codes, you become progressively more analytic in how you treat them and thus you raise certain codes to conceptual categories."

According to Glaser (2004), part of what makes memo-writing valuable is that it prevents jumping to conclusions, and permits thought: "Memos slow the analyst's pace, forcing him/her to reason through and verify categories and their integration and fit, relevance and work for the theory. In this way, he/she does not prematurely conclude the final

theoretical framework and core variables." Corbin and Strauss agree about the importance of memo-writing: "Doing memos and diagrams should never be viewed as chores, or as tasks to be agonized over… [M]emos… grow in complexity, density, clarity, and accuracy as the research progresses… They move the analysis forward and as such are just as important to the research process as data gathering itself."

44.5.2.1 Forms and Genres of Memos

Memos can be long or short. Corbin and Strauss (2008) provide examples of memos related to many distinct perspectives and topics in a GTM investigation; not surprisingly, the length and structure of the memos vary from one-to-two paragraphs to a page or more. Charmaz (2006a,b) provides examples of memos that range from single paragraphs to well-structured essays, with explicit structuring of those essays using headers and sub-headers. By contrast, Dick (2005) writes that he always carries a supply of file cards, so that he can write memos as they occur to him; we infer that most of his memos are briefer than what can fit on a file card. Zaltman and Coulter (1995) used vignettes, and sometimes images. In our own research, our memos have ranged from writing multiple, numbered brief lines scribbled on a single file card, one memo per line, to a three-page, formally structured table that required several hours to produce with a word processor.

Specific memo-writing practices vary widely. Some researchers keep their memos in an organized set of files online. A few researchers record them sequentially in a notebook. Still other researchers write simple or elaborate diagrams (e.g., expanded versions of Figures 44.7, 44.8, and 44.10), or use software applications to generate diagrams from hierarchically structured codes (from open codes to axial to selective to core concept). For collaborative analyses, we often share memos online as documents in a social software application that supports collections of documents with controlled access to each collection. In addition to many textual examples, Corbin and Strauss (2008) described simple tables to explicate the relationship among multiple factors (Figure 44.10a), and causal diagrams to show hypothesized conceptual relationships (Figure 44.10b).*

Some researchers write specific genres of memos, while others do not differentiate. Using a memo classification scheme from Strauss and Corbin (1990), Jaccard and Jacoby (2010) described types of memos as follows:

> Researchers write down field notes to themselves about ideas and insights…which they then consult when analyzing their data, or when they formally posit their theory. One type of memo is called a *code memo*, which is a note relevant to the creation of coding or categories. A *theoretical memo*, by contrast, focuses on theoretical propositions linking categories or variables. *Operational memos* contain directions about the evolving research design and data collection strategies. Memo-writing occurs in the field during data collection and also during data analysis.

In their third edition revision, Corbin and Strauss (2008) proposed six general types of memos, but with less formality in the differentiations: open data explorations; identification and development of categories and dimensions; comparisons and questions; explorations among categories, dimensions, concepts; and development of a story line. By contrast, for Gasson (2004), all memos are "theoretical memos." As with much of the details of GTM, how the researcher adapts GTM to his or her own work is an emergent and highly personal process.

44.5.2.2 Connections through Memos

Stern's statement—that memos can serve as the "mortar" in constructing a grounded theory account (2007)—can be applied in several ways. First, memos can be used to summarize and integrate the findings from categories (Figure 44.11a) or

* However, the notebook format would interfere with another important attribute of memos according to Corbin and Strauss (2008), such that they would be capable of being physically sorted and rearranged. See Section 44.5.2.3. The use of online tools may provide most of the advantages of notebooks (dated, sequential entries) with sort-ability and may facilitate sharing and coordination as well.

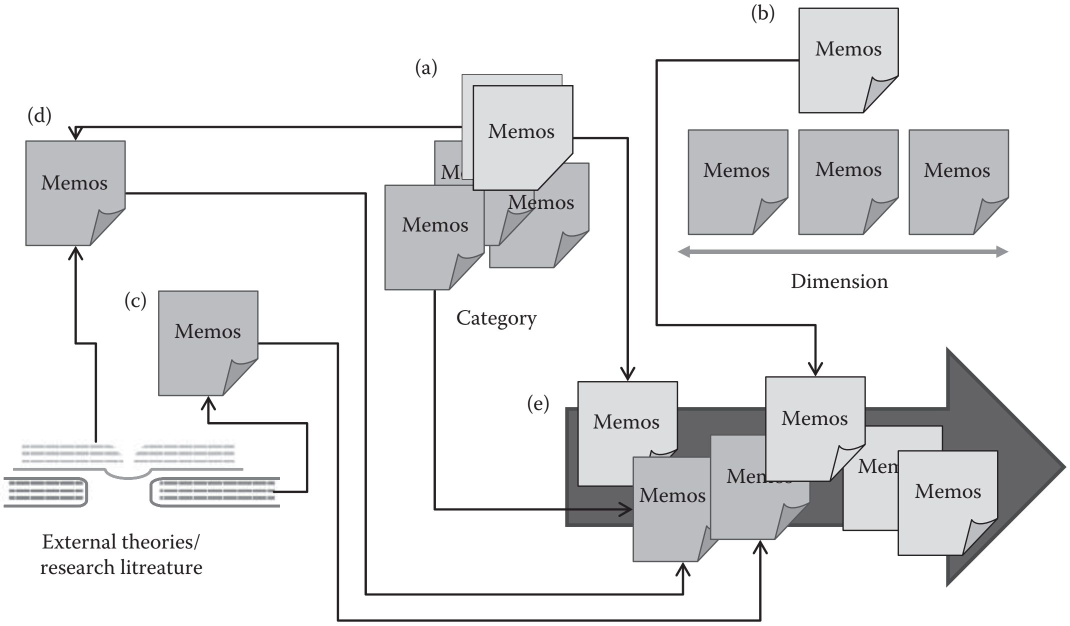

FIGURE 44.11 Memos in grounded theory model. (a) Memos based on category derived from data. (b) Memos based on dimension derived from data. (c) Memo from research literature. (d) Memo from data and research literature. (e) One prescription for writing the report based on the GTM investigation.

from dimensions (Figure 44.11b), that is, from concepts that originate in the data. In addition, as proposed by Glaser (2004) and as described in Pryor's thesis (2005), memos can serve as "mortar" between data and *external* information (Figure 44.11c), and between data and the research literature (Figure 44.11d). Memos provide an opportunity to try out different ways of exploring the meaning of data, or of connecting one item of data with another, or of looking for relationships among data, external knowledge, and the research literature. Some memos turn out to be valuable in report writing, while others can be "carried forward" into subsequent projects.

44.5.2.3 Writing from Memos

As we wrote, above, memos have much intrinsic value to the researcher during the process of doing the research, such as coding clarification; theoretical sampling, exploration of hypotheses; recording of paths not taken, and general support for the human thought and construction that is the core GTM activity. Memos are also valuable in the process of writing interim reports (which may stand as memos by themselves) and more formal results.

Of course, most researchers keep notes. What is special about memos in GTM? Grounded theory memos span predictable ranges, from instance to generalization, from concrete to abstract, from factual to theoretical (see Section 44.5.2.1). Over time, each concept of interest will have multiple memos related to it. When the researcher collects the relevant memos, he or she can assemble them into structure that "tells the story" or "makes the argument" about the relevant concept. Memos, thus, are both a concurrent tool for thinking, and also serve as an investment of sorts for later work, including report writing—as Glaser (2004) says, "a memo fund that is highly sort-able."

If, as Star said, "Theoretical sampling stretches the codes… fractur[ing] both code and data" (Star, 2007), then

> Sorting is essential—it puts the fractured data back together [because] the outline for writing is simply an emergent product of the sorting of memos…. Sorting… has a conceptual, zeroing-in capacity. The analyst soon sees where each concept fits and works, its relevance and how it will carry forward in the cumulative development of the theory.

(Glaser 2004). Glaser (2003) recommends finding a large surface and literally sorting the memos into the writing order for the report (Figure 44.11e). AlKaissi (n.d.) says, perhaps optimistically, "The sort structure is the report structure. It is often just a matter of preparing a first draft by typing up the cards in sequence and integrating them into a coherent argument." However, Stern (2007) cautions,

> The idea is to make labels act as rubrics for all known categories and their properties. Life isn't that tidy, and neither is memo sorting: it turns out that new labels are needed as categories collapse upon one another, and memos turn out to be misfiled and belong to another category.

In this necessarily challenging process, "Sorting helps the analyst integrate the theory; in the physical display of their thought processes, the appearance of the theory begins to take shape" (Stern 2007).

Memo-writing practices have implications for sorting. Dick (2005) and AlKaissi (n.d.) advocate writing memos on cards (e.g., file cards), which are easy to sort on a large table. By contrast, the longer memos described and shown by Charmaz (2006a) and Corbin and Strauss (2008) do not lend themselves to simple physical sorting: Most of these memos contain more than one idea. The diagrams-based memos (Figures 44.7, 44.8, and 44.10) that have been advocated by Clarke (2005) and Corbin and Strauss (2008) are unlikely to appear in their entirety and their multiplicity in a final report. The three-page table that we referred to from our own work presents similar problems.

Like so much of GTM, there is agreement in the overall concept of *writing from memos*, but each researcher will have to find his or her own set of personal best practices. In theoretical terms, memos can be used as a kind of externalization or crystallization of the researchers' thoughts (as in activity theory, e.g., Bazerman 1997), or can serve as a kind of extension of the researcher' cognition (as in distributed cognition, e.g., Ackerman and Halverson 2000; Hollan, Hutchins, and Kirsh 2000). Each researcher thinks differently from other researchers, and our work practices are different, and we think in a social context which may have its own requirements for information sharing at various stages of the grounded theory project (e.g., a researcher working alone as contrasted with a student being advised by a mentor). Some researchers will develop memo-writing strategies that are structured in terms of the eventual sorting process (e.g., AlKaissi, n.d.; Dick 2005; Glaser 2004). Other researchers will choose to make selected memos serve as collaborative documents, or highly specific and tightly focused interim reports on a particular concept (Charmaz 2006a; Corbin and Strauss 2008). Still other researchers will write memos containing first drafts of paragraphs, or even sections for their reports, or combinations of these practices.

44.6 STRUCTURING A GROUNDED THEORY MODEL RESEARCH PROJECT

Earlier, we wrote that there were three simultaneous components in a grounded theory project: working with data, working with theory, and structuring the project. We now turn to the third of those topics.

Grounded theory projects are both easier and more difficult to manage than conventional projects. The ease of management comes from being able to pursue new directions, and to use the researcher's developing knowledges and skills to follow-up on insights and possibilities. As we have said, grounded theory is as much about *thinking* as it is about the data, and it provides the thoughtful researcher with abundant opportunities to think long and hard and creatively and responsibly.

The difficulty of management comes from the potentially unbounded structure of the work. In a conventional, hypothetico-deductive project, the researcher designs a study with a known number of factors, a known number of informants, a fixed (and carefully planned) set of procedures that result in a set of data whose structure is known in advance, and a nearly automatic way of using the data to answer the research question. We know how to conduct these studies, and we know when each step is completed. By contrast, a grounded theory project has no "stopping rule" to tell us when data collection is complete, and when theorizing is complete. How do grounded theory researchers manage this problem?

One of the important concepts in grounded theory is "saturation" or having "saturated categories" (Charmaz 2006a; Clarke 2005; Corbin and Strauss 2008; Glaser 1978, 1992; Glaser and Strauss 1967; Strauss & Corwin 1990, 1998). The development of category or a dimension, from open codes through to selective coding, is a matter of going from concrete data to abstract concepts. Eventually, each new item of data produces less and less change in those abstract concepts—they become stable (a mathematician might say that they "reach asymptote"), and the categories on which they are based become fully connected with other categories and the emergent (Glaser and Strauss 1967) or constructed Charmaz 2006a) core concept. Because the categories are fully informed by data, and no longer develop, they are said to be "saturated." In a study of family violence, Stern (2007) describes the researcher's experience of saturation very persuasively:

> I realized that I had reached the point of saturation when the [informant] was telling me how when he was a small child he stood witness as his mother shot his father dead, *and I was bored*. I made all the right noises…but I knew that my data collection for that study had come to an end.

Another way to think about saturation is to refer back to the concept of abduction. As Reichertz (2007) reminds us, abduction is concerned with *surprise*, and with the structuring of a research project such that we are constructively and creatively surprised by new data and new concepts. When the surprise stops happening—when we are bored—then abduction is no longer taking place, and it is time to stop collecting data (and constructing theory), and time to start writing the report.

The process that we have just outlined is a "perfect" sequence for an academic research project with an unbounded timeframe and infinite resources. In practice, the researcher might face various constraints regarding time, access to informants, and budget—especially in an organizational setting. The stopping rule in the "perfect" academic setting might be "saturation," but in an organizational context, the stopping rule might very well turn out to be "Friday," or "when the budget is exhausted." As Charmaz (2008) reminds us, research takes place in a cultural and an organizational context. The researcher who adopts grounded theory in an organization may need to adapt some of the practices of grounded theory to meet the requirements of that organization.

44.7 APPLYING GROUNDED THEORY TO HUMAN–COMPUTER INTERACTION AND COMPUTER-SUPPORTED COOPERATIVE WORK

Grounded theory began in sociology, and has gained strength in many research disciplines, especially nursing. How can grounded theory be integrated within research and practice in HCI and CSCW?

44.7.1 Use of the Research Literature

A recurring problem in grounded theory is *What weight to give the research literature?* Early work (e.g., Glaser and Strauss 1967) took a firm stand for naïve investigations. Students were urged to postpone reading the research literature in order to remain open to the data, and only the data. This approach has turned out to be problematic in many ways. In the context of HCI and CSCW, research is required to make a novel contribution. We cannot know if our project or problem is novel, unless we have read extensively in the research literature.

There are deeper problems with the position of naïveté, *within* the process of conducting a grounded theory investigation. Kelle (2007) criticized this position as follows:

> The request 'literally to ignore the literature of theory and fact on the area under study, in order to assure that the emergence of categories will not be contaminated' (Glaser and Strauss 1967…) can lead inexperienced users of grounded theory procedures to adopt an unrealistic idea about their work. Novices who wish to firmly observe the principle of 'emergence' often experience the search for categories as extremely tedious and a subject of sometimes numerous and endless team sessions, leading to a proliferation of categories which makes the whole process insurmountable …

How, then, can the research literature enter a grounded theory investigation without distorting the process? Dey (1993) claimed that "there is a difference between an open mind and an empty head. To analyze data, we need to use accumulated knowledge, not dispense with it." Discussing Dey's work, Vasconcelos (2007) adds "In other words, analysis is emergent, but not 'atheoretical'" (see also Goulding [1998]). In HCI and CSCW, this point is particularly important, both in making the argument from the data, and in demonstrating the value of the research as a novel contribution that answers questions relevant to the research literature in our fields.

In Figure 44.2, we offered a summary diagram of how a grounded theory investigation proceeds—from a broad view of the data to a narrower focus, and from a shallow set of categories and dimensions to a richer, deeper, more interconnected set of concepts. In grounded theory research, the theory that emerges (or is constructed) *from the data* is called "substantive theory," whereas concepts from the research literature are called "formal theory." The question thus becomes, *When and how should substantive theory be informed by formal theory?*

44.7.1.1 Sensitizing Concepts

Grounded theorists have discussed an approach to this problem by reference to Blumer's earlier proposal of the "sensitizing concept" (Blumer 1954). A sensitizing concept is to be used as "a starting point in a qualitative study" to "draw attention to important features… and provide guidelines… in specific settings…" (Bowen 2006). Charmaz describes sensitizing concepts as "background ideas that inform the overall research problem" (see also Charmaz [2003]; Glaser [1978]; Vasconcelos [2007]). Earlier in this chapter, we claimed that grounded theory takes advantage of the human tendencies to think and to theorize. In keeping with that claim, we note Bowen's quotation of Gilligan's argument that "Research usually begins with such concepts, whether researchers… are aware of them or not."*

The principled use of sensitizing concepts helps us to be aware of how we think and theorize in this way, and to understand where we are led by the data (in the purer sense of grounded theory) and where we are influenced by the work that has gone before our own research. Based on Blaikie (2000), Bowen (2006) suggests that sensitizing concepts be used *not* as a source of hypotheses to be tested, but rather "to lay the foundation for the analysis" or "to develop thematic categories" from data that have already collected, perhaps then helping to choose the next set of data to be (iteratively) collected.

44.7.1.2 Coding Families

A second strategy for making carefully limited use of the research literature was proposed by Glaser (1978), as a set of "coding families." Glaser offered his coding families in the form of established sets of axial codes, based in broad theoretical backgrounds in sociology, and ready to be applied to data as needed. Coding families include concepts such as causality, limit or range of values, part-whole relations, and collective beliefs. These selected types of relationships, collected by a seasoned researcher, may be one way to inform the work with an attenuated set of results from the research literature: "The conception of coding families makes clear that certain types of theoretical knowledge are clearly helpful in deriving grounded categories from the data" (Kelle 2007).

44.7.1.3 Summary

Our impression is that grounded theorists continue to struggle (as we do) with the "right" balance between maintaining an "open mind," while avoiding the problems associated with an "empty head" (Dey 1993). Researchers in HCI and CSCW will need to inform their choice of research area and problem to be solved with a strong knowledge of the research literature; too much naïveté is likely to lead to repeated work and missed opportunities. What appears to be crucial, is to remain aware of when we are working from the research literature, and when we working from the data, and to make thoughtful choices about how to mix the two perspectives. Discussions of this question, written in the context of HCI and CSCW, would be very helpful, and we hope our colleagues will address these issues.

44.7.2 Presentation of Results and Implications

The fields of HCI and CSCW have their own norms of how arguments are made, and how reports are structured. If a grounded theory project is to be published in these literatures, then of course it must be "rhetorically recognizable,"

* Gilligan's source paper, referred to as a web page in Bower's paper, is no longer available online.

that is, it must present its method and its analysis in a rigorous manner, and it must make a case for the quality of the data reporting and analysis, and for the conclusions that are drawn from the data. We recommend that the researcher indicate clearly whose GTMs he or she has adopted, and (if appropriate) how he or she has adapted the method in response to local circumstances or organizational requirements. Most HCI and CSCW audiences will not be familiar with the special language of grounded theory, so we recommend that the researcher make careful decisions between necessary precision of GTM terms, versus burdening the reader with what may appear to be jargon. GTMs are intended to help the researcher to achieve clarity and precision of thought. The researcher has a responsibility to provide that precision and especially that clarity *to the reader*, in terms that the reader can understand and use in his or her own research.

44.8 CONCLUSION

GTMs are less than 50 years old, and are undergoing change, reformulation, innovation, and experimentation (e.g., Morse et al. 2009). The adoption of GTM in HCI and CSCW has begun even more recently, and researchers in our fields are continuing to learn about the methods, and about how they can be adapted to advantage under the various constraints of HCI and CSCW work in academia, industry, government, and nonprofits. In this chapter, we have presented a summary of our understanding of GTM in 2010, written with the intention that researchers can learn enough from these pages to begin their own practices (the learn-by-doing approach is advised by many of the sources on GT methods). We anticipate rapid growth in understanding of GTM in our fields within the next 5 years. We hope that this chapter helps to spur that growth, and that the new understandings will replace this chapter with a better set of advices and findings.

During this period of learning, growth, adoption, and adaptation, each researcher will be developing her or his own set of practices, and will be struggling with the conflicting advices of the many grounded theorists, as well as their diverse philosophical positions. As Floyd (1987) noted in her account of *process-oriented software* engineering, practices in our field are under development, just as software and hardware are under development. In this chapter, we have attempted to provide a broad survey of practices and the rationales behind them. We have noted the disagreements, while focusing on the commonalities, and we have provided pointers to discussions and divergent approaches that we hope will be useful as each HCI or CSCW researcher navigates this rich, promising, and challenging domain of analysis, thought, action, and passion.

Grounded theory has tended to be used in HCI and CSCW in two distinct ways. Perhaps the greater number of papers have used grounded theory as an analytic method on data that have already been collected. All of the coding methods and iterative theory-construction practices come into play here, except of course for the fullest extent of theoretical sampling (because, in most of these studies, the data set has already been collected, and there is limited or no opportunity to determine a need for more data from a previously unsampled source). We note that many HCI and CSCW web researchers currently face more data than any human can analyze, and that they can, to some extent, exercise theoretical sampling by choosing *which data to focus on* among the huge datasets that come to us in Internet or intranet sampling.

A numerically smaller number of HCI and CSCW projects has used a grounded theory approach that is closer to the "ideal" sociological methods from the 1967 *Discovery of Grounded Theory*, that is, the ability to collect data in small samplings, using constant comparison techniques in order to choose where, how, and with whom the next data iteration should be conducted.

There has been an extended discussion of issues of quality and rigor in GT (Corbin and Strauss 2008; Charmaz 2006a, 2009; Gasson 2004; Muller 2010), including several distinct positions about boundaries, that is, what kind of work qualifies as GTM (Adolph, Hall, and Kruchten 2008; Becker 1993; Cutliffe 2005; Matavire and Brown 2008; Skodal-Wilson and Ambler-Hutchinson 1996; van Niekerk and Roode 2009; and of course the ongoing disagreements by Glaser and by Strauss, cited earlier). In our survey of critiques of GT quality and rigor, we discovered some authors who claimed that the "full" or "ideal" version of GTM was the only valid way to conduct research that could be called "grounded theory." However, we think it is too early for anyone to say, for HCI and CSCW, what "is" or "is not" grounded theory. We make reference again to Floyd's (1987) insights about the development of *methodology* that accompanies the development of technology and of theory. Researchers in HCI and CSCW will continue to develop our fields' understandings of these methods, and as a community of researchers we will make new HCI- and CSCW-based innovations in grounded theory for our domains. Where appropriate, our community will bring our innovations to the sociologists and nursing researchers who have taught us so much about grounded theory, and inform their practices with insights from our own.

What we need now is continued growth and development of GTM in HCI and CSCW, but we principally need discussion. By analogy, it is time to begin to apply the grounded theory concept of "constant comparison" to our own fields, comparing our methods and our findings with other people in HCI and CSCW as a kind of "data about doing GTM research." We will rapidly form iterative theories about what works and what does not, and then we should abductively test those theories in further GTM-based studies. We hope to see not only more papers on grounded theory in HCI and CSCW, but also more workshops and panels, where we can perform a collective "constant comparison" of adaptations of GTM to our fields. To heal the schism and advance the field, Morse et al. (2009) wrote *Developing grounded theory: The second generation*. Perhaps we will soon be able to write and read a collection of papers titled, *Developing grounded theory in HCI and CSCW: The third generation*.

45 An Ethnographic Approach to Design

Jeanette Blomberg and Mark Burrell

CONTENTS

45.1 INTRODUCTION

In recent years, academic and professional researchers and designers working in the field of human–computer interaction (HCI) have looked to ethnography to provide a perspective on relations between humans and the artifacts and solutions they design and use.* Within the field of HCI there are different views among researchers and practitioners on just what constitutes an ethnographic inquiry. For some, ethnography is simply a fashionable term for any form of qualitative research. For others, it is less about method and more about the lens through which human activities are viewed. In this chapter, we will attempt to position the ethnographic approach within historical and contemporary contexts, outline its guiding principles, detail the primary methods and techniques used in ethnographically informed design practice, and provide case examples of ethnography in action.

This chapter provides an introduction to ethnography, primarily as it relates to studies in HCI. We will touch only briefly on some of the more controversial topics current within the field of ethnographic research that have enlivened mainstream academic discourse in recent years. We will point the reader to books and articles where these topics are discussed in more detail. Our primary aim in this chapter is to provide academics and professionals in the field of HCI with a working understanding of ethnography, an appreciation for its value in designing new technologies and practices, and a discerning eye when it comes to reviewing and evaluating ethnographically informed design studies.

45.2 THE RELEVANCE OF ETHNOGRAPHY FOR DESIGN

The turn to ethnography as a resource for design can be traced back to the early 1980s when computer technologies were moving out of the research labs and engineering environments and into mainstream office settings, call centers, manufacturing floors, and educational institutions. There was the realization that the designers and developers of these technologies could no longer rely exclusively on their own experiences as a guide for the user requirements of these new systems. Instead, designers and developers needed a way to gain an understanding of the everyday realities of people working within these diverse settings (Blomberg et al. 1991). In many organizations, market research groups were being asked to provide perspectives on the people and practices that made up these varied settings. However, the techniques most commonly used by market research groups at the time (e.g., attitude surveys, focus groups, telephone interviews, etc.) were not well suited for developing an actionable understanding of what people actually do day-to-day that could inform the design of new products, services and interactive solutions.

Anthropologists and other social scientists had long recognized that what people say and what they do can vary significantly, making reliance on surveys, focus groups, and telephone interviews insufficient for the task. Designers and developers needed a way to get a firsthand view of the on-the-ground realities—the “here and now”—of everyday life in these diverse settings. At this time in the early 1980s, social scientists working at the Xerox Palo Alto Research Center were beginning to explore ways of bringing insights from ethnographic research into a productive relationship with the design of new technologies (e.g., Blomberg 1987, 1988, 1995; Suchman 1983; Suchman, Blomberg, and Trigg 1999). Not long after, other research labs (e.g., Hewlett-Packard, Apple Computer, and NYNEX) followed suit (e.g., Nardi and Miller

* Ethnographic research is often just one of many approaches used to inform design. Usability studies, surveys, business case analysis, scenario planning, future workshops and social network analysis are a few of the approaches that are used in conjunction with ethnography.

1990; Sachs 1995). Today, many industrial research and development labs in the United States have anthropologists and other social scientists with ethnographic expertise on staff (e.g., IBM, Intel, Kodak, Microsoft, Motorola, General Motors, and Xerox, to name but a few).

Ethnographically informed design practices also began to take hold in design firms and consulting companies during the early 1990s (e.g., IDEO, Fitch, and the Doblin group). These early explorations led, in 1993, to the founding of e-Lab, a research and design company that distinguished itself from other design firms at the time by creating an equal partnership between research and design (Wasson 2000). Ethnographic methods were at the center of e-Lab's research approach, with a commitment to base design recommendations on insights from ethnographic research (Robinson 1994). Today there are a number of research and design firms who provide ethnographically informed design solutions (e.g. Adaptive Path, Cheskin, Continuum, GravityTank, HLB, IDEO, and Jump, to name a few).

Furthermore, in the mid-1980s the growth in networked applications and devices, made possible through the availability of local area networks and early Internet implementations, created awareness among designers and developers that they would need a strategy that focused beyond support for single, isolated users interacting with information technologies. They would need a way to understand the information and communication practices of people interacting with one another, both face-to-face and through mediating technologies. Information technologies were increasingly becoming communication and collaboration technologies that consequently demanded an examination of social interaction across time and space. In response, a group of computer scientists, human-factors engineers, and social scientists, somewhat dissatisfied with the dominant perspectives within HCI at the time founded the field of computer-supported cooperative work (CSCW)* (e.g., Grief 1988; Schmidt and Bannon 1992). A group of sociologists at Lancaster University and researchers at the Xerox Research Center in Cambridge, England played a prominent role in helping to shape the ethnographic research agenda within CSCW (e.g., Bentley et al. 1992; Hughes, Randall, and Shapiro 1993; Rodden and Anderson 1994; Hughes, Rodden, and Anderson 1995).

Finally, the explosion of the Internet in the late 1990s accelerated the move of information technologies out of the workplace and into homes, recreational environments and other non-work-related settings. This redoubled interest in the ethnographic perspective as a valuable tool in the design of new technologies and technology mediated services. This presented a new set of challenges for designers as they were asked to design and build applications that leveraged powerful, digital technologies for use by people of all ages, engaged in myriad non-work-related activities in diverse contexts. Although the clamor for all that is the Internet has somewhat subsided, the legacy of that period is that researchers and designers who learned their craft during the Internet boom years have gone on to positions in academia and industry, in both boutique design firms and major companies, and in a variety of industries including advertising, marketing, product development, and IT services. In late 2005, many in the ethnographic design community assembled at an industry sponsored conference, EPIC (Ethnographic Praxis in Industry Conference). The conference brought together a diverse group of researchers working in areas such as product design, workplace studies, and business ethnography to define the scope of a collective agenda and to strengthen professional ties and research connections (Anderson and Lovejoy 2005). This conference (see Cefkin [2009]; Proceedings of Ethnographic Praxis in Industry Conferences 2005–2011) continues today and is a powerful testament to the continuing value of focusing on people's everyday realities and experiences—the here and now—when designing innovative technologies, experiences, and services.

45.3 THE ROOTS OF ETHNOGRAPHY

Ethnography has its historical roots in anthropology, but today is an approach found in most all of the traditional and applied social sciences, and in interdisciplinary fields such as HCI and Human Factors Engineering. In anthropology, ethnography developed as a way to explore the everyday realities of people living in small-scale, non-Western societies and to make understandings of those realities available to others. The approach relies on the ability of all humans to decipher what is going on through participation in social life. The techniques of ethnography bear a close resemblance to the routine ways people make sense of the world in everyday life (e.g., by observing what others do, participating in activities, and talking with others). The research techniques and strategies of ethnography developed and evolved over the years to provide ways for the ethnographer to "be present" for the mundane, the exceptional, and the extraordinary events in people's lives.

More recently within the field of anthropology both the focus on non-Western peoples and the implicit assumptions made about non-Western societies (e.g., that they are bounded, closed, and somewhat static) have undergone a transformation. Today, the ethnographic approach is not limited to investigations of small-scale societies, but instead is applied to the study of people and social groups in specific settings within large industrialized societies, such as workplaces, senior centers, and schools, and specific activities such as leisure travel, financial investing, teaching, and energy consumption, to name but a few. Consequently, new techniques and perspectives have been developed and incorporated into anthropological and ethnographic inquiry. However, a few basic principles have continued to inform and guide ethnographic practice. These principles include

* The dominant perspectives at the time emphasized technological possibilities over the uses and users of technology, the interface requirements of stand-alone applications over networked devices, and human psychology and cognition over social interaction. However, by the late 1990s ethnographically informed design attained a prominent place in HCI research, and today there is considerable overlap between the fields of CSCW and HCI.

studying phenomena in their *natural settings*, taking a *holistic* view, providing a *descriptive understanding,* and taking a *member's perspective*.

45.4 PRINCIPLES OF ETHNOGRAPHY

45.4.1 Natural Settings

Ethnography is anchored in the underlying assumption that to gain an understanding of the world you must encounter it firsthand. As such, ethnographic studies always include gathering information in the settings in which the activities of interest normally occur. This does not mean that ethnographic studies never involve techniques that remove people from those everyday settings or that introduce into those settings artifacts or activities that would not be present otherwise. The insistence on studying activities in their everyday settings is motivated by the recognition that people have a limited ability to describe what they do and how they do it without access to the social and material aspects of their environments. Furthermore, people's ability to fully articulate what they do is constrained by the tacit understandings that guide actions (Polanyi 1966). Finally, some aspects of people's experiences are best studied by observing and recording the ongoing flow of activities as they occur (e.g., people's patterned movements through settings such as retail stores or airports, moment-by-moment shifts in scheduling, etc.).

45.4.2 Holistic

Related to the emphasis on natural settings is the view that activities must be understood within the larger context in which they occur. Historically within anthropology the notion of holism focused attention on the fact that societies were more than the sum of their parts (however these parts were specified). The particular aspects of a society (e.g., the court system) could only be understood in relation to the other aspects of the society (e.g., kinship system, belief system). Today, because ethnography is less often applied to the study of entire societies, the notion of holism has a somewhat different emphasis. Holism holds that studying an activity in isolation, without reference to the other activities with which it is connected in time and space, provides a partial and potentially misleading understanding of that activity. So, for example, investigating online search strategies without understanding how these strategies fit into the larger set of activities in which search is but one component (e.g., in the context of online trading, shopping, or report writing) narrows the possible insights from the study.

45.4.3 Descriptive

Ethnographic accounts have always provided a descriptive understanding of people's everyday activities. Ethnographers are concerned first and foremost with understanding events and activities as they occur, without evaluating the efficacy of people's everyday practices. This is not to say that ethnographic accounts cannot or should not be used to suggest how things could be different or to point out inequities or inadequacies in current ways of doing things. Indeed, as applied in the domain of HCI, ethnography is aimed at identifying opportunities for change. However, there is a strong conviction that to suggest changes or to evaluate a situation, one first needs to understand it as it is. The work practice and technology group at the Xerox PARC (Palo Alto Research Center) developed a slogan expressing this conviction that innovation requires an understanding of the present (Figure 45.1).

Innovation
=
Imagination of what could be
based in a knowledge of what is

FIGURE 45.1 Innovation.

As such, ethnographic accounts strive first and foremost to provide descriptive and not prescriptive understandings of people's everyday lives. In recent years, there have been many challenges to the idea that a purely descriptive understanding is possible. Critics point out that every account is shaped by the perspectives of the researcher, the goals of the project, and the dynamics of the relationship between the investigator and those studied, to name but a few factors that shape ethnographic accounts. While we do not argue with this position, we contend that the value of ethnography for design is not diminished by recognition that our accounts are always located and partial.

45.4.4 Members' Point of View

As already alluded to, ethnographers are interested in gaining an insider's view of a situation. They want to see the world from the perspective of the people studied and describe behaviors in terms relevant and meaningful to the study participants. As such, ethnographers are interested in the ways people categorize their world and in the specific language people use to talk about things. This perspective is sometimes at odds with the requirements of quantitative survey research in which the relevant categories must be known in advance of the study and in which the categories and the language used cannot vary across participant groups. In quantitative approaches, the terms and categories used are likely to be those of the research community and not those of the study participants, which can undermine the validity of the results (see Section 45.7 for further discussion of this topic).

45.5 THE POSTMODERN INFLECTION

The scientific paradigm within which ethnography evolved has come under serious questioning over the last quarter century as social studies of science have shown how scientific knowledge production is shaped by the larger social context in which scientific inquiries take place (Latour 1987; Latour and Woolgar 1986; Pickering 1980). As part of this critical discourse, ethnographic accounts have been challenged for their veracity. Likewise the authority of the ethnographic voice has been questioned (Clifford 1988; Clifford and Marcus 1986; Marcus and Fischer 1986). These challenges have come from a number of fronts, most significantly from study participants who increasingly are able to read ethnographic accounts (Said 1978) and from feminists who saw in many ethnographic accounts a Western, male bias (Harding 1986; Smith 1987; Wolf 1992; Yanagisako and Delaney 1995). These challenges have made researchers from all fields of inquiry more aware of how their research is shaped by the particular time and place in which it occurs. It is our view that knowledge of the world is always mediated by presuppositions, be they cultural, theoretical, or practical, and as such no ethnographic account is value-free. But we also contend that this does not diminish the value and efficacy of an ethnographic approach as a resource for designing new technologies, experiences, and services. Maintaining the illusion of a theoretically neutral and value-free absolute "truth" is not necessary to establish the value of ethnographic research in design. By striving to describe and understand how people operate in and construe their everyday "realities," ethnography can provide useful frameworks and roadmaps to guide the design of "people-centered" solutions.

45.6 ETHICAL ISSUES

As will be discussed in more detail later, ethnographic research requires developing the trust and participation of the people studied. Without this trust participants will be reluctant to allow researchers into their homes, boardrooms, and classrooms and they will not openly share their everyday experiences and concerns. Anthropologists have long realized that such a privileged, trusted position requires reciprocity—if you allow me access to your world, I will protect your interests. This bargain has not always been easy for ethnographers to keep. Over the years there have been examples of ethnographic research, where, wittingly or not, the situation of the people studied has been compromised.*

In the context in which ethnographic research is being used to inform the design of new products and services—ones that will change people's lives—it is critical that the ethnographer reflect on the impact this research could have on study participants. Of course, it is not possible to control all the ways findings from ethnographic research will be used, nor how innovations informed by these studies will be integrated into people's lives. But the ethnographer can work to protect study participants from immediate harm (e.g., that was caused by divulging a worker's identity to management) and can inform study participants of possible longer term negative impacts (e.g., job losses brought about by introduction of new technologies). As ethnographic research has moved into new contexts (e.g., HCI, organizational development), it has been necessary to think creatively about how our ethical guidelines map to these new conditions. However, we cannot lose sight of the importance of protecting the interests of those who have agreed to participate in our studies be they workers in organizations, traders on Wall Street, or mothers of special needs children.

45.7 ETHNOGRAPHIC METHODS

The ethnographic method is not simply a toolbox of techniques, but a way of looking at a problem, a "theoretically informed practice" (Comaroff and Comaroff 1992, quoted in Agar 1996:7). The methods and techniques outlined later in this chapter have been developed over the years to enable the development of a descriptive and holistic view of activities as they occur in their everyday setting from the point of view of study participants. We are not attempting to be exhaustive in our presentation, nor do we want to suggest that there is a fixed set of canonical ethnographic methods and techniques. We encourage researchers to continue developing new techniques as the circumstances require (e.g., studying "virtual" communities, globally distributed workgroups, technologically mediated interactions). What remains constant in the ethnographic approach is a commitment to describe the everyday experiences of people as they occur.

45.7.1 Research Planning

One of the keys to a successful research project is the creation of a plan of action to guide the research and support changes and adjustments that inevitably must be made as the project proceeds. Research planning can be divided into three general stages: (1) formulating research objectives, (2) devising a strategy for selecting study participants, and (3) selecting appropriate research techniques and approaches.

Research objectives follow from the specific questions to be addressed by the research. It can be useful to develop an explicit statement that clearly articulates the objectives of a given study. This statement acts as a beacon to help keep the research on track through the many twists and turns of a project. For example, if the research aims to inform the development of a software application that will help doctors manage patients' records, the research statement could be something as simple as "understand how doctors manage patient records through all the phases of treatment and in the varied settings in which they practice medicine." Over the course of a project, the research objectives' statement (along with the research design and plan) may change as a project team coalesces and learns about the experiences of the people in the particular domain of interest.

45.7.2 Study Participants

Once the research objectives have been identified, a strategy for selecting study participants (sometimes referred to as a "sampling strategy") is devised that answers two primary

* To mitigate such negative impacts, the American Anthropological Association has developed a code of ethics that provides guidance for people engaged in ethnographic research. This code outlines the appropriate disclosures and protections that should be given to study participants. (Fluehr-Lobban [1991] provides a discussion of ethical issues in anthropological research.)

questions: (1) what types of participants best suit the research objectives and (2) how many participants should be included in the study to achieve the research objectives? The strategy for selecting study participants is influenced by the research focus (e.g., shopping behavior vs. workgroup collaboration) and may include selecting at different levels of abstraction (e.g., which organizations, which workgroups, and which individual employees). In addition, as Cohen (2005) has cautioned, attention should be given in making these choices for those who might intentionally or inadvertently be excluded from the study and as such rendered invisible to the research lens.

Several types of sampling strategies are employed by social science researchers, which fall under two main categories: (1) probability and (2) nonprobability (Bernard 1995).[*] Our focus in this chapter is on nonprobability sampling, as that is most commonly employed in ethnographic research.[†] The nature of ethnographic work, as well as recruiting constraints often demand selecting participants based on criteria other than a strict probability.

Four types of sampling fall under the rubric of nonprobability: (1) quota, (2) purposive, (3) convenience, and (4) snowball (Bernard 1995). When sampling by quota, the researcher specifies which groups are of interest (e.g., women, teenagers, truck drivers, people who use software X, organizations with fewer than 100 employees, etc.) and how many will be needed in each group. The number of groups chosen will depend on the research objectives and the amount of time available, but the basic idea is to cover the range of possible variation one would expect across the target population. Practically speaking, when identifying the variables or factors that should be considered in sampling to enable visibility into possible variations in experiences and practices, the ethnographer will often presumptively identify "differences that may make a difference" in the experiential domain of inquiry. For example, if the focus is on how people manage their personal finances, the researcher might deliberately strive to specifically sample people with varied financial situations in addition to life/career stages or family situations. To ensure the desired variability is covered—particularly when the researcher is dependent on others to provide access to or recruit the participants for a study—it is useful to create a "screener,"[‡] a questionnaire-like instrument designed to identify characteristics that are appropriate for a given project. Quota sampling is only possible when the desired participants[§] are easy to identify in advance and recruit. If it is not possible or desirable to specify how many participants will be in each sampled group, a purposive sampling strategy may be called for. This sampling strategy is based on the same principles as quota sampling, but the number of participants for each group is not specified.

Convenience and snowball sampling rely on a "sample as you go" strategy. This is required in situations in which you do not know in advance who will be available to participate or which individuals or groups should participate. Convenience sampling entails selecting people who are available, meet the requirements of the research, and are willing to participate. One might use this strategy, for example, to observe and interview people as they shop in a grocery store.

Snowball sampling relies on participants referring others whom they think would be good candidates for the research, or on researchers identifying individuals or groups to be included in the study as the research proceeds. Because this method utilizes existing social networks it is especially valuable when desired participants are initially inaccessible or reluctant to participate (e.g., CEOs, drug users, club members) or when the relevant population cannot be known in advance.[¶]

45.7.3 Gaining Access

One of the challenges for ethnographic research is gaining access to field sites and study participants. Access to institutional settings often requires getting permission from management to observe and interview employees, or from school officials and parents to spend time in classrooms. In some cases, written permission that specifies certain terms and conditions (e.g., how confidential information will be protected) is required before researchers are allowed onsite. In other cases, recruiting agencies may be used to identify participants and financial incentives may be offered for participating in the study. The time (and skill) required to establish these initial relationships and agreements should not be underestimated.[**]

45.7.4 Observation

As discussed earlier, ethnographers are interested in understanding human behavior in the contexts in which it naturally occurs, making observation one of the hallmark methods of the approach. In academic settings, it has been common for anthropologists to spend a full year at a given field site. While

[*] The intent behind probability sampling, or statistical sampling, is to generalize from the research sample to a larger population with a specified degree of accuracy, measured in terms of probability. All types of probability sampling require a randomly selected and relatively large sample size.

[†] Using nonprobability samples does not mean we cannot make general statements. If participants are chosen carefully, one can obtain reliable data with as few as four or five participants (Nielsen and Landauer 1993). Additionally, a recent case study demonstrates that smaller, nonrandomly selected samples can produce the same results as large-scale survey research for as little as 1/100 of the cost (Green 2001). A nonprobability strategy also does not preclude conducting a statistical analysis or measuring differences between individuals or groups using nonparametric statistics, such as Fisher's Exact Test or nonparametric correlation measures. Their limitation is that they cannot be used to make claims about larger populations within a specified degree of probability.

[‡] Screeners are an essential tool if using an external recruiting agency to locate study participants.

[§] For sampling purposes, participants need not be individuals, but could be families, households, workgroups, or other naturally occurring entities.

[¶] Johnson (1990) provides a more detailed discussion of sampling in ethnography.

[**] Anthropologists have been accused in the past of only studying the disempowered and disenfranchised because these individuals were less likely to feel powerful enough to refuse participation in ethnographic studies. Although important in all contexts, when studying people with more power and ability to say no (Nader 1974), it is often necessary to demonstrate how their participation will be of benefit to them, their community or workplace, or the wider society.

this continues to be the case for more traditional ethnographic studies, shifts in research focus (e.g., away from studies of entire societies), and in study locations (e.g., away from isolated, hard to reach settings) have resulted in more varied research designs which may involve shorter, intermittent fieldwork periods in one or more locations. Moreover, in some applied settings (e.g., enterprise work environments) the time available for field observation may be constrained, sometimes allowing for no more than a few days in any one setting.

45.7.4.1 Why Observe?

One of the fundamental axioms in the social sciences, and anthropology in particular, is that what people say they do and what they actually do are frequently quite different. Studies have shown verbal reports to be inconsistent with observed behavior in a number of areas including (among many other examples) shopping behavior (Rathje and Murphy 1991), child rearing (Whiting and Whiting 1970), recycling (Corral-Verduga 1997), and health habits (Rich et al. 2000).

The discrepancies between verbal reports and behavior can be due to a variety of factors. People may be concerned with their image and so report, consciously or not, behavior that is more socially acceptable. Along these same lines, participants may respond to questions in a particular way in an attempt to please the researcher. Another source of disparity between behavior and verbal reports is that people are often not aware of their actual behavior because it is so habitual. Such tacit knowledge is often not easily accessible through interview techniques alone (D'Andrade 1995).

The limitation of human memory is another reason why interview data can differ from observations. When asking participants about past events, or recurring patterns of behavior, our memory may be selective and skew responses in any number of directions, sometimes in predictable patterns (Bernard 1995).

The complexity of social life is another reason individual accounts of an event may miss certain relevant details. The environments in which humans interact are extremely dynamic and complex—composed of social relationships, artifacts, and physical spaces—and making it difficult for individuals to fully envision, let alone articulate after the fact, what is going on.

45.7.4.2 The Researcher's Observational Role

When it comes to observation, there are varying degrees to which the researcher can become integrated into the scene. At one end of the spectrum the researcher may become an observer-participant. In this role, one attempts to be as unobtrusive as possible, quietly observing events from a discreet, yet strategic, position. At the other end of the spectrum is the participant-observer. In this situation, the researcher is actively involved in the events observed (e.g., a researcher who goes through the training to be a machine operator in an industrial environment).

There are pros and cons associated with each type of role. While being fully integrated into the action provides a researcher with firsthand experience of events, taking good notes in this context is difficult at best. A great deal of energy is spent trying to fit in rather than on attempting to make sense of the events in the context of the research objectives. In such cases, one must rely on memory of the events when writing up field notes after the fact. Taking a more observational role affords a wider perspective on events and the time to record and reflect on events as they unfold. On the downside, it precludes the opportunity to experience the activity firsthand. In many research situations, the ethnographer's position moves between these two extremes, sometimes occupying a hybrid position of both partial participant and outside observer.

45.7.4.3 Structuring Field Observations

Before setting out to observe, decisions need to be made about what, where, and when to observe (Whiting and Whiting 1970). One might decide to observe individuals as they go about their work and daily routines (person focused), a technique sometimes referred to as "shadowing" (Wasson 2000). The researcher might also decide to focus on a specific event, such as a meeting or software education class (event focused), or observe the activities that occur over time in a given area, like an office or store (place focused). One can even shift the subject of observation to an artifact, such as a document, and record its transformation as it moves from person to person or along a development path (object focused).

45.7.4.4 Video Recording

Given the complexity of human activities it is impossible to notice and record in real time everything of interest to the researcher. This is one reason video cameras have become increasingly popular in fieldwork. Video records can be used as a reference to supplement field notes. The ethnographer also has the advantage of being able to watch events multiple times and change levels of analysis or observational focus with subsequent viewings (e.g., interaction between people vs. the movement of one individual in and out of a scene).

Video recording also allows people not primarily involved in the fieldwork to participate in the analysis and opens up the range of perspectives that can be bought to bear on the analysis (e.g., Blomberg and Trigg [2000] used video collections in interactions with product developers; also see Brun-Cotton and Wall [1995]; Karasti [2001]; Suchman and Trigg [1991]).

Video cameras can also be used to record events in the absence of the researcher. Not only does this free the researcher to be involved in other activities, but the camera also can be a silent presence* in situations where an outsider (even a well-trained participant observer) would be seen as intrusive (e.g., child birth, counselor-student interactions, board room deliberations, etc.). Video recording however requires devoting time later to review video records and incorporate relevant information into the analysis.†

* However, the expressed permission of the participants in the interaction is needed in these cases as well.

† A variety of software applications now exist that can help the researcher manage and analyze recorded on video. Caveat, for example, allows the researcher to select and annotate images/events of particular interest. A more sophisticated (though less user friendly) program is observational coding system that provides for a more quantitative analysis.

45.7.5 Interviewing

Interviewing is a central tool of ethnographic research (Gubrium and Holstein 2002). Conducted and interpreted in light of the potential differences between what people say and do, interviews are critical in developing understandings of members' perspectives. Interviews can be placed on a continuum from unstructured to structured, with at one extreme the casual conversation and at the other a formal structured interview.

Ethnographic interviews are most often open-ended, particularly during the early stages of fieldwork when the ethnographer is just beginning to get a perspective on the activities and people studied. The more unstructured format gives the researcher the freedom to alter the line of questioning as the interview unfolds. The researcher essentially is learning what questions are important to ask. Unstructured, however, does not mean haphazard or lacking purpose. The researcher will know the research objectives and the topics to be explored when entering the field, and will usually have an interview protocol to serve as a (flexible) guide for the interview. While the protocol provides a basic framework for an unstructured interview, the participant plays a major role in the direction the interview takes. As Bernard (1995) wrote, the idea is to "get an informant on to a topic of interest and get out of the way." When the interview moves to a topic of particular interest, the researcher can then probe deeper to elicit more details. Indeed, interviewing is something of an art, and one of the key skills an ethnographer learns is the art of "interrupting gracefully" (Whyte 1960).

In an open-ended interview it is important to avoid using an interrogation style of questioning (e.g., "yes or no" questions) which is designed to uncover the "facts." This defeats the purpose of keeping the interview open to allow for a wide range of responses and for the participant to express his experiences, in his own way, in his own words. Using too structured a format constrains the range of possible answers, increases the chances of missing critical pieces of information, and increases the risk that discoveries will be limited by the ethnographers' preexisting concepts, assumptions, and hypotheses. It is critical to provide opportunities for participants to convey their stories and perspectives in their own way and for the researcher to be surprised by what is said.

As a project progresses and patterns begin to emerge, interviews can become more structured and the line of questioning less broad. The researcher begins to narrow in on topics that are particularly informative and relevant to the research objectives. Questions become more focused and specific as answers to previous questions guide the follow-up questioning.

Once the range of responses is known and themes begin to emerge, the researcher may want to structure interviews further. A host of structured techniques exist. Some are designed to identify the ways people organize information within a specified domain, such as free listing, card sorts, triad's tests, and paired comparisons (Romney, Batchelder, and Weller 1986; Weller and Romney 1988). Other techniques, such as questionnaires and surveys,* are used to assess variations between two or more groups or to establish the representativeness of the findings for a larger population. The main idea behind these techniques is to keep the form and content of the questions consistent for each respondent, thus allowing for differences among the sample population to be ascertained. Conducting structured interviews at the end of an ethnographic study has the advantage of allowing the question structure and language to reflect the way participants talk about and organize experiences, thus increasing the validity of the survey findings.

45.7.5.1 The Interview as a Communicative Event

The interview has become somewhat ubiquitous in western societies and is viewed as a reliable means of acquiring information of all kinds (e.g., attitudes toward tax increases, the value placed on education, preferences for certain products, basic demographic data, etc.). However, as Briggs (1983) points out, what is said in an interview should not be thought of as "a reflection of what is 'out there'" but instead must be viewed "as an interpretation which is jointly produced by the interviewer and respondent" (p. 3). This view compels us to regard the interview as a communicative event in which the structure and context of the interaction conditions what the researcher learns. This is no less the case in highly structured interviews (see Jordan and Suchman [1990] and Moore [2004] for a critical analysis of the ecological validity of survey research). Briggs recommends that we adopt a wider range of communicative styles in our interactions with study participants, particularly styles that are indigenous to the study population.

45.7.5.2 Interviewing Rules of Thumb

While there are no hard and fast rules for interviewing, a few general guidelines will help facilitate the interview process and increase the chances of obtaining useful information. The following are some points to remember:

- Interview people in everyday, familiar settings. Not only does this make the participants more comfortable, it allows them to reference artifacts in the environment that play an integral part in their activities. Moreover, a familiar environment is full of perceptual cues that can help jog the not-so-perfect human memory.
- Establish and maintain good rapport with participants, even if it slows the interview process.
- Do not underestimate the value of casual conversation. Some of the most insightful information comes from informal conversations when social barriers are lowered.
- Assume the respondent is the expert and the researcher the apprentice. This not only shows the

* A good introductory book on surveys is How to Conduct Your Own Survey (Salant and Dillman 1994). Readers interested in a more advanced treatment of the subject are referred to Babbie (1990).

respondent respect, but also gives them confidence and facilitates conversation. Even if the interviewer happens to be more knowledgeable on a particular topic, the goal of an ethnographic interview is to understand the respondent's perspective.

- Use lack of knowledge as a discovery tool. Respondents will always know more about their own experiences than the interviewer. In this context, do not interrupt unnecessarily, complete a respondent's sentences, or answer the questions. Again, the idea is to learn about the respondent's point of view, not the researcher's. In this context, the researcher's "inevitable ignorance" about the experiences of another person can be a powerful tool.
- When conducting an open-ended interview, avoid asking "yes or no" questions. Responses to these questions provide less information than questions beginning with "what" or "how."
- Be flexible enough to adapt the line of questioning when necessary. Human experiences are complex and full of surprises.

45.7.6 Connections between Observation and Interviews

As noted earlier, one of the defining qualities of ethnography is its emphasis on holism. To obtain this holistic view, combining different sources of data is useful (Agar 1996). Observation alone is seldom enough to adequately address research objectives. As such, observation is invariably coupled with interviewing. Interviews can extend and deepen one's understanding of what has already been observed. Similarly, interviews can be conducted prior to observing, giving the researcher a better idea about what is most appropriate to observe.

Interviews can also be conducted in the context of ongoing activities, sometimes referred to as "contextual" or "in situ" interviewing. Instead of setting aside a specific time and place for an interview, the researcher creates an opportunity to ask questions as participants go about their daily activities. The strategy can be extremely useful in getting answers to questions that are prompted by observation of ongoing activities.

45.7.7 Self-Reporting Techniques

In cases where the domain of interest transpires over a long period, or in which direct observation is not practically feasible, self-reporting techniques can be very valuable. This methodology is especially good at revealing patterns in behavior or obtaining data that is otherwise inaccessible (Whyte 1984). A number of self-reporting techniques exist which vary in terms of form, focus, structure, and mechanism of self-reporting. Common techniques range from simple written diaries to visual storybooks, and more recently to Internet-based blogs.

45.7.7.1 Diaries

Traditional diaries consist of written records, which might include personal thoughts or descriptions of specific behaviors or accounts of events in which an individual participates (Zimmerman and Wieder 1977; Carter and Mankoff 2005). The focus, format, and degree of structure of diaries used in ethnographic research vary depending upon the research objectives, ranging from structured activity logs which invite participants to capture and describe specific aspects of their experiences for each entry, to relatively unstructured forms in which diarists are provided only with general instructions. Study participants might be asked to keep diaries regarding the specific contexts, foci, modalities, and outcomes of their interactions or they might simply be asked to describe their experiences over time while using a specific product.

Diaries are obviously not a substitute for direct observation. However, they are valuable tools for ethnographers, expanding opportunities to learn about behaviors that cannot be observed because of practical constraints and limitations on time and resources (Gillham 2005).

How diaries are analyzed depends on the research objectives and resource constraints. If time permits, follow-up discussions with participants to clarify points or gain a deeper understanding of the meaning behind the words can be useful. The texts can also be coded for themes, key words, or phrases and patterns examined across individuals or between groups.*

45.7.7.2 Visual Stories

Visual stories are essentially pictorial diaries that employ images in addition to text in order to document experiences. They can be particularly valuable when working with language limited participants, such as children, or in situations where words alone are inadequate to capture the essence of the subject (Johnson et al. 1997). Much like more traditional text-based diaries, visual diaries can be employed and structured in any of a number of ways. Wasson (2000), for example, described giving participants a written guide directing them to take photographs of their interaction with a product under study. They were then asked to organize the developed photos into a story that made sense to them, and researchers conducted follow-up interviews over the telephone.

A more open-ended framework can also be informative. Interested in cultural differences between Italian and American fishermen, Johnson and Griffith (1998) instructed participants from both groups to take photographs of whatever they wanted. After developing the film, Johnson coded the pictures based on their content and found significant thematic differences between the groups, which added to his understanding of differences in cultural values of the two groups of fishermen.

A more recent derivation of the visual story utilizes a video camera which allows the participant to provide a running

* With varying degrees of success, text analysis software has been used to help with large data sets. Some noteworthy programs are Ethnograph, NUD*IST, E-Z-Text, and NVivo.

narrative alongside the visual content. Being able to experience the two sources of information simultaneously provides the researcher with a rich record of an activity. Blomberg, Suchman, and Trigg (1996) used a video-story approach in their study of the document practices of lawyers. They set up a stationary video camera in the law office of a study participant and asked him to turn on the camera whenever he had occasion to retrieve documents from his file cabinet. The running narration recorded on videotape provided insights into the everyday use of the file cabinet that helped inform the design of an electronic file cabinet. The pervasiveness of mobile phones with built-in cameras has enabled the use of the visual diary technique. Researchers are able to set up urls where participants can upload their photos or video recordings with commentary as they document selected aspects of their lives (Palen and Salzman 2002).

45.7.7.3 "Blogs" and "Tweets"

Online tools for self-reporting, communication, and social networking have continued to evolve rapidly. The concept of weblogs or "blogs"—in which a website is used to post online entries that may include textual narratives, digital photos, or digital video or audio (Nardi, Schiano, and Gumbrecht 2004) has more recently been followed by the broad adoption of digital tools for "microblogging." The latter is best exemplified by the popular service provided by Twitter (founded in 2007), which enables someone to publish and disseminate short text "microblogs" or "tweets"—text messages of up to 140 characters—for others to read or "follow." Although not developed specifically to support ethnographic inquiries, blogs and "microblogs" can be potentially very valuable research tools. Blogs may be particularly useful as a way for participants to self-report their use of online tools in the context of their online activities. Blogs also enable researchers to review participant posts as they occur as well as to engage in asynchronous online exchanges and dialogues with participant "bloggers." These interactions might be viewed as virtual analogs to the questioning that occurs during shadowing or on site observation. Indeed, as blogs increasingly are used in ethnographic research (e.g. Berry and Hamilton 2006), they may blur the boundary between self-documentation and interviews, resulting in a blend of online self-reporting and intermittent online "conversations" via threaded participant and researcher posts.

In addition, some ethnographers have begun to experiment with posting their research notes via blogs, enabling research and design team members to review and comment asynchronously and in near real time. By making observational and interpretive notes more readily visible to teams, the ethnographer may promote dialogues which can inform further observations as well as accelerate and heighten impact of research on design.

Microblogs or "tweets" can provide near real-time snippets from the stream of experience when direct observational shadowing is not possible or practical. Indeed, although not specifically directed at ethnographers, Twitter actually provides tips ("twitip") about why and how to do research with Twitter (http://www.twitip.com/twitter-for-research-why-and-how-to-do-it-including-case-studies/). While blogs and tweets can be done quickly, relatively easily, and while participants are mobile, as with any self-reporting methodology, there is always the possibility that the activity of self-reporting may alter the phenomena being studied.

45.7.8 Remote "Virtual" Observation: Digital Ethnography

Continuing technological developments—in video, audio, wireless, network applications, global positioning system (GPS) tracking capabilities, and pervasive computing—have created new opportunities to "observe" and collect rich and dynamic information across geographies in real time as well as asynchronously. These technologies increasingly enable ethnographers to "virtually" observe in a wide variety of contexts. Using digital video and audio, people's behaviors can be tracked and analyzed as they interact with computer supported products and Internet-based networks.* Indeed, these technologies (along with the use of other digital tools such as blogs and microblogs) enable what some have begun to refer to as "digital ethnography" (Masten and Plowman 2003; Murthy 2008; Mason and Dicks 1999; or even "netnography" by Xun and Reynolds [2010]).

The pervasiveness of the "webcam" is perhaps the simplest illustration of how technology has expanded the observational capabilities of ethnographers. Internet-enabled digital video cameras can stream video in real time and can be remotely controlled. This digital video and audio can be viewed by multiple people across geographies either in real time or by accessing video archives. Such techniques and information sources can be particularly useful for geographically distributed research and design teams or where the activities of interest are widely distributed making direct observation difficult.

In addition, computer and online sensing, tracking, and analytic technologies that monitor, gather, collect, and integrate information on computer mediated activities can be a useful source of information for ethnographers. Although early tracking and analytic technologies required complex sifting and analysis of massive amounts of data to find meaningful nuggets, more recent tools enable sophisticated tracking of individual paths and activities as well as the ability to model online behavior. For example, scenario-based behavioral models (e.g., of online shopping, exploratory behavior, task completion, etc.) which define hypothesized patterns or sequences ("funnels") of online behavior can be used as an analytic lens to understand individual or group online behaviors. To date, these tools have been used primarily to measure aggregate completion of online tasks (e.g., online shopping, self-service) and to identify obstacles to user success

* The ability to virtually observe and track behaviors presents many ethical issues that cannot and should not be ignored. It is critical that ethnographers establish guidelines and protections if they engage in electronic, digitally enabled observations.

(e.g., usability issues). However, over time and in conjunction with other sources of data and information they may become useful tools for ethnographers interested in patterns of online behavior and technology adoption. This may become particularly important as ethnographers attempt to understand the formation and interactions of distributed virtual communities (e.g., Rheingold 2000; Wilson and Peterson 2002).

The potential for using (and misusing) these sources of information will likely increase as pervasive computing increasingly enables the identification of (and response to) individuals across multiple physical and digital environments and the tracking of their activities. The collection and use of digitally enabled behavioral observations obviously needs to be carefully constrained by ethical considerations, particularly the respect for privacy and informed consent. In addition, as with any behavioral observation, it is critical to understand the context in order to interpret the meaning and significance of the behavior. In this respect, tracking computer-mediated behaviors by itself is insufficient and may simply result in the collection of massive amounts of relatively meaningless data. However, if used in conjunction with other sources of information (e.g., self-reports that illuminate peoples' intentions and meanings), patterns in digital behavior can illuminate aspects of behavior that are difficult or impossible for a human researcher to observe.

For example, it has been increasingly common for teams designing online services and tools to examine individual and aggregate patterns of online behavior (as reflected in web server logs or "client side" logs that are generated as a function of what users do online) to both identify usability issues as well as to examine patterns of technology, product, and service adoption over time (Kantner 2001).

45.7.9 Artifact Analysis

Ethnographers have long had an interest in the material world of the people they study (Appadurai 1988). The artifacts people make and use can tell us a great deal about how people live their lives.* Artifact analysis can be an important part of contemporary ethnographic studies (e.g., Rathje and Murphy 1991). For example, conducting an artifact analysis of the stuff on people's desks can say a great deal about the people's work practices (Malone 1983). Similarly, studying the contents of an automobile's "glove box" can tell a great deal about how the car is used. Depending on the kinds of research questions asked, it may be useful to include the collection and analysis of specific artifacts.

45.7.10 Recordkeeping

Although the authority of the ethnographic voice derives in part from the fact that the ethnographer is present and witness to events of interest, the ethnographer should not rely exclusively on experiential memory of these events. In all ethnographic research it is essential to keep good records. Field notes should be taken either during or soon after observing or interviewing. The specific nature of the notes will depend on the research questions addressed, the research methods used, and whether audio or video records supplement note taking. Field notes should at least include the date and time when the event or interview took place, the location, and who was present. Beyond that, notes can vary widely, but it is often useful to indicate differences between descriptions of what is observed, verbatim records of what is said, personal interpretations or reflections, and systematic indications of the flow of observed events and activities. When working with a team of researchers, field notes need to be understandable to other team members. This is often a good standard for the specificity of field notes even when working alone. If such a standard is maintained, it will be more likely that the notes will be useful to the researcher months and even years later, in the event reanalysis or a comparative study is undertaken.

45.8 QUALITATIVE AND QUANTITATIVE DATA

In Section 45.7.6, we touched upon the complementary nature of observational and interview techniques and the benefit of combining these two approaches. Triangulation of data can serve to connect quantitative and qualitative data as well. Sometimes, prior to the start of a project the only data available is quantitative, sometimes in the form of survey data focused on population characteristics. Qualitative data derived from ethnographic research can complement quantitative research by providing a meaningful context for interpreting the quantitative results. Qualitative techniques allow researchers to dig deeper after a survey has been tabulated, and aid in interpreting and explaining trends that the quantitative data might reveal (Guest 2000). In addition, qualitative data can inform the content and language of more structured questions, thus making them more meaningful and relevant to the participants.

45.9 ETHNOGRAPHY IN A GLOBAL CONTEXT

While ethnography has its roots in the study of small-scale, non-Western societies, the application of ethnography in the design of products and services until very recently has focused primarily on groups and individuals located in the developed regions of the world (e.g., North America and Europe). Two recent developments have led to a shift in the center of design activity. One is the emergence of the economies of less-developed countries, particularly Brazil, Russia, India, and China, the so-called BRIC countries, which are rapidly becoming major markets for products and services. An interest in serving these growing markets has led some firms to invest in designing products and services specifically for them by directly engaging designers, developers, and potential users from these developing regions (e.g., Bell 2004; Foucault, Russell, and Bell 2004). The second development is the rapid increase in the use of Internet-enabled information

* Archaeologists rely almost exclusively on the artifacts that remain in archaeological sites for their interpretations of the behavior and social organization of past human societies.

technologies that connect workers, consumers, citizens, and organizations distributed around the world including developing regions.

45.9.1 Globally Distributed Interactions

The methods and techniques of ethnographic research must contend with the increasing number interactions both at work and in domestic spheres that take place "virtually" between people separated in space and time. This is a challenge for ethnographic techniques that were developed to study communities of people who interact face-to-face. Ethnographic techniques and approaches must be adapted both practically and analytically to this new context where many more interactions are mediated by information technologies (e.g., instant messaging, blogs, twitter, SMS, e-mail, telephone, web conferencing, shared digital workspaces, and repositories) that transform traditional notions of place, community, and real-time interaction. In many enterprises, work teams are made up of people who are not co-located, many of whom are highly mobile in their work activities, requiring interactions to take place through conference calls, instant messaging, SMS, e-mail, and even microblogging (Zhao and Rosson 2009). Furthermore, in some regions of the world, people travel significant distances for jobs and other opportunities. In these cases, interactions with friends and family, as well as with others living away from their native communities, are enabled by communication technologies (Horst and Miller 2005; Green, Harvey, and Knox 2005). Various strategies have been developed to study distributed, multisited groups including team ethnography (placing researchers in multiple locations), perspectival ethnography (focusing on the view from one of the local sites), and virtual observations (observing digitally mediated interactions).

45.9.2 Multisited Ethnography

The challenges of studying ethnographically an increasingly interconnected and globally distributed world became an important topic for anthropologists in the mid-1990s with the publication of an article by Marcus (1995) that raised the question of whether and in what ways ethnography, with its traditional reliance on the "field site" was well suited for the study of the contemporary experiences of people around the world. Taking a multisited approach was viewed as a way to apply an ethnographic perspective to theoretical and practical concerns in the study of migration, Diasporas, technologically interconnected (virtual) communities, and globalization more generally. Multisited ethnography addresses strategies for studying geographically distributed activities and groups (Coleman and von Hellermann 2011; Falzon 2009; Hannerz 2003).

Instead of defining the field site as a single location the emphasis is on capturing the connections between people, places and things regardless of their geographic proximity. This then raises the question of how to circumscribe the study in the absence of having a single field site. However, local alone rarely delimits an ethnographic study relying more often on the research questions being addressed to define what is in and out of focus. On this view the bounds of the study is always constructed and cannot be given by place alone.

That said there is still the practical issue of how to limit the many possible physical sites in order to devote enough time to any one of them. One strategy has been to pick a "focal" site and then move beyond the focal site as research dictates given the resources available. For example, while a particular call center might be deemed the focal site for the research, other sites such as workers' local domestic residences or the more distant communities of their origin might also be included in the study.

45.9.3 Shifting Center of Design Activity

As new markets open up around the globe, many businesses and organizations see opportunities to create products and services specifically for these markets recognizing that the products and services suited for the developed West may not be appropriate for these other regions. As such these firms may establish design initiatives focused on and located in countries like India and China. In some respects ethnography has come full circle with the application to design, contributing to understandings of the contexts of people living in culturally and linguistically diverse settings (the sites in which ethnographic practice first developed). More than ever ethnographic principles and practices are applicable and necessary as the center of design activity moves outside the developed West, in particular the principle of members point of view and the focus on "what is" as a resource for innovation and design.

45.10 DESIGNING WHAT?

The application of ethnography to support a design agenda was directed initially toward informing the design of technologies, tools, and products. However, attention has expanded to include the use of ethnography to inform the design of experiences (Pine and Gilmore 1999), services (Kieliszewski, Bailey, and Blomberg 2010; Kimbell 2009; Mager and King 2009; Thomke 2003), organizational processes, and business strategies and models. In addition, educational institutions and programs (e.g. the "d-school" at Stanford University; Design Ethnography program at University of Dundee, Applied Anthropology programs at California State University at San José and North Texas State) are dedicated to teaching design thinking to address a myriad of problems beyond the design of products. Ethnographers are now involved in projects and contexts that span a range of problems including the design of the next e-mail application, business models to reach small and medium businesses with IT services, customer services for retail banking, integrated health care services, and Internet delivered social networking services.

45.10.1 Products

The application of ethnography to product design has received the most attention in the literature partly because many of the pioneers in the field worked in corporate research organizations of major technology companies (e.g., Xerox, Apple, and HP). In addition, early commercial applications of ethnographically-informed design often focused on the design of consumer products, from cleaning products to automobiles to toys (Elab, Doblin group, Sonic Rim). It is not surprising therefore that many view product design, whether high-tech products like personal digital assistants and online calendar applications or everyday consumer products like breakfast cereals or cold remedies, as the primary application of ethnographic research (Squires and Byrne 2002).

45.10.2 Experiences

The publication of the Experience Economy (Pine and Gilmore 1999) marked a shift in design focus to include the experiences that products and other artifacts enabled. Pine and Gilmore argued that the real challenge for businesses is creating engaging experiences for both consumers and corporate customers. The admonishment by a number of business gurus to pay more attention to the customer in the design of products also contributed to this expanded focus. Customers, it turned out, cared less about the products themselves and more about what the products enabled them to do or experience. Businesses became concerned with delivering quality experiences in which the products took on more of a supporting role. The canonical example often cited for this shift to an experience economy is Starbucks, where what is being sold is not simply a cup of coffee, but the experience of buying and consuming the coffee at Starbucks, including the elaborate choices available, the wireless access provided in the stores, the exclusive access to trendy music, and so on. In many commercial contexts user experience design has become the new moniker for the application user-centered design approaches, including ethnographically-informed design, to the development of new products and services.

45.10.3 Services

The service sector has come to dominate much of the world economy and increasingly new services are the site of significant change in the way we work and play (e.g., online dating services, GPS tracking services, business process outsourcing services). Many innovative services are enabled by new technologies that provide the platforms* on which new service relationships are built. However, the service is marketed and not the technology that facilitates its delivery. Ethnographically-informed design strategies are now being applied to service design (Kimbell and Seidel 2008; Jones and Samalionis 2008; Mager and King 2009; Thomke 2003). In addition, recent advances in Web 2.0 technologies have created opportunities for the development of a wide range of services, including public services to improve government, health care and community services, and commercial services to enable firms to connect with their customers (c.f. Scola-Streckenbach 2008; Dittrich et al. 2003).

Kimbell (2009) argues that service design developed in conjunction with changes in design practice brought about by the widespread use of networked media technologies. The "outputs" of designs were expanded beyond stand alone technologies to include the "arrangement of interfaces to distributed devices." And through these interfaces new services were being delivered. On this view the focus of design was on the services delivered and less on the individual devices that enabled the delivery. Many small firms and in-house research and design departments now offer service design along with product and experience design.

45.10.4 Organizational Processes

Workflow systems have become ubiquitous within many organizations, orchestrating everything from employee travel-reimbursement processes to customer online-purchasing procedures. With this comes the opportunity to inform the design of these technology-enabled organizational processes through the study of existing work practices and processes. Here again the design focus is not so much on the underlying technologies (e.g., SAP, Siebel) that manage the workflow, but on the processes themselves. This is not to say that these studies will have no impact on the underlying technologies—for example, making them more flexible or end user configurable. But the design focus is on the workflow requirements, how people will interact with these systems and will be supported in executing processes (Bowers, Button, and Sharrock 1995; Dourish 2001; Randall, Rouncefield, and Hughes 1995).

45.10.5 Business Strategies and Models

Ethnographic research is also playing a role in the design of business strategies and models. Organizations are realizing that their competitive advantage is only partly related to the quality of their products and services. Equally important are the business strategies, including channels to the market, relationships with business partners, and the composition of employees. Many new business models have emerged in the last decade that capture new revenue streams such as advertising (e.g., Google, Yahoo!), selling software as a service (e.g., salesforce.com), and facilitating networks of sellers and buyers or customers and providers (e.g., eBay, regional IT distributors). Ethnographic research is contributing to the design of these new business models.

45.11 Making Ethnography Matter: Communicating and Applying Ethnographic Insights to Design

This section outlines some of the ways in which the insights derived from ethnographic work can be represented and communicated in order to effectively inspire and guide the design of products and services. These ways of representing and communicating what is learned are intended as examples

* See, for example, service-oriented architectures.

of how ethnographic work can be made relevant for design. However, before we outline some of these representational forms and practices we should consider the possible purposes of our representational activities.

45.12 ENHANCING THE WORKING MODELS OF DEVELOPERS

In order to design a product or service for people, designers must have at least an implicit working view of the people who will interact with the system. Such working frameworks and perspectives may include assumptions about a range of essential characteristics of the people who will engage with the product or service and the contexts in which they will do so (Newman 1998). Indeed, some would argue that successful design requires a high degree of "empathy" with the target population (e.g., Leonard and Rayport 1997; Koskinen, Battarbee, and Mattelmäki 2005). Implicit and/or explicit assumptions or knowledge about "users" may be formed through some combination of direct experience (e.g., interacting with and/or observing people in the target population) and secondary learning (talking with others about the target group, viewing videotapes of target activities, reading, analogy to other directly experienced groups, etc.). However formed, the working "models" of designers/developers may be of varying levels of complexity, robustness, coherence, consistency, and viability. The broad, deep, and contextualized understanding provided by ethnographic research can enrich the design team's implicit working models.

45.13 SUPPORTING INNOVATION

The design of products and services for people obviously poses a range of potential creative challenges at varying levels of complexity. What problems should be solved? What should be built? What kinds of experiences should be supported or enabled? What features and functions would be useful, compelling, and satisfying for a particular group of people in a particular domain or context? How can current or emerging technological capabilities be used to enhance a particular group's experiences, or to solve a particular problem? Even if there are clear parameters defining the functionality that will be built (e.g., a set of "requirements"), design teams must still generate a compelling, easy to use, useful, and satisfying way of delivering that functionality. By providing an understanding of the human domain (patterns of relationship, systems of meaning, organizational structure, guiding principles or rules, etc.), ethnography can promote creativity that matters (Robinson and Hackett 1997)—relevant innovations that create new, realizable opportunities.

45.14 EVALUATING AND PRIORITIZING IDEAS

Design teams not only face the challenge of generating innovative ideas and concepts, but also the equally important task of evaluating and prioritizing ideas and options that arise from various sources (e.g., business stakeholders, end users, development teams). Although there are obviously many evaluative methods (e.g., scenario-based user testing, etc.), models derived from ethnographic research and analysis (e.g., scenarios, mental models, process models, personas, etc.) can provide a critical lens through which development teams can evaluate and prioritize ideas based on how they may fit into or change people's experiences. The need for evaluation and prioritization may occur at various points throughout the development process, ranging from decisions about features and functions, broad directions for design concepts, and so forth.

45.15 SHARED REFERENCE POINTS

The learning derived from ethnographic analysis, particularly when represented as explicit representations and models, can serve as an experiential guidepost for individual designers and design teams throughout the development process. Even though these representations do not prescribe or specify what should be done, they can aid developers by focusing attention on essential aspects of an experience, highlighting variations in the experiences, and limiting exploration of experiential "dead ends." In other words, they can provide a general structure and direction within which a team can develop a shared understanding and focus its creative energies.

45.16 INFORMING USER ADOPTION STRATEGIES AND PLANS

Ethnographic insights not only inform the design of products and services, but they also guide the generation of effective strategies for promoting adoption of solutions. Understanding the current state, how people operate and view their experiences today can enable the identification of experiential and social barriers inhibiting adoption. This understanding also can point to the levers or factors that can be used to overcome barriers to change and accelerate adoption. Particular designs will invite or require changes in user behavior and experience which can be better anticipated if the current state is well understood. Ethnographic understanding enables designers and change agents to move beyond the general factors outlined in some of the major models of user adoption (e.g., Rogers 2003 diffusion model) to specific insights and contextual factors that are meaningful and important to specific sets of users. For example, cross-cultural ethnographic research on current work practices conducted by the second author in a large global enterprise prior to the rollout of a new business process and an associated web-based tool, highlighted the differential impact that the solution would have on users in varied geo-cultural settings. In this case, users in Japan would be asked to shift from a highly cumbersome manual process, primitive offline tools and artifacts, and an unreliable and confusing collaborative process to what for them would be a highly streamlined, labor saving set of tools and work practices. In contrast, users in key North American settings would be asked to shift from a highly automated, simple, and familiar process to one that involved learning a new tool, and a new process that added extra work steps. General communications to promoting the new tools and processes as "easy to use" and "labor saving," would clearly have fallen on deaf ears in North America while potentially resonating with users in Japan.

45.17 REPRESENTATIONS AND MODELS

Whether the focus is on designing products, experiences, services, processes, or business strategies, the researcher must find ways to ensure that ethnographically derived insights effectively inform design innovations and decisions. Researchers can help make connections between ethnography and design in many ways. At the most basic level, this is achieved through active engagement, integration, and collaboration of researchers and designers.* Subsequent to conducting ethnographic inquiries, researchers can engage with design teams by acting as user proxies (e.g., helping to formulate and/or review design concepts in scenario-based reviews, providing feedback regarding relevant user expectations and behaviors as they relate to design concepts and decisions, etc.). Conversely, the active and direct involvement of designers in key elements of ethnographic fieldwork (e.g., participating in observations and interviews, collaborative analysis sessions, reviewing video and audio recordings and user artifacts, etc.) can enrich their understanding of the people who will interact with and use the solutions they design.

Although these forms of engagement are valuable, they limit the ability of teams to take full advantage of ethnographically derived understandings. They are restricted in the impact to the scope of the direct interactions between ethnographers and designers. This can be particularly limiting when designing multifaceted solutions, working with large and/or distributed design and development teams.

45.17.1 The Value of Representations and Models

To increase the impact of ethnographic research, explicit representations or models can be created which distill and communicate essential insights about people's experiences in forms that can be applied to design problems and decisions. Although the definition of model can be the subject of debate (as can the distinction between representation and model), for our purposes we are using the term to refer to explicit, simplified representations of how people organize and construct experiences and operate in relevant domains. The important point here is that well-constructed representations which communicate effectively can help connect everyday patterns of activity and experience with design solutions. More specifically, representations and models are tools that can serve a number of purposes including enhancing the working models of designers/developers, supporting innovation and creativity, evaluating and prioritizing ideas and concepts, and providing shared reference points for design teams.

45.17.2 Types of Representations and Models

Representations and models can vary, ranging from personas and scenarios to more abstract mental models. The number, type, and form of models vary as a function of what is being designed, the audience, and the constraints on the design process (e.g., Chapters 42 and 43). For example, teams designing organizational tools may find it useful to model work environments and detailed task sequences; teams designing learning tools and programs may want to represent particular skill domains, as well as learning processes.

Practitioners have developed a variety of representations and models to inform the design-and-development process. For example, Beyer and Holtzblatt (1998) described a set of five work models (flow model, cultural model, sequence model, physical model, and artifact model) to reflect different aspects of a work domain. Pruitt and Grudin (2003) articulated the value (and risks) of personas to inform the design process, while Carroll (2000) described the value of scenarios.

The varying scope, form, complexity, and function of different types of models are illustrated in following examples.

45.17.2.1 Experience Models

The model presented in Figure 45.2, is one of several developed in the context of ethnographic research and analysis for a financial services company serving individual investors. This company aimed to develop web applications that would facilitate customers' active engagement in the investment process with particular financial instruments. The model was intended to articulate and visualize a financial development process as well as the varied meanings of "money." This particular model highlighted the role of "practice" in developing the confidence and knowledge to become engaged in the investment process, and the iterative/recurrent nature of the process, as people learned to deal with new financial instruments and domains (e.g., securities, bonds, options, etc.). Moreover, it illustrated the distinctions that people make between "real," "play," and "foundational" money and the relationship between these categories, investment behavior, and financial development. To oversimplify a bit, people are more fully engaged and active in the investment process when they view the assets/investments as "real" (e.g., money that is used to address their current and emerging needs, pay bills, etc.) rather than as "play" (e.g., stock options that are perceived as intangible and somewhat imaginary) or "foundational" (e.g., savings for the future that are left "untouched"). As people have an opportunity to "practice" and develop their knowledge, they may move from construing a particular financial instrument or activity as "play" to "real." These notions suggested that web applications in this domain should not be focused on simply providing a wealth of financial information or a plethora of tools. Instead, these patterns helped to foster the generation of numerous ideas about ways to engage people in playful learning in the financial domain, with the aim of facilitating the financial development process.

* As noted earlier, the ethnographer should develop an understanding of the types of design decisions that the design team will need to make and a sense of what they need to know to inform those decisions.

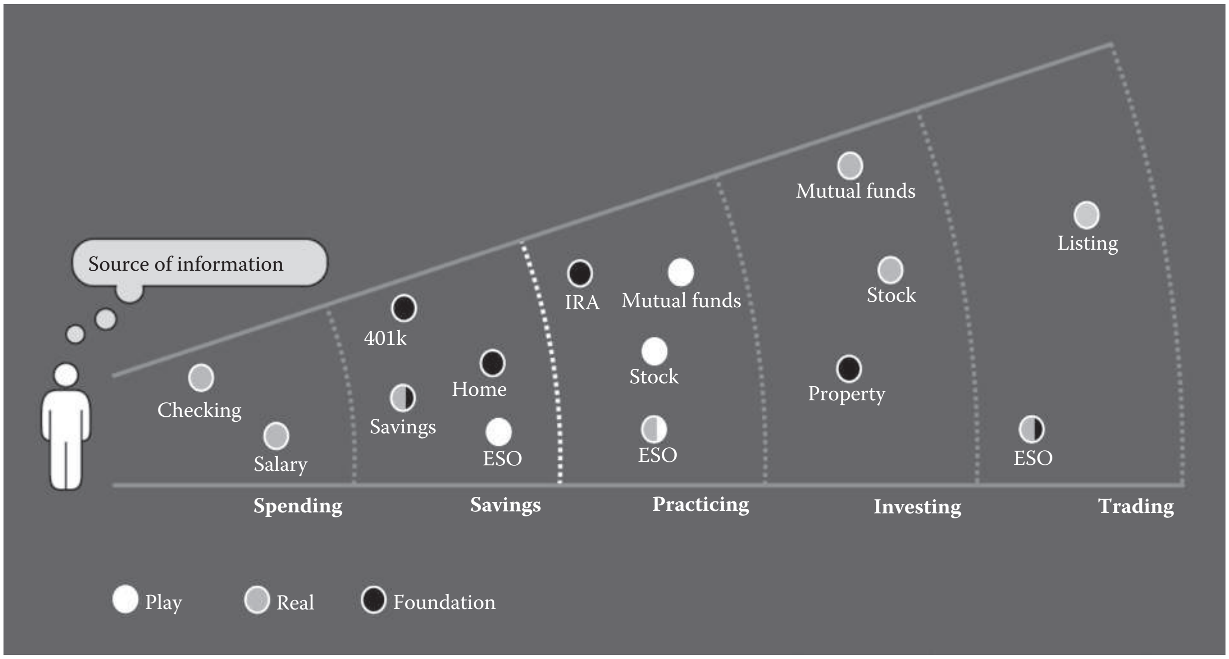

FIGURE 45.2 Experience model of financial development zones.

45.17.2.2 Process Models

Process models attempt to represent how a dynamic experience "works" and/or unfolds over time. They can range in focus from relatively circumscribed task-flow models that outline how an individual completes a specific task, to broader characterizations of more holistic change processes (e.g., health care behavior change, technology adoption, etc.). For example, a health services company aimed to develop an "electronic medical record system" (combining client server applications with web-based "portals"). This system would, among other things, increase the efficiency and effectiveness of their medical practice, enable patients to view their health records online, and ultimately empower patients and foster a proactive approach to wellness and health care (both by clinicians and patients).

At the outset of the engagement, the health services company had generated a rather long requirements list (several hundred features and functions) and a particular view of the structure and function of the web components of the system. It was clear that the budget for this initiative was not sufficient to build a system that met all of the initial "requirements." Perhaps more importantly, it was unclear which components would ultimately add the most value for the various stakeholders (clinicians, patients, the business owners, etc.). Ethnographic research examining the experiences of and relationships between clinicians and patients in context (in clinic settings and in homes) provided the means of prioritizing and evaluating potential features, functions, and design concepts.

Experience models of varying levels of complexity regarding the health management process were developed. For example, one of the simpler models (see Figure 45.3) described how individuals, in the process of adopting an active/proactive stance in relation to health issues, move through varying "stages of readiness." A more comprehensive, integrative model highlighted the ways in which various factors interact in influencing a person to take action in addressing a health issue and mapped the role of various health care-related activities (e.g., monitoring, motivating, learning, sharing, building rapport) in various stages of readiness. The combination of these models enabled the team to identify the most important opportunities for facilitating progression towards a proactive orientation to health, and provided guidance in identifying ways to provide messages and experiences tailored to a person's stage and readiness.

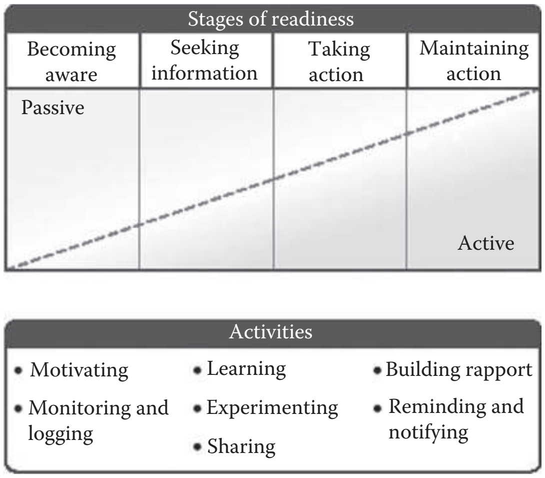

FIGURE 45.3 Stages of readiness model.

45.17.2.3 Personas

One of the primary challenges in developing interactive systems is to design them so that they meet the needs of varying users, who may play different roles, engage in varied tasks, have different motivations and strategies, and so forth. Profiles or personas are abstract representations of the users of a solution (Pruitt and Grudin 2003; Pruitt and Adlin 2006) that may be informed through ethnographic studies. Personas can help development teams understand and anticipate how certain types of people may experience and interact with technology solutions or services. For example, Figure 45.4 shows a simple persona developed to guide the design of interactive tools promoting the adoption of various financial and health benefit programs in a large enterprise. Note that the persona focuses characteristics (attitudes, life stages, scenarios, etc.) that are most relevant to the person's experiences in managing financial and health-related concerns.

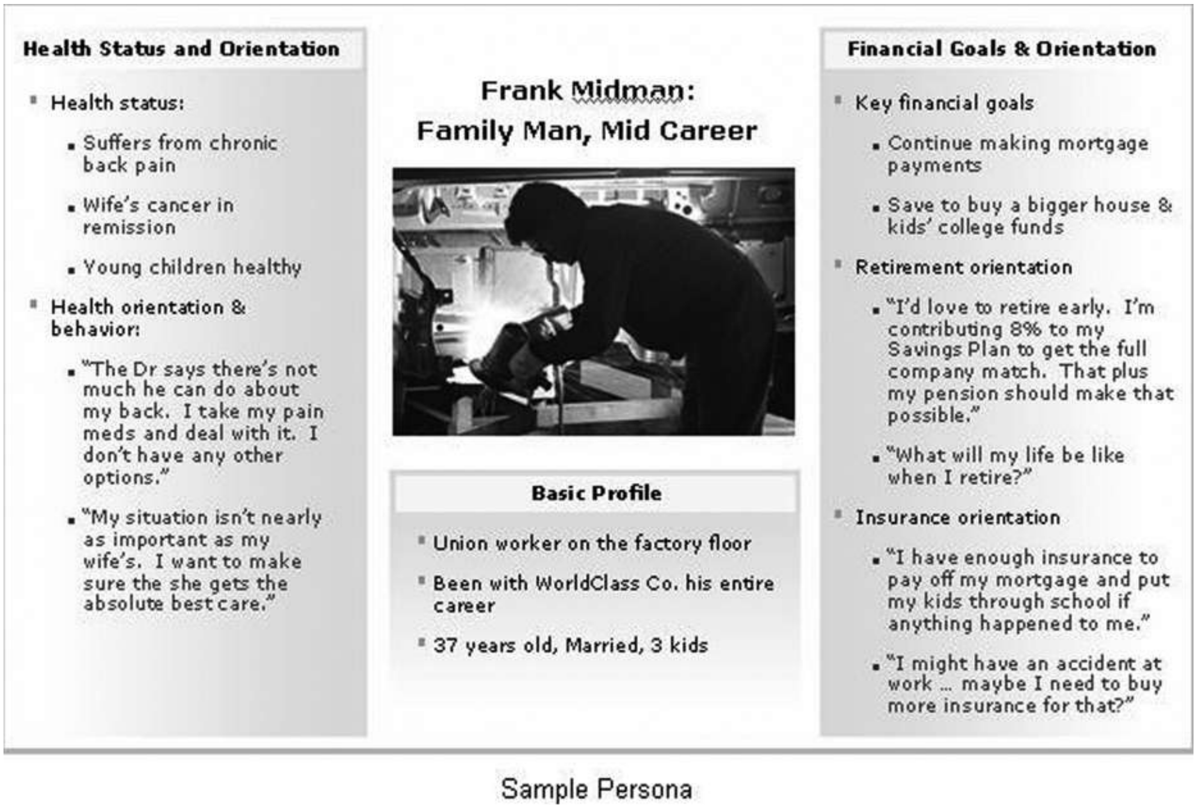
The value of personas can be enhanced by making them visible and dynamically present for design and development teams (e.g., posters displayed in project rooms, multimedia representations that are reviewed with development teams, role-playing scenarios and walkthroughs based on profiles, etc.). Rich and dynamic representations of essential characteristics of individuals can serve as a common frame of reference for communication and a tangible reminder to development teams regarding the people for whom they are designing the system. Moreover, personas can be used systematically in a range of ways to help teams make design decisions. For example, Pruitt and Grudin (2003) described specific techniques they have used to systematically apply personas to aid in feature prioritization decisions.

45.17.2.4 Scenarios

Scenarios are another way ethnographic research findings can be portrayed (Carroll 2000; Nardi 1992; Sonderegger et al. 2000; Chapter 48 of this book). Scenarios illustrate experiences and actions as they unfold in specific contexts or situations (Figure 45.5) and can be documented in various forms ranging from narratives to annotated visual flow diagrams. They may highlight interactions (with computer systems, people, business entities, etc.), decisions processes, activity sequences, influencing factors, and so forth. They also may illustrate the different ways in which varied groups or types of people experience and navigate through similar situations. Analysis of scenarios can foster the identification of areas of difficulty ("pain points") and experiential gaps (or opportunities), that may be addressed or enhanced through various design solutions. When integrated with personas, they can illustrate how different target audiences navigate through the same situation, which in turn can suggest ways in which solutions can and should be adapted for varying target audiences.

45.17.2.5 Service Blueprints

As service design has become a more important arena for the application of ethnographic approaches, designers and researchers have looked for ways of representing services.



Health Status and Orientation

- Health status:
  - Suffers from chronic back pain
  - Wife's cancer in remission
  - Young children healthy
- Health orientation & behavior:
  - "The Dr says there's not much he can do about my back. I take my pain meds and deal with it. I don't have any other options."
  - "My situation isn't nearly as important as my wife's. I want to make sure the she gets the absolute best care."

Frank Midman: Family Man, Mid Career

Basic Profile

- Union worker on the factory floor
- Been with WorldClass Co. his entire career
- 37 years old, Married, 3 kids

Financial Goals & Orientation

- Key financial goals
  - Continue making mortgage payments
  - Save to buy a bigger house & kids' college funds
- Retirement orientation
  - "I'd love to retire early. I'm contributing 8% to my Savings Plan to get the full company match. That plus my pension should make that possible."
  - "What will my life be like when I retire?"
- Insurance orientation
  - "I have enough insurance to pay off my mortgage and put my kids through school if anything happened to me."
  - "I might have an accident at work … maybe I need to buy more insurance for that?"

FIGURE 45.5 Scenario flow model.

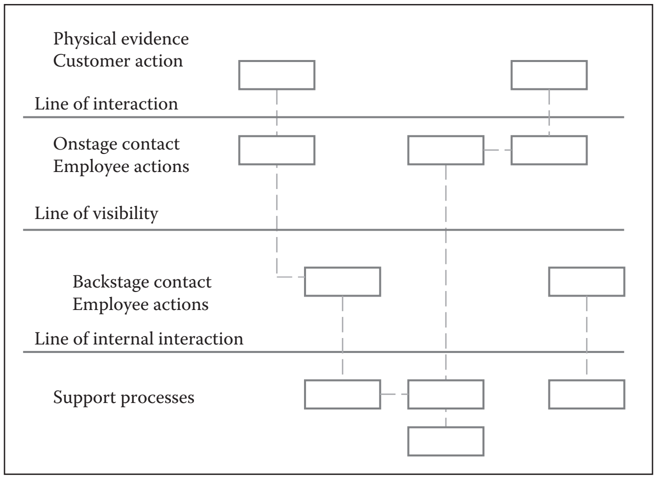

FIGURE 45.6 Service blueprint elements.

Service Blueprinting is a service design tool and a way of representing people, interactions, organizations, and artifacts that make up a service. The approach first introduced to enable innovation in services (Shostack 1984, 1987, and 1993) has evolved and become a standard way of describing services, introducing change in how the service is delivered, or designing radically new services. Service blueprinting was initially introduced as a process control technique (Bitner, Ostrom, and Morgan 2008) for services that provided more precision than verbal descriptions and could therefore identify possible failure points. Service blueprinting is now focused on improving the service experience, noting just those places where the service recipient comes into contact with the provider or provider organization. Central to the service blueprinting representation is a distinction between front stage and back stage or those aspects of the service that involve or require interaction with the customer and those that occur behind the scenes, in the provider organization. Importantly service blueprinting highlights the customer's role in providing the service and as such focuses attention on the experiences of "users" of the service. Service blueprinting shares similarities to both process models and scenarios in that the representation focuses on the often linear unfolding of a service (e.g. from the time you walk into a bank, approach the teller, complete your transaction, and depart). Service blueprinting allows service designers to focus on where the customer interfaces with the service provider and to connect those interactions with the activities taking place outside their view, but nonetheless critical to providing the service (see Figure 45.6).

45.17.2.6 Mental Models

The concept of a "mental model" has a long history in cognitive science and has been utilized in a variety of ways in HCI and interaction design (e.g., Gentner and Stevens 1983; Johnson-Laird 1983, 1996). For example, Norman (1983) used the term mental model to refer to the "internal conceptualizations that people form of the things with which they interact." More broadly, mental models can be defined as representations of how people make sense of and think about an experience or a product or service. Although ethnography does not enable one to directly "observe" how people create meaning, it does aim to develop views onto how the people studied understand and make sense of their world. In the current context, interpretation and representation of ethnographic findings in the form of mental models can inform the design of products and services by highlighting the key conceptual facets of experiences, the categories that people apply, the questions they ask, the principles they apply, the ways they think and flow through problems and information. The insights reflected in such models can help shape numerous aspects of a product or service including the organization and architecture, the nomenclature and labels, and the interaction design.

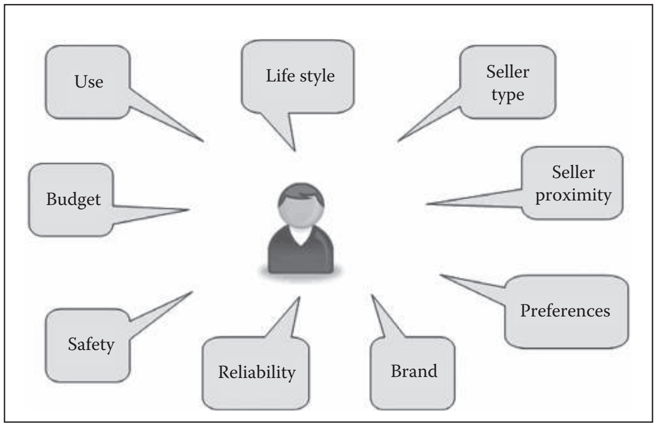

FIGURE 45.7 Simple metal model of car buying criteria.

For example, a simple mental model representing the key questions and criteria that people apply when looking for a car (see Figure 45.7) can inform the entry points and exploration criteria (e.g., faceted navigation categories and criteria) presented to users of an automotive classified website. A mental model representing the primary and secondary questions that design engineers think about when selecting and designing parts or assemblies for new vehicles (see Figure 45.8) can similarly inform the design of a discovery application aimed at helping find the best parts for their products. Engineers are aided in their exploration and decision making through the selection and presentation of important data sources organized by meaningful categories such as form, fit, function, environmental compliance, cost, reliability, and lifespan. These provide search and discovery entry points and refinement and exploration criteria.

45.17.2.7 Mock-Ups and Prototypes

Representational artifacts, be they paper prototypes, mock-ups, or working prototypes, can play an important mediating role in connecting use requirements and design possibilities. When informed by studies of practice, these design representations respecify practices and activities in ways that are recognizable to practitioners. The prototypes go beyond simple

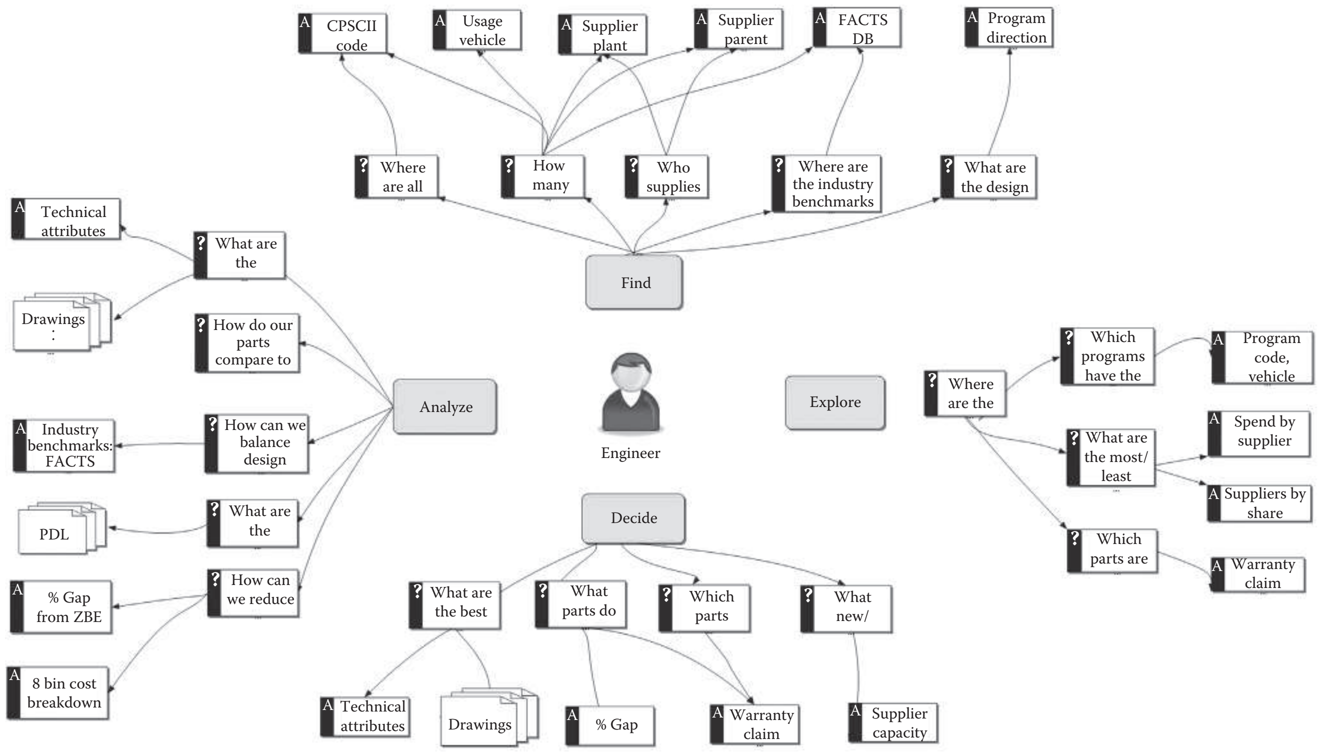

FIGURE 45.8 Design engineers' mental model for selecting and designing new vehicles.

demonstrations of functionality to incorporate materials from participants' sites, embody envisioned new technological possibilities, convey design ideas in relation to existing practices, and reveal requirements for new practices. Prototyping practices as such recover and invent use requirements and technological possibilities that make sense each in relation to the other (Suchman, Blomberg, and Trigg 2002). In addition these representational artifacts facilitate the communication of what has been learned about technologies-in-use to the larger research and technology-development communities.

In an ethnographic study of engineering practice at a state Department of Highways, design prototypes critically deepened the researchers understanding of the requirements of the work of document filing and retrieval (the focus of the study). At each step, from early design discussions with practitioners, to the creation of paper "mock-ups" of possible interfaces to the online project files, and finally to installing a running system at the worksite, the researchers became more aware of the work's exigencies. For example, in recognition of some of the difficulties that engineers experienced with their filing system various alternative document-coding strategies that augmented the existing filing system were designed. Through successive rounds, in which engineers were asked to code documents using mocked-up coding forms (both paper-based and online) the researchers' understanding of the requirements of the work deepened. Eventually, the search and browsing interfaces evolved to be more finely tuned to the requirements of the engineers' work (e.g., Trigg, Blomberg, and Suchman 1999).

45.17.3 Caveat Regarding Representations and Models

Although representations and models are valuable tools for connecting ethnographic understanding and design, they also can have negative effects. Although grounded in observations and other forms of ethnographic inquiry, models are always a selective interpretation and construction of experience. Thus, while representations and models can focus attention on and illuminate important aspects of experience, they can also become reified stereotypes and constraints that inhibit design possibilities. Ongoing inquiry, a critical perspective, and a willingness to evolve the representations in the face of new learning are essential to maintain the viability and value of models for design.

45.18 RELATION TO OTHER QUALITATIVE APPROACHES AND PERSPECTIVES

The ethnographic approach has strong connections to and affinities with other approaches that have contributed to the development of the field of HCI, namely distributed cognition, activity theory, ethnomethodology, and participatory design. In addition, the connections between ethnography and usability testing have grown stronger in recent years with some innovative approaches to combining user testing with observations and interviewing in more naturalistic settings. There is not space here to go into depth on any of these approaches. Our aim is simply to highlight relations between these approaches and ethnography, and provide a way to distinguish between them.

Distributed cognition (sometimes referred to as social or situated cognition) was first introduced to the HCI community by Lave (1988) and Hutchins (1995). Distributed cognition located cognition in social and material processes. When it was introduced, it challenged the dominant paradigm within HCI, that cognition primarily involved the psychological and mental processes of individuals. The connection between distributed cognition and ethnography is not only in the insistence that our understanding of human activity be located outside individual mental processes, in human interaction, but also in the conviction that to gain an understanding of human activity, ethnographic, field-based methodologies are required.

Activity theory also shares with ethnography a commitment to field-based research methodologies. In addition, there is the shared view that behavior (activity) should be a primary focus of investigation and theorizing, and a recognition that objects (artifacts) are key components in descriptive and explanatory accounts of human experience (e.g., Engeström 2000; Nardi 1996).

Ethnomethodology is often used interchangeably with ethnography in HCI literature. This is not only because the terms are etymologically similar, but also because many of the social scientists contributing to the field of HCI have adopted an ethnomethodological approach (e.g., Bentley et al. 1992; Button and Harper 1996; Crabtree 2000; Hughes, Randall, and Shapiro 1993; Hughes et al. 1994; Hughes, Rodden, and Anderson 1995) with its focus on locally and interactionally produced accountable phenomena. Ethnomethodology's particular set of commitments (e.g., Heritage 1984) are not shared however by everyone working within the ethnographic paradigm.

Participatory design does not have its roots in qualitative social science research, but instead developed as a political and social movement, and as a design approach committed to directly involving end users in the design of new technologies (See Chapter 49; also Schuler and Namioka [1993]; Kensing and Blomberg [1998]). Within the HCI context, participatory design has shed some of its political and social-action underpinnings, and often is viewed primarily as a set of methods and techniques for involving users in design. Its connection to ethnography is in the commitment to involve study participants in the research, and in the value placed on participants' knowledge of their own practices. Also in recent years, those working in the field of participatory design have incorporated ethnographic techniques (e.g., Crabtree 1998; Kensing, Simonsen, and Bødker 1999) as a way of jointly constructing with participants knowledge of local practices.

Traditional usability testing, with an emphasis on controlled studies and directed scenario-task based testing of design artifacts is often regarded as antithetical to an ethnographic approach. However, over the years, many have begun to "reframe" usability testing (Buur and Bødker 2000) and integrate methods and approaches derived from ethnography and participatory design into usability testing, blurring the boundaries. For example, Kantner, Sova, and Rosenbaum (2003) describe "field usability testing," conducting testing in context with users in their own environments, working on their own goals with their own artifacts and "task objects" as a means of learning about people's everyday activities and needs, as well as gaining insight into how people might interact with and use complex products in the contexts of their own lives. The continued evolution of pervasive and mobile computing provides additional incentive to explore how people interact with products and services in context. Field testing and virtual observations and interactions with people as they use technologies in the context of their ongoing mobile routines and activities (e.g., Gallant 2006), may actually become the norm as interacting with stationary artefacts becomes a smaller part of the HCI ecosystem and as recording and communication devices become increasingly ubiquitous (e.g., mobile phones equipped with video cameras and GPS tracking capabilities).

The key lesson for both "ethnographers" and "usability testers" is that combining observing and inviting users to interact with design artifacts in the context of their natural environments and everyday activities can be both efficient and valuable. Balancing open ended exploration and observation with personally meaningful, in context scenario-based assessments can yield extremely useful insights about how to make products and services more effective and "usable," how people operate and make sense of human computer interfaces, how people improvise and use new technologies and solutions in unexpected ways, and how potential barriers and facilitators shape user adoption.

45.19 ETHNOGRAPHY IN ACTION

The following two case studies show how an ethnographic approach was applied in the design of a program to change health-related behaviors and to reconfiguring service interactions in IT outsourcing services. The two cases point to the role of ethnographic research in rethinking basic assumptions about what motivates and enables employee choices in one case and the place of IT performance data in building and sustaining client-provider relationships in the other. In addition, specific design recommendations followed from these two studies.

45.19.1 Case Study 1: Designing a Program and Website to Change Health Care Behaviors

A large global company, providing health insurance coverage to over 60,000 of its employees in the United States, developed a multifaceted program to reduce its health care costs and optimize the health and productivity of its workforce. The major goals were to provide reliable health care information and to promote better health care decisions. The program provided a number of online and offline resources for employees (e.g., a 24-hour medical hotline, a research team that would provide gather and summarize treatment outcome research findings for severe medical conditions, online access to a leading edge medical information/content website, etc.). The company initially promoted the program through a series of face-to-face workshops designed to convey the limitations

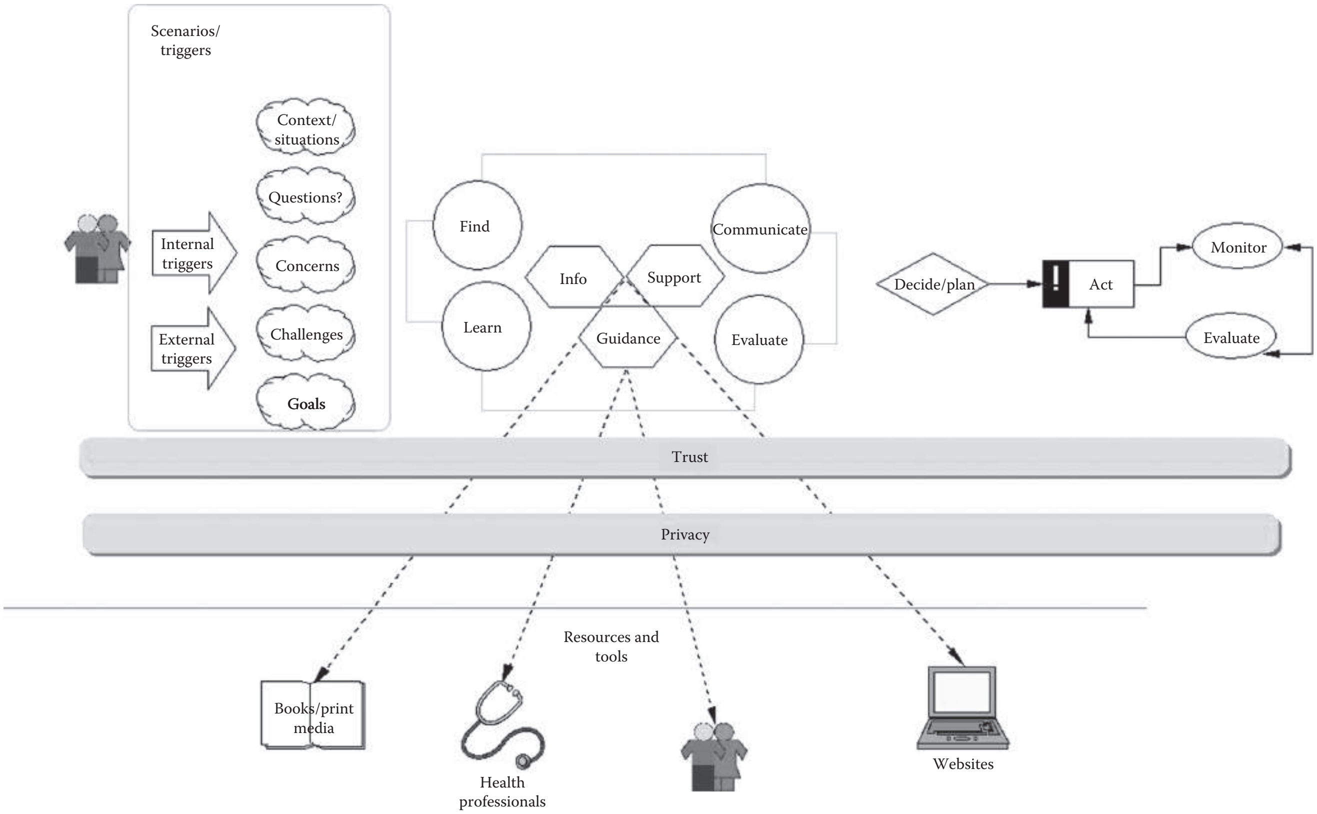

FIGURE 45.9 Healthcare decision-making model.

of standard medical practice, encourage a consumer-oriented approach to health care, and make people aware of resources provided by the company.

After the initial launch, the team became concerned that the health program resources, including the website were being underutilized by employees, limiting the potential impact and value for both employees and the company. In this context, the team initiated a study to evaluate the current program and website as well as to establish clear user models and strategic frameworks to guide website/program redesign efforts. To meet the project objectives, the research team conducted ethnographic inquiries combined with scenario-based exercises. In order to extend the participant sample as well as deal with practical constraints (very limited time and resources), the team conducted some of the interviews and assessments remotely, via telephone and web conferencing tools. Ethnographic inquiries focused on understanding the varied ways that people managed their health care (and/or the health care of family members), including their overall orientations to health and wellness, relationships and interactions with health care providers (and other family members), and their health care–decision-making processes. The latter included understanding the online and offline resources and tools that people used and the major health care scenarios they addressed. After exploring and profiling participants' health care experiences, they were asked to work through an actual health care decision scenario, while being invited to engage with the program resources and website.

Based on these inquiries, the research team developed a number of experience models including a set of personas highlighting key variations in health care orientation and behavior that the program/website design team would have to accommodate; a simple typology of health-related scenarios (e.g., managing severe and chronic medical conditions, dealing with common everyday health care issues, and "wellness"/risk reduction); scenario flow models documenting how varied types of people made decisions (Figure 45.9) and used a range of resources to address key health scenarios.

These models along with other resources generated numerous insights about limitations of the current website and program, opportunities for program/website enhancement, and design recommendations. For example, user profiles and scenario models showed how the program was fragmented and did not effectively align with people's key health scenarios, forcing an individual to painfully sift through resource information and descriptions to figure out which resources might be most relevant and useful in a specific scenario. In addition, the program and the website did not adequately address "wellness"/risk reduction scenarios which represented a significant concern for almost all employee segments and presented an important opportunity for the company to promote a proactive and preventative approach to healthcare.

In order to connect the user insights with the program/website design, the team articulated a number of design principles and a specific scenario-based design framework (Figure 45.10). This framework highlighted the value of

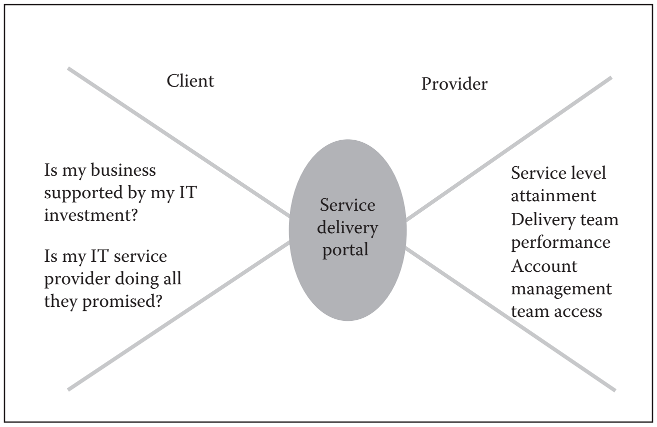
organizing the website (and other program elements) based on key healthcare scenarios, aligning and prioritizing resources and inviting specific modes of action that were most important in each scenario, and enabling relevant "cross-scenario" awareness and behavior that would provide value to users and support program objectives (e.g., a person who came to the website to learn about current research findings on the effectiveness of an experimental treatment for diabetes, might also be invited to explore the value of changes in diet or exercise to manage diabetes, etc.). In addition, the framework highlighted the importance of embedding strategic messages regarding health care (e.g., importance of evidence-based medicine, proactively taking charge of one's health and health care, etc.) and implicit invitations to change health care behaviors throughout the site design.

The ethnographic research led the team to rethink a number of major assumptions, which in turn led to redesign of program strategies, resources, and the website. From a program perspective, the research highlighted the fact that the vast majority of employees had already adopted many consumer attitudes and behaviors and were leveraging a number of trusted health resources (in contrast to initial assumptions of limited "consumerism"). This led the team to reconsider the positioning of specific program resources, shift strategic messaging, and generate novel program strategies including behavioral "rewards" programs that supported proactive and preventative behaviors. The initial research inquiry also led the team to implement a continuous assessment program to continue to monitor program impact and changes in employee experiences and behaviors.

45.19.2 Case Study 2: Service Provider-Client Interactions: Enabling Sustainable Relationships in IT Outsourcing Services

The design of a web-based portal to facilitate interactions between service providers and their clients (see Figure 45.11) was the focus of an ethnographic study examining the communication and knowledge sharing practices of executive level employees in both the service provider and the client organizations (Blomberg 2008a). This research was directed at service innovation to establish and maintain sustainable client-provider relationships in IT outsourcing services. In particular the portal development effort was initiated to



Client
Provider
Is my business supported by my IT investment?
Is my IT service provider doing all they promised?
Service delivery portal
Service level attainment
Delivery team performance
Account management team access

FIGURE 45.11 Portal facilitated client-provider interactions.

increase client access to service performance metrics and, in so doing, allow greater information transparency (Blomberg 2008b). A primary way in which clients and providers track IT performance is through Service Level Agreements (SLAs), which detail contractual relationships between service provider and client, and describe the metrics that will be used to regulate and monitor the performance of the delivery teams (Long-Tae, Jong-Wook, and Woon-Ki Hong 2001; Marilly et al. 2002). The SLA specifies the level of service the customer can expect from the provider. Service Level Attainment metrics are tracked each month, and failure to perform as expected can result in penalties that the provider must pay. Typically the service provider is obliged to provide monthly reports that describe actual performance metrics in relation to the attainment levels specified in SLA. A key element of the initial portal design was the provision for presenting to the client "real-time" IT performance metrics as detailed in the SLA. This design direction led to an ethnographic study on how IT service performance metrics were currently made available to executive level clients.

Interviews and observations of IT executives from the provider and client organizations highlighted how performance information was communicated via either face-to-face meetings or teleconferences where executives reviewed the performance numbers and arrived at "negotiated" understandings of what accounted for the numbers and what should be done to address any shortcomings. Through these interactions service providers and clients arrived at the "meanings" of the performance metrics which enabled them to develop both immediate and longer term plans to mitigate problems and, as appropriate, expand the scope of the engagement.

It became clear that providing accurate, real-time performance information alone would do little to enable effective communication and might instead undermine trust between executives from the client and provider organizations. For example, knowing that response times for help desk calls were behind targets was not as important as understanding the causes of the slower response times and having confidence that steps were being taken to address the situation. Logging onto the portal to access performance information without the opportunity to understand the meanings behind these data could create confusion and unnecessary concern on the part of the client.

This research finding led to the recommendation that real-time interactions between clients and providers be explicitly supported, including during face-to-face meetings. The design specification had not included provisions for downloading performance data to a spreadsheet or other applications so that it could be easily shared and referenced in meetings between the executives. It was in these interactions that the meanings of performance metrics were negotiated and changes to address performance issues were agreed.

The study also showed how IT performance measures and reporting formats evolved over time in response to adjustments in the service contract or in response to requests from the client to visualize performance data in different formats (e.g. bar charts instead of, or in addition to, tables). These changes facilitated discussions between providers and clients when specific IT decisions were under deliberation. The providers were motivated to comply with these client requests, even if they were not specified in the contract, to strengthen their relationship with the client and ultimately the long term health of the account. This led to the recommendation that changing the way performance data were presented should be within the control of the service delivery teams. The design specification had not included this capability, instead requiring that the code be rewritten by those who developed the original portal.

In these ways our design recommendations centered on enhancements to the portal technology that would better support interactions that facilitated the negotiation of the meaning of performance data, enabled changes in the reporting needs of the client and provider, and more seamlessly integrated the portal reporting format and interactions taking place face-to-face or via teleconference. The study showed that making performance metrics available alone would not achieve the objectives of portal no matter how accurate the data were and how accessible they were in real time.

45.20 CONCLUSION

Ethnographic studies have become an important tool for designers and development teams designing new information and communication technologies and new IT-enabled services. Today in academic, institutional, and corporate settings there is the realization that understanding the everyday realities of people living and working in a wide range of environments and engaged in a myriad of activities is essential for creating technologies and services that provide engaging and productive experiences for their users.* Emerging from recent research and practical experience is the recognition that representational tools (models, personas, scenarios, mock-ups and prototypes, service blueprints, etc.) and design-and-development practices (collaborative data analysis, video review sessions, etc.) are necessary for connecting ethnographic studies and technology design. Insights from ethnographic studies do not map directly onto design specifications or straightforwardly generate "user" requirements. Instead ethnographic studies must be connected and integrated with design agendas and practices. Those wishing to leverage the potential of ethnographic studies should not only understand what motivates the approach and is at its foundation (e.g., natural settings, holistic, descriptive, members' point of view), but also should recognize the importance of creating the conditions in which design can take advantage of ethnographic insights.

The Development Process

Section B: Design and Development

46 Putting Personas to Work

Employing User Personas to Focus Product Planning, Design, and Development

John Pruitt and Tamara Adlin

CONTENTS

Personas are a relatively young and popular technique used to help bring users into the forefront of people's minds during the difficult process of developing products and services. Yet, for many practitioners, the persona method remains largely ill-defined, haphazard, and mysterious. In this chapter, we present a simple framework for approaching the technique—the *persona lifecycle*—that sheds light on how personas fit into a standard development cycle. We then provide a little detail on two critical aspects of the method—creating and using personas. Our goal is to enable the reader to quickly and easily get started with the technique with a greater likelihood for success.

46.1 IT IS HARD TO BE USER CENTERED

In the best of all worlds, everyone working on a product would always be thinking of the needs of every person who will ever use the product. Real information about users would inform every decision and the resulting product would perfectly satisfy everyone who uses it. In practice, it is hard enough to get everyone working on a product to think about users at all (see Grudin [1990, 1993], for a discussion of obstacles and constraints in product development organizations). To deliver on the promise and benefits of user-centered design (UCD), we have to find creative ways to inject accurate information about real users into the chaotic world of product development.

It is a rare product indeed that does everything you want it to do in the way you want to do it. Why? Because, despite the fact that building products based on what real people need and want seems obvious, putting users (or rather, information about users) truly at the center of the design and development process is extremely difficult. Why is it so hard to be user centered?

First, being user centered is just not natural. Our more natural tendency is to be self centered—to design a product based on our own wants and needs (sometimes even when we are not an actual user of the product). Self-centered design is perhaps better than technology-centered design (another common inclination), but most of the time, the people on your product development team are not representative of the target audience for your product. Thus, as many practitioners in the UCD field have long evangelized (see, e.g., Nielsen [1993]), it is important to understand the user.

Second, users (really, people) are quite complicated and varied. It takes great effort to understand their needs, desires, preferences, and behaviors. And, pleasing some of them does not necessarily result in pleasing all of them.

Third, those doing the user and market research to understand your users (and others who are just more in touch with your users, e.g., the sales team and the support team) are not typically the people who design and build the product. Those who collect the data try to communicate the information it contains by creating presentations or reports, which are helpful only if they are absorbed by the right people at the right times. If the important information about users is not available at the right time, or is difficult to understand and remember, your development team will forge ahead to design and build the features they think their users would like.

46.1.1 The Word "User" Is Part of the Problem

When UCD was a new idea, simply injecting the word "user" into a design and development process was powerful: it challenged the status quo. Unfortunately, incorporating the word "user" into everyday corporate discourse is not enough to foster effective UCD.

Everyone (we hope) assumes that they are building products with users in mind; in many organizations, anyone asked would probably answer "yes, I think about the user a lot." However, people who talk about the "user" are almost never asked to further define the term and it is a sure bet that each person in the organization would describe the users in a different way. If everyone in the organization does not have a clear and consistent understanding of *who* they are building the product for, the product can fail. It is our contention that the word "user" cannot provide the clarity that is required.

> "User" is a catchall and ultimately a mean-nothing word. It reflects a technology-centric, rather than a people-centric view of the Web. To call someone a user is largely meaningless. The phrase "user-friendly" should never have had to be invented. It implies that technology is inherently hostile and that a new discipline—usability—had to be invented to make it friendlier. After all, we don't refer to cars as "driver-friendly."
>
> We don't refer to bicycles as "cyclist-friendly." We don't refer to chairs as "bum-friendly."
>
> **Gerry McGovern**
> *Consultant, gerrymcgovern.com.*
> *(From "Don't call people users." April 1, 2002.)*

Personas add the detail and specificity needed to provide product development teams the understanding needed to create user-centered products.

46.1.2 Personas Move Us beyond the Word "User"

Personas are fictitious, specific, and concrete representations of target users. Personas put a face on the user: a memorable, engaging, and actionable image to serve as a design target. The term "personas" was originally adopted and popularized by Alan Cooper in his 1999 book, *The Inmates Are Running the Asylum: Why High Tech Products Drive Us Crazy and How To Restore The Sanity* (see also, Cooper and Reimann [2003]).

Personas were born out of a short tradition in the UCD community toward user and system modeling and out of a somewhat longer tradition in marketing around market definition and customer representation. Perhaps the earliest was industrial designer Henry Dreyfuss who wrote about "Joe and Josephine," the heroes of his book *Designing for People* (1955), which were created to inform the physical design of objects and spaces. Geoffrey Moore, in his book *Crossing the Chasm* (1991), described the notion of "target customer characterizations"—images of customers, which are meant to replace or supplement impersonal and abstract market segments (see, e.g., Sissors [1966] or more recently, Weinstein [1998]). John Carroll (1995, 2000a, 2000b) has been a longstanding proponent of scenario-based design, which typically includes terse representations of users called actors or agents (see also Jacobson [1995]; Jacobson et al. [1992], regarding "actors" in "use cases"). Carroll argues that scenarios help designers and analysts focus on assumptions about people and tasks.

These and most other representations of users or customers (e.g., see Constantine and Lockwood [2001, 2002]; Mello [2003]; Upshaw [1995]) are typically *not* well-rounded or complete descriptions, but instead are confined to a few key details and specific contexts. Moreover, they just do not seem real, as they are devoid of life and personality. Personas, on the other hand, seem like real people. As such, personas carry information about users to your product team in way that other representations cannot. Personas enable us to move beyond our habit of referring to "users" and find a better way to communicate about and focus on the real people we want to use our products. Personas can humanize vast and disparate data sources, capitalize on our ability to remember details about individual people, and, in so doing, provide a usable and useful alternative to refer to "the user." Personas do the job of creating a concrete, focused, and stable definition on your audience. Based on our own experience with the approach, we believe that when created with data and used thoughtfully during the product development process, personas

- Make assumptions and knowledge about users explicitly, creating a common language to talk about users meaningfully
- Allow you to focus on and design for a small set of specific users (who are not necessarily like you), helping you make better decisions
- Engender interest and empathy toward users

These benefits as stated are really just a means to an end. Most importantly, as with all UCD techniques, the final goal is to create better designs, better products. We believe personas help accomplish this.

Support for these claims has been slow to accrue. The initial evidence was primarily based on a handful of case studies, anecdotes, and methods papers (see, e.g., Dantin [2005]; Freed [2004]; Grudin and Pruitt [2002]; Hourihan [2002]; Junior and Filgueiras [2005]; Kujala and Kauppinen [2004]; Levinson [2003]; Markensten and Artman [2004]; McQuaid, Goel, and McManus [2003]; Sinha [2003]; Shyba and Tam [2005]; see also the numerous sidebar stories in Pruitt and Adlin [2006]). Since the publication of our original book, more objective evidence in support of the method has begun to appear, including some experimental studies (e.g., Dharwada 2006; Long 2009). In Long's study, for example, groups of students were asked to solve a design problem in which some students used personas and others did not. Students using personas produced designs with better usability attributes. Their findings also suggested that personas can improve communication and facilitate more constructive discussion.

Additionally, there is a growing collection of conference presentations and peer-reviewed papers describing new case studies and extensions of the method (e.g., Antle 2006; Chang, Lim, and Stolterman 2008; Dharwada et al. 2007; Haikara 2007; Hill and Bartek 2007; Khalayli et al. 2007; Miaskiewicz, Sumner, and Kozar 2008; McGinn and Kotamraju 2008; Nieters, Ivaturi, and Ahmed 2007; Panke, Gaiser, and Werner 2007; Siegel 2010; Triantafyllakos, Palaigeorgiou, and Tsoukalas 2009; Tychsen and Canossa 2008). Most if not all of these report positive outcomes using personas or some general improvement to the approach.

Of course, the persona method has not been without critics (e.g., Chapman and Milham 2006; Chapman et al. 2008) and there are a few documented cases where personas did not result in beneficial effects (e.g., Blomquist and Arvola 2002; Rönkkö et al. 2004). Still, the lion's share of the evidence now points in favor of the method.

SIDEBAR 46.1 The Genesis of Personas in Product Design: Cooper Takes "Play Acting" One Step Further

Kim Goodwin
Vice President and General Manager, Cooper

With the publication of *The Inmates Are Running the Asylum* in 1998, Alan Cooper introduced the world to personas as a practical interaction design tool. However, Alan and the folks at his leading design consultancy, Cooper, had already been using personas for years.

In 1983, Alan was working as a solo software inventor. While working on a project management program he called "Plan*It" Alan realized he needed to understand more about how project managers thought, so he interviewed a handful of people. A woman named Kathy, who seemed the most typical, was the basis for the first persona-like model in Alan's head. While waiting for his program to compile, Alan would playact a project manager very much like Kathy, using the way she thought and worked to make decisions about the design of the application. Alan eventually sold Plan*It to Computer Associates, who sold it to the public as SuperProject. After that success, Alan went on to use this technique on other projects, including the visual programming language that became Visual Basic.

Later, when Alan ventured into consulting, he found that he could not just do what seemed right, because he first had to persuade other people. For this reason, on a 1995 project with Sagent Technologies, Alan created Chuck, Cynthia, and Rob—the first real, Goal-Directed personas. After some initial resistance, they worked as Alan had intended: they provided a way to keep everyone focused on what users really wanted to do, rather than on all the things they might do. (1) Since then, Cooper designers have refined and formalized the methods for researching, creating, and applying personas over the course of hundreds of projects. Many practitioners have begun using personas—some with excellent results, others not. The most common reason for failure? People miss the thing that makes personas so uniquely effective: they are based on a qualitative understanding of how real people behave and—equally important—why they behave that way.

Today's best personas are well researched, focused on behavior, and documented as a short-story writer would describe a beloved character with sympathy, respect, and just enough backstory to help you understand what makes them tick. (2) Effective personas are based on the kind of information you cannot get from demographics, survey data, or suppositions, but only from observing and interviewing individual people in their own environments. That qualitative, firsthand information is not only essential to design—it is essential to persuasion. If you cannot effectively persuade the programmers to build it, the executives to fund it, and the marketers and sales people to sell it, then the best design in the world is a failure. Personas are not just effective because they are accurate representations of human behavior. They are effective because they help both designers and stakeholders understand user needs at a gut level, which—in spite of all you hear about return on investment (ROI)—is where most business decisions are made.

46.2 MAKING PERSONAS PRACTICAL: THE CREATION OF THE PERSONA LIFECYCLE METHOD

If personas are such a good thing, why isn't everyone using them? Perhaps one answer is that creating and using personas is easier said than done. When we first started talking to persona practitioners in 2000, we noticed that many people in the UCD community could see the value of personas in their own work and to their organizations. However, those that tried to create and use personas were running into a fairly consistent set of problems in their persona efforts. While the idea of creating a set of target users is fairly straightforward, the actual process to create and use personas can be quite complex. We heard many of the same questions over and over again, such as the following:

- How do you decide whether personas are the right thing to do in your organization?
- How do you incorporate data into personas? What kinds of data work, and what kinds of data do not work?
- How do you know if personas are worth the effort it takes to create them?
- How do you communicate personas once they are created?
- How do you use personas to design great products?
- What do you do with personas once a project is finished? Can you reuse personas?

As we continued our research over the following years, we discovered that many practitioners were having less-than-stellar experiences with personas. Those that were able to create data-driven personas were finding that, if they are not well communicated and managed, even well-crafted personas are easy for designers and developers to ignore. At worst, poorly executed persona efforts yield no increase in user-focus and leach time and resources from other UCD techniques and other methods that can improve product quality. We found the following four common reasons for the failure of persona efforts:

- The effort was not accepted or supported by the leadership team.
- The personas were not credible and not associated with methodological rigor and/or data.
- The personas, and the techniques around using personas, were not well communicated.
- The product design and development team did not understand how to use the personas.

Once we fully understood the questions and common causes of failure, we focused our attention on finding solutions based on the input and insights of dozens of persona practitioners. The persona lifecycle was the result.

46.3 THE PERSONA LIFECYCLE

The persona lifecycle is a metaphorical framework that breaks down persona creation and use into sequential phases that map onto the life stages of human reproduction and development. There are five phases in this framework: (1) family planning, (2) conception and gestation, (3) birth and maturation, (4) adulthood, and (5) lifetime achievement and retirement (see Figure 46.1). The phases of the persona lifecycle framework bring structure to the potentially complicated process of persona creation and highlight critical (yet often overlooked or ignored) aspects of persona use.

As the name indicates, the persona lifecycle is a cyclical, mostly serial process model. As the illustration in Figure 46.1 shows, each stage builds on the next, culminating but not ending at adulthood. You will notice that the illustration also shows that final stage, lifetime achievement and retirement, is not immediately followed by the first stage. This is because different persona efforts culminate and restart in different ways; personas can be reused, reincarnated, or retired depending on the project.

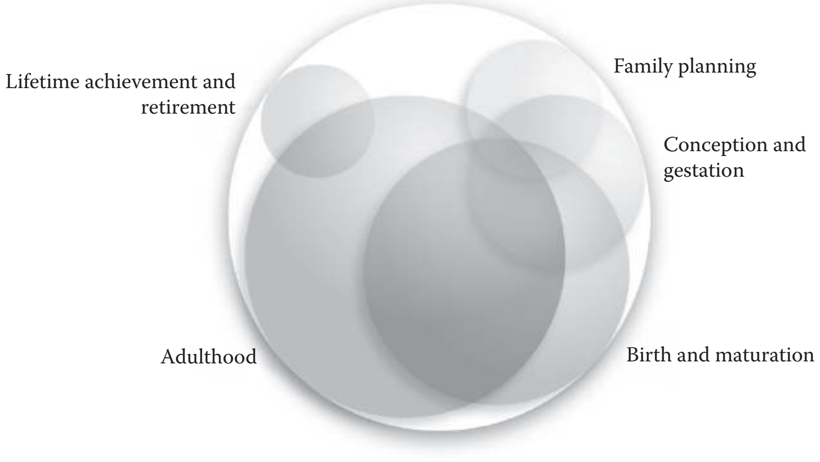

FIGURE 46.1 The five phases of the persona lifecycle. This diagram is designed to show both the order of the phases (from family planning through conception and gestation, birth and maturation, adulthood, and finally lifetime achievement and retirement) and the relative amount of effort and importance related to each phase.

If your company has already adopted some UCD methods, you should find that the phases of the persona lifecycle augment your existing process and help you get involved earlier in the product development cycle. Keep in mind that the persona lifecycle is not meant to replace other UCD tools and is not a complete user-centered product design method on its own. Rather, the persona lifecycle is an organized collection of processes and tools that will complement other familiar methods. You will use personas to enhance these other methods, particularly where there is a need for user definition and reference.

In the remainder of this chapter, we will discuss all of the phases of the persona lifecycle, focusing primarily on conception and gestation and adulthood because they are the least understood and, in many ways, the most critical phases for a successful persona effort. Conception and gestation and adulthood contain information on how to create personas from data (and/or assumptions, as necessary) and how to use completed personas in the planning, design, evaluation, and release of your products.

46.3.1 Phase 1: Persona Family Planning

Successful persona efforts are ones that are designed to solve specific problems for specific organizations and specific products. That is, personas created for one product cannot be easily adopted for another product. To be successful, you have to know what kinds of problems you want to solve and decide whether or not personas are the best way to solve them. Persona *family planning* is the strategy and planning phase that precedes the creation of the personas.

There are three major activities during the family planning phase:

1. *Researching your own organization* (which we call "organizational introspection")
2. *Creating a "persona core team"*
3. *Data collection*

46.3.1.1 Organizational Introspection

Before you begin any persona effort, you (perhaps with the help of the persona core team you assemble) should do some careful thinking about the particular problems you want to solve with your persona effort. While personas can help in many ways over the entire design and development cycle, they cannot solve every problem and they are not guaranteed to be accepted by the people you feel need them most.

Successful personas are those that meet the needs of *their* users and are built to fit seamlessly into their host environments. In the case of personas, the users are your colleagues, and the environment is your workplace with its existing design and development process.

Ironically, it is easy to forget to turn our analytic eyes on our users, the people on our teams and in our organizations who use the "products" we produce (e.g., research reports, storyboards, scenarios, prototypes, and other artifacts). We forget to carefully consider who our teammates are, their roles and responsibilities and goals, and what is working for them currently and what is not. We heap our user-focused processes onto teams who are interested and curious, but who, ultimately, just need to get their jobs done. As far as most product teams are concerned, they already know the fastest and most effective way to do their jobs; when push comes to shove and deadlines loom closer, your colleagues will inevitably revert to tried-and-true work habits.

Organizational introspection is, in simple terms, working to answer the following questions:

- What resources do we have for personas and other UCD activities?
- What product problems do we want to solve with personas?
- What process problems do we want to solve with personas?
- How can we ensure that the personas will be accepted and used by our colleagues?

Answering these questions now will allow you to decide whether personas will be appropriate and helpful. The answers will help you to create reasonable goals for the persona effort and predict the challenges you are likely to encounter as you create, introduce, facilitate use of, and maintain your personas. Armed with that information, you will create a plan for your persona effort that will target the application of your personas to appropriate aspects of your development process. Additionally, this information will help you determine what measures of success (and ROI) will be needed at the end of the project.

46.3.1.2 Creating a Persona Core Team

Personas are a simple idea, but they are inevitably more work than anyone expects. Successful persona efforts involve a core team of 2 and 10 people who are willing to find time in their calendars to dedicate to both persona creation and to helping evangelize the value and uses of the personas to the rest of the organization.

People you invite to join your core team do not necessarily have to understand personas to be helpful; people who are sensitive to the need for user focus in your company will make excellent core team members.

Your goal is *not* to create a team that will duplicate research or communication efforts; rather, it is to consolidate some aspects of these efforts such that they all contribute to the creation of personas. Plan to include the people who are already involved in user research, market research, business analysis, task analysis, or any other user- or customer-focused research or profiling activity. If you have colleagues in any of the following specialties, you should put them on the "short list" for inclusion on the core team:

- Information architects, interaction designers, and HCI specialists
- Usability specialists, user researchers, and ethnographers

- Technical writers and documentation specialists, training specialists
- Market researchers, business analysts, and product managers

These colleagues are likely to understand the value of personas, both for the organization and for their own projects. They bring with them a deep commitment to UCD, experience studying, analyzing, and designing solutions for target users, and an interest in new methods to bring user focus into the entire organization.

46.3.1.3 Identifying Data Sources and Collecting Data

From one-on-one interviews to widely published reports, there are thousands of data resources available to persona practitioners. Generally speaking, personas are best created from a combination of qualitative and quantitative research. The amount and types of data you will collect will depend on how much time and money you have to spend and your own evaluation of how much data will be necessary to create "good" personas for your project. If warranted and possible, you will do some original user research of your own, though this endeavor tends to be the most time consuming of all.

Most companies have a great deal of data "hanging around." Market research reports, customer segmentation studies, customer service logs, web usage logs and statistics—all of these sources can be reused in your persona effort. In fact, we recommend that you postpone future data collection efforts until after you analyze the data you already have during the conception and gestation phase of the persona lifecycle. This process will help you review your existing data sources from a new perspective, and you will be able to target future data collection projects to "fill in the holes" of your current understanding of your users. Look for both internal sources (like market research reports and interviews with product support specialists and other subject-matter experts) and external data sources (like public websites that provide statistical and demographic information).

As you identify and collect data sources, we also recommend that you identify and evaluate current assumptions about users that exist within your organization. The only assumptions that can harm your product are the ones you are not aware of. We strongly believe personas are much more credible and helpful if they incorporate and refer to real-world data. However, if data is simply unavailable, or you have no time to collect and analyze the data that is available, creating *assumption* or *ad hoc* personas is extremely worthwhile. One of the major organizational benefits of personas is their ability to focus everyone on a shared understanding of who the user is and what he or she really needs out of the product you are designing and building. The key word here is *shared*: everyone in your organization will inevitably build an internal understanding of the users of your product no matter what you do. If, through your efforts, they all picture the same users—even if this picture is built on assumptions—your product will benefit.

Family planning ends at the point at which you have established that personas are right for your organization and current project, you have buy-in from key individuals, you have a persona core team in place, you have a solid plan for the rest of the persona effort that suits your product team's needs, and your initial research and data gathering are complete.

SIDEBAR 46.2 Using Assumption Personas to Help a Multidisciplinary Team See the Need for Personas

Graham Jenkin
User-Centered Design & Research Executive,
Bank of America e-Commerce/ATM

In most companies, there are a range of team members that need to come together to define and build customer experiences: product managers, marketers, engineers, researchers, and user experience professionals. While the need for personas may be obvious to user experience professionals, other team members may require some creative persuasion.

At Bank of America, the e-Commerce User-Centered Design & Research (UCDR) team used "assumption" personas to obtain cross-team support for a dedicated persona development effort for its Online Banking product.

Online Banking team members from UCDR, Marketing, and Product Management were interviewed and asked to imagine one consistent customer profile and to make *assumptions* about that customer's relationship to the bank, usage patterns, motivations, goals, needs, frustrations, and attitudes toward technology.

The variation in the team members' assumptions was striking. Some assumed that Casey—the assumption persona: a young, urban professional—had strong loyalty to the Bank of America brand, while others assumed that she had no loyalty at all. Some assumed that Casey used Online Banking for day-to-day financial triage, while others assumed she used it for "big picture" planning. Some assumed that Casey was "geeky and wired," while others assumed she preferred to wait for family and friends to introduce her to new technology.

Of course, no one was right. Team member assumptions were exactly that—assumptions based on intuition and lacking in data.

When the interview results were shared, there was no doubt on the next action. Team members could not agree on who precisely Casey was, but they were unified in agreeing to develop and use a single set of personas based on real customer data.

46.3.2 Phase 2: Persona Conception and Gestation

Persona conception and gestation is the process of translating raw data into information and that information into personas. A lot of the work during the conception and gestation phase centers on collaboratively filtering data and organizing information—both information that arises out of the data you collect in family planning and information that arises from other sources, such as inherent knowledge of how people behave, your business or product strategy, the competitive marketplace, and technological affordances related to your product domain.

In this section, we will summarize the process we recommend for getting from raw data to completed personas. This process is designed to work best as a series of collaborative meetings with your core team. The first three steps cover persona conception; Steps 4 through 6 describe persona gestation.

46.3.2.1 Step 1: Identify and Assimilate Assumptions

Start with assumptions? After all this emphasis on data? You bet. Your completed personas will incorporate lots of data—but you will be introducing them into an organization that is overflowing with assumptions. If you can, identify categories of users that are important to your business and product domain.

How does your company refer to users today? Every company tends to already have a set of terms they use to describe the relationships and/or differences between their users. These terms are usually collections of defined *user roles, user goals*, and/or *user segments.*

Users defined in terms of segments (e.g., shared demographics or psychograpics):

- A large software manufacturer may think about their users as small businesses, medium businesses, large businesses, or home office users.
- A travel agency might be used to thinking about their users as *recreational travelers, families*, or *business travelers.*

Users defined in terms of roles (e.g., relationships they have with a system):

- A company that makes online presentation software might think about their users as *audience members, presenters, presentation designers*, and *technical support professionals.*

Users defined in terms of goals (e.g., what they are trying to achieve, in their own terms):

- An online bank might think that the most interesting differences between their customers are that they have different goals: *I have to feel my money is safe, I have to be able to access my account from anywhere*, or *I do not care about anything except low fees.*

The goal is simply to identify the ways people in your organization *already* talk about categories of users. Identifying these categories now (even if they are based solely on assumptions) will help you structure your data processing and build a bridge between the ways people think of users today and the data-driven personas you will create. When you are ready to communicate and use your personas, you will find it much easier to do so if you can describe them in language that is already familiar—even in the case where your data suggests that the initial categories should be replaced by different ones.

46.3.2.1.1 Get the Rest of the Assumptions out on the Table

Sit down with your core team and lots and lots of yellow sticky notes. Spend 30 minutes or so getting as many assumptions down on sticky notes as you can. Write one assumption on each sticky note. These assumptions should describe what you think your company's users are like as individuals. For the core team working at an online presentation, software company might create include the following:

- Forty-six-year-old sales guy who lives on the East Coast and has a hard time staying up-to-date with the latest product innovations taking place at the San Francisco home office.
- CEO who has to give a keynote presentation at a large conference, but he has to do it remotely.
- Investor relations specialist who has to present financial data to analysts and stakeholders at least once per quarter.
- Marketing manager who has to make sure that the key marketing messages for his or her company are distributed to the right people at the right times.

After everyone has created as many sticky notes as they can, it is time to find patterns in the assumptions. To do this, you will conduct an affinity exercise. Write the major categories of users (the ones you identified in Step 1) far apart from each other on a large sheet of paper. Ask everyone to place their sticky notes on the paper so that sticky notes with similar or related assumptions are near the appropriate category and near each other, and dissimilar assumptions are far apart. This exercise should be a fairly noisy, collaborative experience, as members of the core team discuss placement and groupings of their sticky notes.

If there are sticky notes that do not relate to any of the listed categories, create new areas on your large sheet of paper for them. As the exercise progresses, groupings of related sticky notes start to form "clusters." When the team feels that they are finished clustering, ask them to label the clusters. For example, one cluster could be labeled "Marketing people" and another, elsewhere on the big sheet of paper, could be labeled "Investor relations people."

Discuss what you have found as a group. Are there any surprises? It is a great time to think about the kinds of information you would like to find in your data, or collect directly from users. Your data will validate and enrich the categories or it will provide solid information to show that the existing categories are inappropriate. It will also allow you to define important subcategories of users that should also be expressed in personas.

46.3.2.2 Step 2: Process Your Data

It is time to process your raw data to extract information relevant to your user and product domains and then identify themes and relationships. While there are many ways you can go about processing your data to create personas, we strongly recommend that you conduct an affinity exercise like the one you have just done with assumptions. Before you get started, assign a number to each of your data sources.

46.3.2.2.1 Identify Key Data Points (Factoids) in the Data Sources

The first step in processing the data is to consume and filter the information that is in each of the research reports. You do this because not every data point in a given study/report is relevant to the definition of your target audience or the design of your product. Whether it is done before or during the meeting, ask your core team members to highlight findings that they think are key to understanding your target audience or that are highly insightful toward defining aspects of your product. In other words, you want them to look for findings that are relevant to your market, industry or domain. Highlight any facts that seem important to your product's audience or to the product itself.

Each important factoid should be copied or cut out of the original document. Remember to note the source and page number on each factoid so you can trace them back to the original sources later. We recommend that you use blue sticky notes for this exercise (signifying "cold, hard facts"). Whatever color you use, do not use the same color that you used for the assumption stickies; you will need to be able to distinguish between the assumptions and the factoids.

46.3.2.2.2 Assimilate the Factoids

Now the interaction (and fun) begins. To do the assimilation, everyone will get up and add their factoids to the clusters you created in the assumption exercise. Do not be afraid to move any of the stickies around as you do this—you can move assumptions, factoids, or even entire clusters as you assimilate.

As you continue assimilating, keep your eyes out for large clusters, or "puddles," of 8–10 or more sticky notes. Large clusters can usually be broken down further, and you should do this if you can. Usually, we recommend that everyone find spots for their stickies and then pair up to review the clusters together. During this "clean up" phase you will be able to break up puddles, add descriptive labels to clusters, and generally ensure that the clustering makes sense. Stop when the activity dies down and few stickies are still being moved.

Note that you will have clusters that contain both assumptions and factoids, but you will probably also find clusters of assumptions (with no factoids) and clusters of factoids (with no assumptions). This is illustrated in Figure 46.2. All three types of clusters are helpful. Clusters of assumptions without factoids will help you identify topic areas in which you need to collect more data. Clusters of factoids without assumptions tell you that there are aspects of your customers that you have not thought a lot about yet.

SIDEBAR 46.3 The Cooper Method: Collect Data Directly from Users and Identify Patterns to Create Personas

Kim Goodwin
Vice President and General Manager, Cooper

Some people have great success with personas, while others do not. Why is that? First, it is important to understand that even the best personas will not solve all of your problems—scenarios, design judgment, and visualization skill are equally important. Assuming you have all of those things, the key to success with personas is to do the right kind of research and to make sure your personas truly reflect your findings.

1. START WITH THE RIGHT KIND OF RESEARCH

"Personas" that are made up without data are not really personas, and although they can still be useful thought exercises, they are far less effective than real personas that are based primarily on ethnographic user data. Ethnographic techniques are valuable because they assume that an interview subject's attitudes and behaviors are so habitual as to be unconscious. Rather than asking users what they want, it is more effective to focus on what users do, what frustrates them, and what gives them satisfaction. By combining interviewing with direct observation—preferably in the actual usage context—you can get a lot of data very quickly. Observation also helps minimize dependence on users' self-reported behavior, which is often inaccurate.

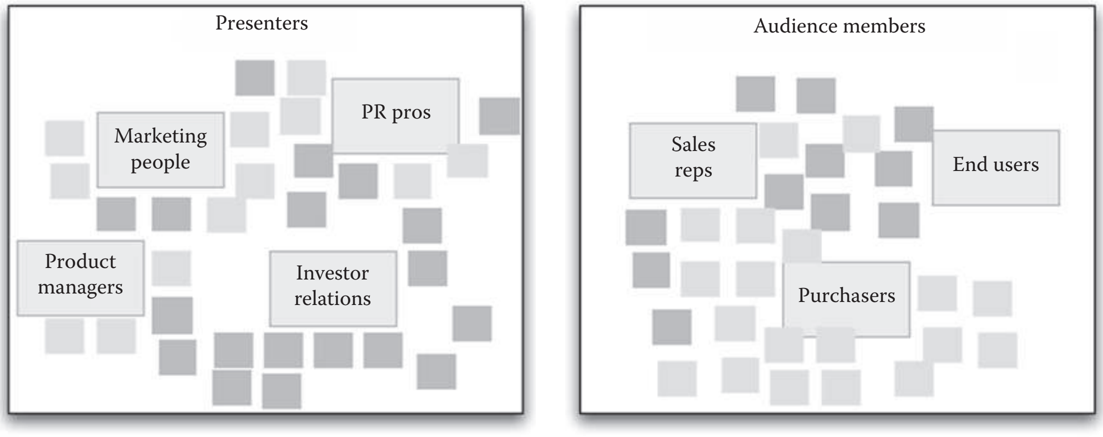

FIGURE 46.2 An example of clustered assumptions (lighter squares—"yellow" stickies) and factoids (darker squares—"blue" stickies) with cluster labels (larger squares—"pink" stickies) and initial categories of users.

At Cooper, we send the designers out to do the research, so they see the problems firsthand and develop empathy with the users. We may occasionally have three interviewers, but two of them are consistent across all of the interviews; this makes synthesis much easier later on. We spend 45 minutes to an hour with individual people. It would be easy to write a whole chapter on research techniques alone, but there are a few fundamental points. First, ask a very broad question (such as "Could you think of a typical work day recently, and walk me through it?") This raises a number of issues the interviewers can pursue without needing to ask leading questions. Another important technique is to stay case-focused; in other words, ask for specific instances rather than generalizations. This will get you more detailed and more accurate information. Also, be sure to look at and ask questions about artifacts or aspects of the environment. Finally, focus on actual behavior and frustrations, rather than asking the users to design the product for you.

Contrary to some expectations, this kind of research can be done in anywhere from a few days to a few weeks. You will know you can stop interviewing when you can predict how each user will respond; this means patterns are beginning to emerge. If you have the time and budget, you can verify your findings with quantitative surveys or other techniques, but these cannot replace direct observation.

2. IDENTIFY BEHAVIORAL PATTERNS FROM THE DATA

Once you finish interviewing, list all of the behavioral variables for each user role, that is, ways in which interviewee behavior differed. In an online shopping domain, for example, you might have variables such as frequency of shopping, degree of enjoyment, and price versus service orientation. There may also be demographic variables that seem to affect behavior, such as age or technical skill. Be wary of focusing on demographics during persona creation, since behavioral variables will have far more impact on the design. Note that if you are doing an enterprise application, each role will have its own set of behavioral and demographic variables. Although the number of variables will differ from project to project, it is typical to find 20 or so variables per role. Map each interviewee against the appropriate set of variables, then look for people who clump together across a large number of the variables. When you have found a set of people clustering across six or eight variables, there is a good chance that you have found a major behavior pattern that will form the basis of a persona.

3. TURN YOUR PATTERNS INTO PERSONA DESCRIPTIONS

For each pattern, add details based on your data. Describe the current potential usage environment, typical workday (or other relevant time period), current solutions and frustrations, relevant relationships with others, and goals. Avoid the temptation to add a lot of irrelevant personal detail; if you are designing an e-mail tool, it does not matter that your persona wants to be an actress. One or two bits of personality can bring an otherwise dull persona to life, but too much biography will be distracting and will make the persona less credible as an analytical tool. If every aspect of the description cannot be tied back to real data, it is not a persona—it is a creative writing project that should not be used for making critical design and business decisions. Describe each persona in a one- or two-page narrative that helps stakeholders understand what makes them tick.

4. USE THE PERSONAS TO DRIVE SCENARIOS, REQUIREMENTS, DESIGN … AND COMMUNICATION

Use your personas to develop scenarios; put the personas in realistic future situations and envision how they would like a magic black box of a product to work. These scenarios will lead you to a set of needs you can discuss with stakeholders. You can describe requirements from the personas' point of view, which leads to less resistance than requirements that come from you. Once there is agreement on the requirements, additional scenarios (along with good design skills!) will help create the conceptual framework for the design. When you illustrate the design direction in a scenario, stakeholders are more likely to see the value of the solution. Personas will help you all the way to pixels and specifications, and even through implementation.

46.3.2.3 Step 3: Identify Subcategories of Users and Create Skeletons

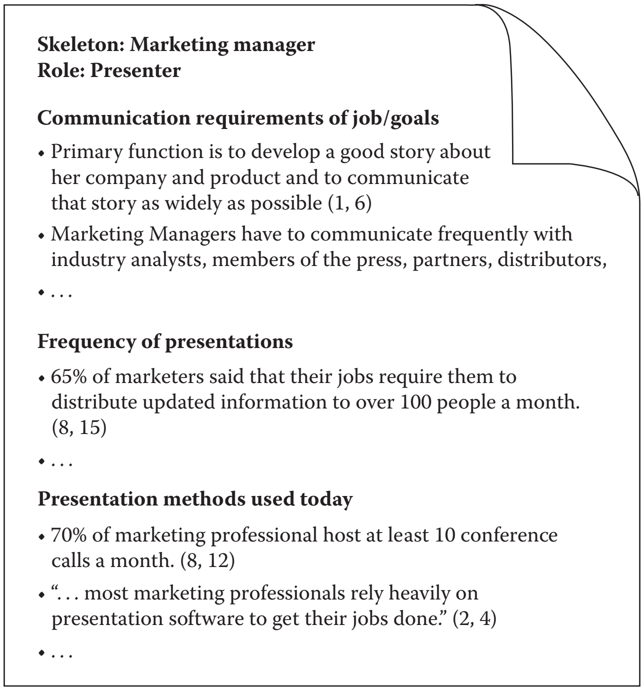
Look at the data clustered under each of your user categories. As a team, evaluate and discuss the possibility that each category should be divided into two or more subcategories. Consider roles, goals, and segments in this assessment. As you identify subcategories, you can write them on a whiteboard and you may also find it helpful to transfer the subcategory names onto sticky notes and place them appropriately in your assimilated data. In doing this exercise, you are simply exploring the possible groups of users that have emerged from your data. Try to identify "differences that make a difference" within each category, based both on the clustered assumptions and the clustered factoids.

46.3.2.3.1 Create Skeletons

Once you have identified and agreed upon the categories and subcategories of users, you are ready to create skeletons. Skeletons are very brief, usually bulleted lists of distinguishing data ranges for each subcategory of user. Skeletons help your core team transition from thinking about categories of users to focusing on specific details; they also allow your team to present the key findings of the assimilation exercise to stakeholders.

Create one skeleton for each of the subcategories you identified. On each skeleton, list the cluster labels that relate to that subcategory; these cluster labels will become headings in your skeleton (see Figure 46.3). Because you will be comparing and prioritizing skeletons against each other, it is important that each one contain at least somewhat comparable information. Consider including common characteristics or headings across all of your skeletons. (If you do this, you may find that you are missing information for some skeletons. In those cases, either leave that information blank, perhaps marking it as "need data," or make an informed estimation about what it might be. If you do the latter, be sure to indicate that it is an assumption to be followed up on.)

Feel free to create as many skeletons as you and your team feel are necessary to "cover" the discoveries you made during the clustering processes. You will have the opportunity to combine and prioritize them in the next steps.



Skeleton: Marketing manager
Role: Presenter

Communication requirements of job/goals

- Primary function is to develop a good story about her company and product and to communicate that story as widely as possible (1, 6)
- Marketing Managers have to communicate frequently with industry analysts, members of the press, partners, distributors,
- . . .

Frequency of presentations

- 65% of marketers said that their jobs require them to distribute updated information to over 100 people a month. (8, 15)
- . . .

Presentation methods used today

- 70% of marketing professional host at least 10 conference calls a month. (8, 12)
- ". . . most marketing professionals rely heavily on presentation software to get their jobs done." (2, 4)
- . . .

FIGURE 46.3 An example of a skeleton created out of assimilated data. Note that the skeleton includes factoids grouped according to topic; it does *not* include any narrative details or "personalized" information.

SIDEBAR 46.4 Sometimes Categories of Users (and Personas) Should Be Based on Verbs, Not Nouns

Karen McGrane
Vice President, User Experience, Avenue A | Razorfish

Though the method of developing personas is relatively new, it seems a given that a persona maps to, well, a person. The approach taken by user-centered designers focuses on understanding the needs, goals, and mindsets of a given individual. A persona usually describes a single, stable individual, whose interaction with a company, product, or website stays consistent throughout the experience.

What happens when the goals and mindsets of an individual user can change rapidly over the course of their relationship with a company—or even over the course of a single session? When we observed people visiting the *New York Times* website, we realized that individual users did not fall neatly into a single mode of use. People tended to switch their goals over time. People used the site differently in the morning, when they wanted to read headlines and catch up on the day's news, as compared to the afternoon, when they might be looking to take a break over lunch or between meetings. We often observed people change modes in the course of a single session, moving fluidly from a news-reading mode, scanning headlines, into a planning mode, where they would research restaurants and read movie reviews.

When it came time to document our personas, we realized that the standard way of documenting them would be limiting. We did not want to imply that "Ketan, a 54-year-old technology consultant" was our only "news junkie," or that "Lisa, a 32-year-old account executive" would always operate in a "planning mode." Making a one-to-one connection between the person and the action seemed inaccurate, since we knew each person would most certainly take multiple actions during their use of the site.

What's more, putting the emphasis on the noun (the persona) rather than the verb (the activity) did not really help the *New York Times* achieve their business goals. While they absolutely wanted to create a usable experience for a visitor operating within a given mode, they also wanted to know what would prompt someone to change modes—since shifting modes extends the experience to more page views and more frequent visits. As experience designers, we concluded that we did not need to focus on the person(a). We needed to focus on the activity—the verb, the action, the mode of use (Figure 46.4).

Clients are eager to understand their customers better, and many focus on personas as the tool that will help them do that. In the future, I will encourage my clients to think about other means of understanding customer behavior. I think one of the most important ways they can do this—outside of personas—is to learn more about customer goals and modes of use.

46.3.2.4 Step 4: Prioritize the Skeletons

Once you have a set of skeletons, it is time to review them in preparation to get feedback from all stakeholders. When you meet with stakeholders, you will evaluate the importance of each skeleton to your business and product strategy and prioritize the skeletons accordingly. The stakeholders will help to identify a subset of skeletons to develop into personas.

Before you meet with the stakeholders, it is a good idea to do some initial prioritization of the skeletons. The core team should carefully review the skeletons you have created and make sure you agree that each one truly does reflect a "difference that makes a difference" between subcategories of users as identified earlier. In many cases, it will be possible to reduce the number of skeletons by combining several of them. Once you have a set that you feel should not be further reduced, prioritize them in a way that makes sense to the core team. This will give the stakeholders as "strawman" to work with—and that is easier than asking them to prioritize a series of skeletons from scratch. As you do this, think about the following:

- Is this category or subcategory important to our product (relevant, unique, illuminating)?
- How important is it to our business?
- Are there any groups missing?
- Are some of the categories almost right, but a few of the characteristics are "off" and need to be tweaked?

Note that you should prioritize skeletons *within* each major category of users. For example, prioritize all the "business traveler" skeletons relative to one another, and the "families" skeletons separately. Eventually, you will want to know the priorities of your personas *across* these categories, but first you will need to narrow in on the correct skeletons *within* each category.

Now schedule a meeting with stakeholders empowered to make decisions about the strategic focus of the company. If stakeholders are not aware of the data and general process that led to these skeletons, present that information before

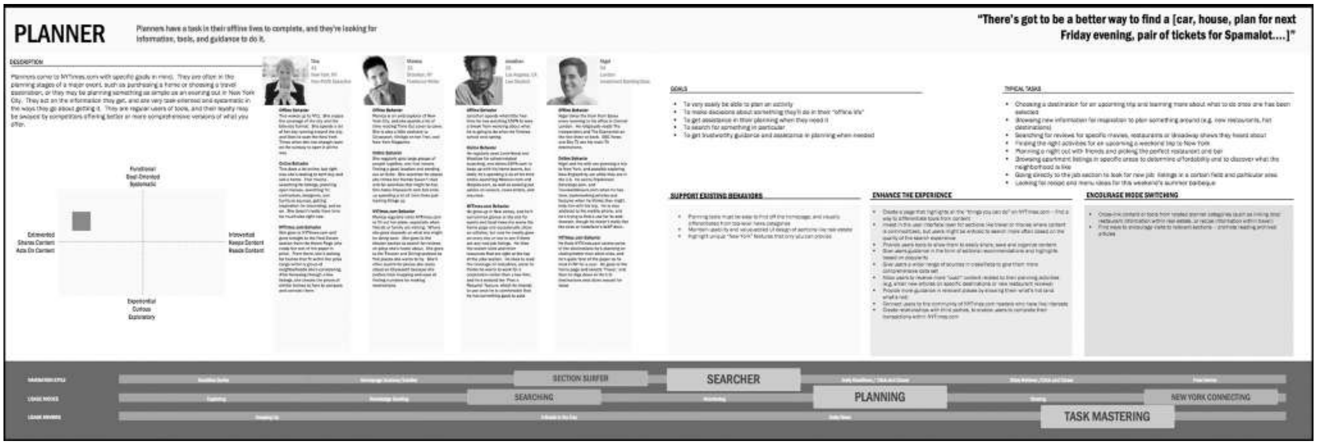


FIGURE 46.4 One of the "verb-based" persona posters for the *New York Times* project. Note that the poster is focused on the word "Planner" and not on a specific persona name. In fact, the "Planner" poster includes details about four individual personas.

introducing the skeletons to them. Introduce the skeletons in one category at a time, and ask them to assign priorities based on the following:

- Frequency of use: How often would each skeleton use your product? Daily users would likely be more important regarding design decisions than those that only use your product once a month.
- Size of market: Roughly how many people does each skeleton represent? Larger markets are usually more important than smaller ones. Do you plan to aim your new product at a new market? In that case, you might consider the importance of a small market with growth potential.
- Historic or potential revenue: How much purchasing power does each skeleton encompass? If this is a new product, you may have to estimate this amount (e.g., through trade journals, market trends, market research, understanding spending behaviors in different by related markets). In many cases, users might not directly make the purchase; someone else buys such products for them. Still, they may influence those purchase decisions.
- Strategic importance: Decide who is your most strategically important audience. Is it those who make the most support calls, those that rely on your product for critical activities, those that use your competitor's product, those that do not use yours or anyone's product yet? Are you trying to expand or grow your market? If that is your primary goal, do your skeletons include nonusers, technology pioneers, or trend setters? Which target audiences will help your team innovate or stretch?

Prioritization can be difficult, and your first meetings will likely end in requests for more data. For example, stakeholders might ask you to find data on the market size for each of the skeletons before they feel comfortable prioritizing. If prioritization feels impossible, it might mean that the business goals are not clear. This can lead to some delicate conversations. In general, remind the stakeholders that you want to prioritize the skeletons so that they accurately reflect the company's vision for itself and the product. The stakeholders *must* be involved in the prioritization of the skeletons, because they are the ones who are setting the course for the business. Be willing to go back and try to find more data if necessary.

46.3.2.5 Step 5: Develop Selected Skeletons into Personas

You now have a reduced set of basic skeletons. Your task at this point is to enrich these skeletons to become personas by adding additional data as well as concrete and individualized details to give them personality and context. You will also include some storytelling elements and photos to make them come to life.

As you build on your skeletons, all the details of your personas will be encapsulated in a "foundation" document. Foundation documents contain the complete definition of a given persona, but they do not have to be long or difficult to create. Depending on your goals and the needs of your team, your foundation document could range from a single page to a long document. Creating a foundation document for each persona will provide you and your team with a single resource you can harvest as necessary as you create your persona communication materials. At the very least, complete personas must include core information essential to defining the persona and the goals, roles, behaviors, segment, environment, and typical activities that make the persona solid, rich, unique, and more importantly, relevant to the design of your product.

If you are extremely time and resource constrained, you can start with brief one-page or resume-style foundation documents. Then, as you find the time, you can always come back and add to the information in these short foundation documents.

When you are deciding which characteristics to include in your foundation documents, think about the types of information that will be most helpful to your core team and to the development team. We recommend you include at least rudimentary information in each of the following categories:

- Photo(s)
- Name
- Age
- Personal details/family life
- Income/spending habits
- Work/job details
- Use environment/artifacts
- Activities/use scenario
- Knowledge/skills/abilities
- Goals/motives/concerns
- Likes/dislikes
- Quotes
- Market size/influence

To create the content of these sections, you will turn the characteristics in your skeleton personas into very specific, concrete values. These specific details turn your collection of facts into representations of people. For example:

- High-Tech, publicly traded companies *becomes* "PrinterCo"
- Works in a communications role *becomes* Marketing Manager
- Seventy percent female *becomes* Megan, Dianne, Irene, and so on.
- Lives in a major metropolitan city *becomes* Chicago, LA, or Houston

As you replace factoids with specific details to enrich your persona, copy the factoid or set of factoids into a comment or a footnote in your foundation document. A lofty but worthy goal is to have every statement in your foundation document supported by user data. You likely will not achieve this, but the attempt helps you to think critically about your details, and highlights places where you might want to do further research.

46.3.2.5.1 *Moving toward Precision Means Moving away from Accuracy*

In many cases, the accuracy of your data lies in its ranges (not just central tendencies, but descriptors of variance, percentages and skew), and by selecting precise descriptors, you are going to lose some of that accuracy. For example, if a category includes males and females, you cannot create a single individual who "represents" the entire category. Rather than trying to represent every nuance of the entire category, try to pick values that are reasonable, believable and meaningful.

Think of your data, and your categories and subcategories of users, as describing *neighborhoods* of related users of your product. As you create your personas, you are describing a single, specific "resident" of each neighborhood; as in real life, each resident inhabits his or her neighborhood, but no one resident can represent all the qualities of all the people in the neighborhood.

46.3.2.5.2 *Incorporate Narrative and Storytelling Elements*

Enriching your terse skeletons into personas that are realistic and engaging requires some storytelling. To do this well, consider that you are trying to "tell the story" of the data in your foundation documents with narrative. What do your personas sound like and act like? What can they do or not do? Turn your factoids and specific details into a running story; a sequence of actions and events with interaction and even a plot. Demonstrate their interactions with people, objects, and systems. In the best case, these stories are modeled on real, representative cases revealed through qualitative research.

Narratives in persona documents usually are written in third person, active voice. The following is an example of a beginning descriptive overview for a marketing manager named Megan written as a narrative:

> Megan is the product marketing manager for PrinterCo, a leading printer manufacturer. Part of Megan's job is to create and foster the company's image as a cutting-edge technology company. Her primary function is to develop a good brand about her company and product and to communicate that brand as widely as possible. She spends her time thinking about how to educate people about PrinterCo's products and to build relationships between customers and PrinterCo.

Be careful when evoking stereotypes or any information that could elicit a strong personal response. When in doubt, choose details that help others see your persona as a real person, with particular goals, needs, and interests that are understandable. Allow realism to win out over political correctness; avoid casting strongly against expectations if it will undermine credibility. Break the mold if it helps get people on board with your effort. Alan Cooper addresses this issue by stating: "all things being equal, I will use people of different races, genders, nationalities, and colors." (p. 128)

46.3.2.5.3 *Illustrate Your Personas*

Each persona needs a face, a photo or set of photos, to make them real. We believe real photos or illustrations are critical; they help your team believe in the personas and understand that each persona describes a single person. The choice of what specific photos to use is a hard one. These illustrations of your personas are extremely influential, and can significantly affect how your personas are perceived.

A photo is more than just a face; the model's clothing, expression, activity, and general appearance along with the setting and background will all communicate or even dictate some of the characteristics of your persona. You can either take advantage of this fact or continually fight it. In general:

- Avoid "slick" stock photos. Photos of models *look* like photos of models—not of real, everyday people. A great alternative is to take photos of friends-of-friends. Do not use photos of a person that anyone on the product team knows. If you do take your own photos, take many! You can use different photos at different times to keep people interested in the personas.

- If you cannot take your own photos, look for photos online. Flickr.com is a great example of an online photo sharing site, and you can look in the Flickr “Creative Commons” area for work by photographers who are willing to let others use their photos royalty-free. Do a search for “portraits” to find hundreds of potential personas!

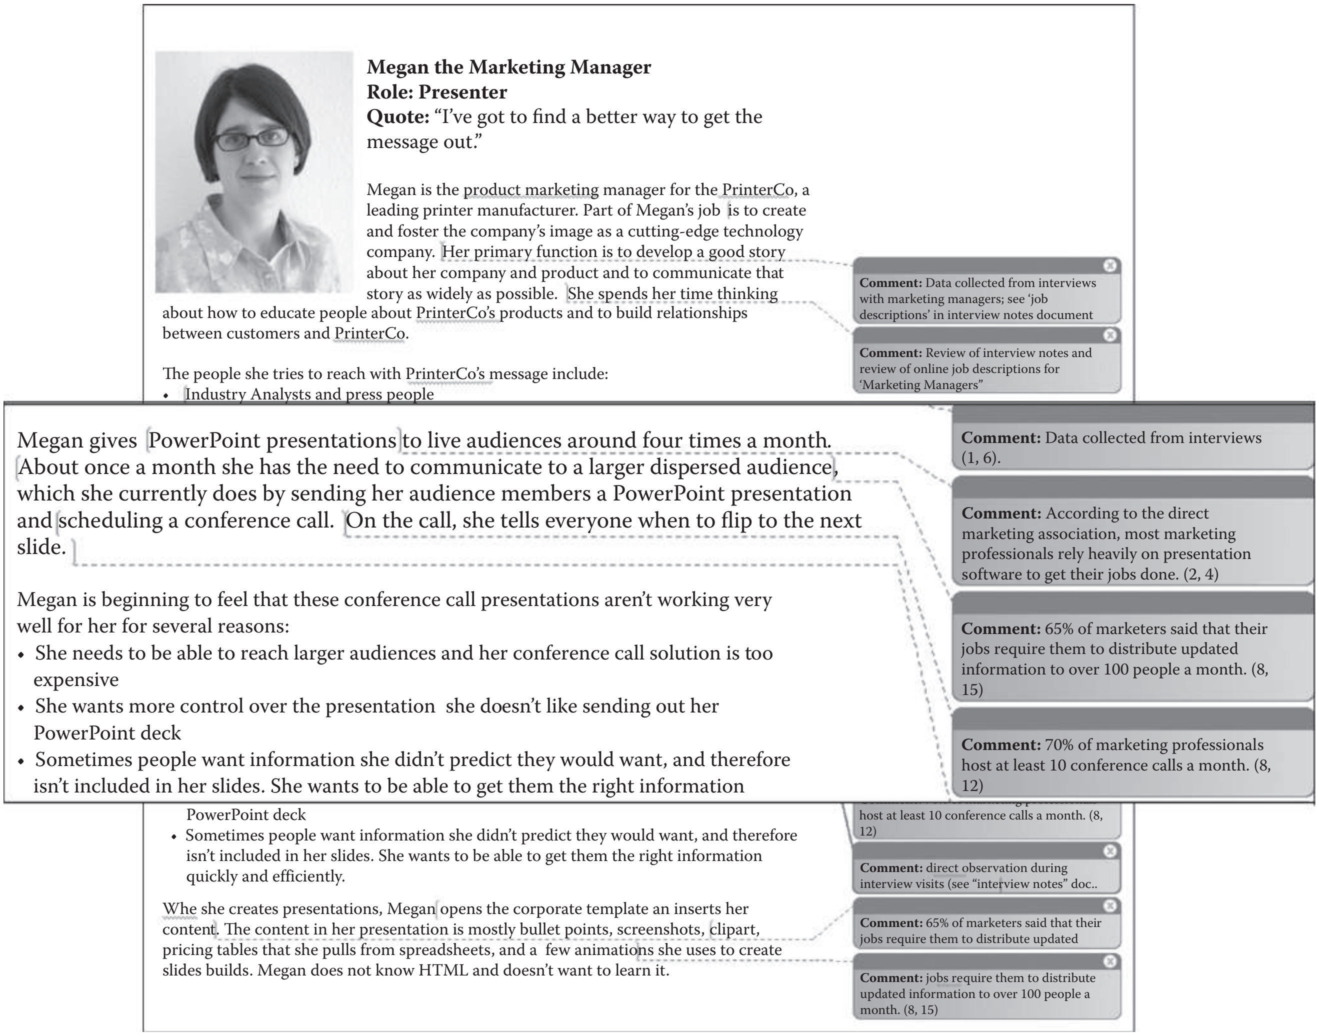
If possible, include multiple photos in your foundation documents to illustrate your persona (Figure 46.5).

46.3.2.6 Step 6: Validate Your Personas

Once you have added details, it is important to double-check to make sure your final personas still reflect your data. Your goal is to ensure that you did not stray too far away from your data when you made their characteristics specific and concrete and added elements of story telling. While it is true that personas cannot and do not need to be completely accurate, you do want to ensure that they reflect the essential information about your target users that you found in your data. If you built assumption personas, you want to ensure that the personas you created really do capture the assumptions in your organization.

To validate your personas, you can do one or more of the following:

- Review your personas against the original data sources
- Have experts, those who are closest to your users, review your personas
- Have representative users of each persona review “their” personas
- Conduct “reality check” site visits with real people that loosely fit into each persona’s category or role
- Conduct large sample surveys or interviews and apply statistical analysis or modeling



Megan the Marketing Manager
Role: Presenter
Quote: “I’ve got to find a better way to get the message out.”

Megan is the product marketing manager for the PrinterCo, a leading printer manufacturer. Part of Megan’s job is to create and foster the company’s image as a cutting-edge technology company. Her primary function is to develop a good story about her company and product and to communicate that story as widely as possible. She spends her time thinking about how to educate people about PrinterCo’s products and to build relationships between customers and PrinterCo.

Comment: Data collected from interviews with marketing managers; see ‘job descriptions’ in interview notes document

Comment: Review of interview notes and review of online job descriptions for ‘Marketing Managers”

The people she tries to reach with PrinterCo’s message include:

- Industry Analysts and press people

Megan gives PowerPoint presentations to live audiences around four times a month. About once a month she has the need to communicate to a larger dispersed audience, which she currently does by sending her audience members a PowerPoint presentation and scheduling a conference call. On the call, she tells everyone when to flip to the next slide.

Comment: Data collected from interviews (1, 6).

Comment: According to the direct marketing association, most marketing professionals rely heavily on presentation software to get their jobs done. (2, 4)

Comment: 65% of marketers said that their jobs require them to distribute updated information to over 100 people a month. (8, 15)

Comment: 70% of marketing professionals host at least 10 conference calls a month. (8, 12)

Megan is beginning to feel that these conference call presentations aren’t working very well for her for several reasons:

- She needs to be able to reach larger audiences and her conference call solution is too expensive
- She wants more control over the presentation she doesn’t like sending out her PowerPoint deck
- Sometimes people want information she didn’t predict they would want, and therefore isn’t included in her slides. She wants to be able to get them the right information

PowerPoint deck

- Sometimes people want information she didn’t predict they would want, and therefore isn’t included in her slides. She wants to be able to get them the right information quickly and efficiently.

host at least 10 conference calls a month. (8, 12)

Comment: direct observation during interview visits (see “interview notes” doc..

Whe she creates presentations, Megan opens the corporate template an inserts her content. The content in her presentation is mostly bullet points, screenshots, clipart, pricing tables that she pulls from spreadsheets, and a few animations she uses to create slides builds. Megan does not know HTML and doesn’t want to learn it.

Comment: 65% of marketers said that their jobs require them to distribute updated

Comment: jobs require them to distribute updated information to over 100 people a month. (8, 15)

FIGURE 46.5 A portion of an example persona foundation document. Note that the callouts on the side of each page are “factoid” references.

These five approaches are not mutually exclusive, nor are they the only means to validate your personas. Treat the validation process as an opportunity to gather even *more* data about your users, incorporating significant findings back into the persona definitions.

46.3.2.6.1 Completed Personas Do Not Mark the End of User Research

At the point that you finish the creation of your personas, you may be tempted to think that you do not need to further understand (do research) or involve real users in the development of your product. From our perspective, this could not be further from the truth. We believe personas are a great starting point for understanding and incorporating user information in the development cycle.

46.3.3 Phase 3: Persona Birth and Maturation

Personas are typically created (contained) and communicated as static documents or posters that provide a snapshot of interesting and relevant information about users. In fact, the foundation document we describe above is a case in point. These artifacts have proven helpful, largely because they help make information about users highly accessible, engaging, and memorable to people making decisions. However, such representations of users are not "alive." They are depicted as motionless portraits, usually contained within a single, finite document and presented as such. There is no room for growth or development. That is, unlike a character in a book or film, such descriptions do not evolve. Moreover, the team using them is supposed to "get to know them" almost instantly. When we get to know a friend, neighbor, colleague, or even a character in a favorite book or TV show, we *build up* an understanding of them, a relationship with them. Once we know people, we are able to understand why they do what they do, what they want, and what they need. Engendering this level of understanding is the next frontier for user representation.

We believe you have to enable the personas to "come to life," allowing them to be alive and to develop in the minds of the people using them. Toward this end, we propose that persona practitioners must do the following:

- Embrace the challenge of communicating information about users through narrative and storytelling
- Incorporate a variety of formats and media to communicate the essential persona characteristics
- Maintain a lifecycle perspective when educating colleagues about the personas
- Allow the people using the personas to extrapolate from and extend them

In other words, personas should be more than a static collection of facts. Personas are compelling stories that unfold over time. To be very clear, we are NOT suggesting that personas change drastically over time, take on new characteristics, or develop new skills; they are not to be moving targets. We believe that successful personas and persona efforts are built progressively; just like we get to know people in our lives, we must get to know personas (and the data they contain) by developing a relationship with them. No single document, read in a few minutes or posted on a wall, can promote the kind of rich, evolving relationship with information about users that is the cornerstone of good product development. No single document can contain the wave of scenarios and stories that your personas will inspire. Personas must be aided, if they are to *live in the minds of your colleagues*. As long as the personas are well-built, data-driven, and thoughtfully communicated, the product team can use the personas that come to exist to generate new insights and seek out the right details when they need them.

Like parents sending young children off to school, you and your core team will send your personas into your organization to interact with other people. The personas are fully formed but may continue to evolve as your team becomes familiar with them. Problems at this phase can lead to a lack of acceptance or visibility or personas that "die on the vine" and disappear from the project. More subtly, your personas may come to be misconstrued and misinterpreted. Successful persona birth and maturation requires a strong, clear focus on communication to ensure that your personas are not just known and understood, but adopted, remembered, and used by the product team. The birth and maturation process includes the following:

- Creating a persona campaign plan to organize your work in birth and maturation and adulthood
- Introducing the personas (and the persona method) to the product team
- Ensuring that the personas are understood, revered, and likely to be used, (e.g., creating artifacts to progressively disclose persona details)
- Managing the minor changes to the persona descriptions that become necessary after the personas are introduced

At this phase, you must be prepared to answer the difficult questions that will inevitably come up as you introduce the personas; you will have to be prepared to discuss the process you used to create the personas, their utility, the ways you would like the product team to use the personas, and the ways you intend to measure the value of the persona effort. The work you did in the family planning phase will come in quite handy as you prepare your answers to these inevitable questions.

SIDEBAR 46.5 Using Personas to Build Teams

Aviva Rosenstein

Manager, Design Research, Yahoo! Media Group

The Yahoo Photos team supports an application for sharing, printing and organizing personal photos. This team has been in the vanguard in adopting Agile development approaches at Yahoo as an alternative to the traditional waterfall development process. To make this transition to an Agile approach successful, we needed to find ways to bring engineers and designers together into a single, cohesive team.

When introducing the persona set to the project team, I used our design personas to create connections between the engineering and design staff while, at the same time, familiarizing the entire team with our target customers, by creating a simple game requiring knowledge of each of the personas' characteristics. The design team scheduled a happy hour to introduce the personas, created handouts and posters with information about each persona, and invited the entire product team, including all the designers, developers, and product managers assigned to the property to come play the game.

The exercise was a success; everyone had to study the persona artifacts to determine what questions they could ask, which gave them a head start in internalizing our personas. In addition, the game provided an enjoyable context for designers and engineers to cross social barriers and begin interacting with each other.

The persona artifacts served as "boundary objects" (Star and Griesemer 1989): a way of bridging communication gaps between disparate functional and organizational worlds. The exercise itself broke down the barriers that existed between the engineering and design groups and allowed the design team to get the rest of the developers to empathize with the needs of our customers, but the actual impact of the persona artifacts went even further. After this exercise, team members commonly and naturally began to use our personas to refer to actual customers and their needs, in storyboarding, use cases and requirements documentation. Project management used the personas to communicate value propositions with executive staff. Marketing used the persona artifacts to communicate target audience characteristics to our outside public relations (PR) agency. Design management used the handouts to communicate requirements to an outside design firm retained to develop a specific part of the service. It gave all of the teams a shared language for talking about our business. In addition, introducing the persona set in an informal and engaging way encouraged adoption among the various disciplines contributing to the overall success of the project.

46.3.3.1 Persona Artifacts

You can use a variety of methods to communicate personas to the members of your product team, including websites, posters, illustrations, Word documents, Visio diagrams, live actors, and videos. Remember that the artifacts and materials you create to communicate information about personas are very important—they are the user interface (UI) for your personas and the data behind them. Well-thought-out and well-designed persona materials can add credibility to your entire persona effort and help enormously with your persona communication campaign (Figure 46.6).

We define three major categories of persona artifacts:

- *Buzz generators.* These artifacts should be designed to build up anticipation about the introduction of the personas. They are usually posters with relatively little information on them. Buzz generators can give hints about the fact that personas are coming (e.g., a poster that says "do you know who your users are?") or begin to introduce the personas themselves (e.g., a wanted-style poster showing just a persona's photo, name, and perhaps role: "Meet Barry the Business Traveler").
- *Comparison facilitators.* Comparison facilitators are helpful after everyone has been introduced to the personas. These artifacts should be designed to help people understand key differences between the personas. For example, you could create a table-style poster that lists the personas across the top and highlights different goals, technical abilities, challenges, and so on across each row.
- *Enrichers.* As the design and development process continues, you can use enricher artifacts to refresh everyone on specific aspects of each persona. For example, when the team begins working on security features, you could create enricher artifacts that describe the security challenges for each of the

I want to create something f children, so they always know how I care about them.

FIGURE 46.6 The Yahoo! Photo persona artifacts helped bridge a communication gap between functional and organizational worlds.

> personas. You might also send out a monthly e-mail "from" each persona to update the team on their goals and needs. You can also create fun artifacts as enrichers; for example, you can hand out candy bars that have new "persona" labels listing salient facts about each persona. Anything that helps keep the personas fresh and alive in the minds of the team is a good thing!

Note that it does not take a lot of these artifacts to have an effective communication campaign. Be very strategic and frugal in your choices. Approach the creation and distribution of your persona artifacts carefully.

46.3.3.1.1 Agree on the Specific Goal of the Artifact

Why are you creating this specific artifact? The goal will probably be related to one of the three categories of artifacts we described earlier.

46.3.3.1.2 Agree on the Audience, Timing, and Distribution Method for the Artifact

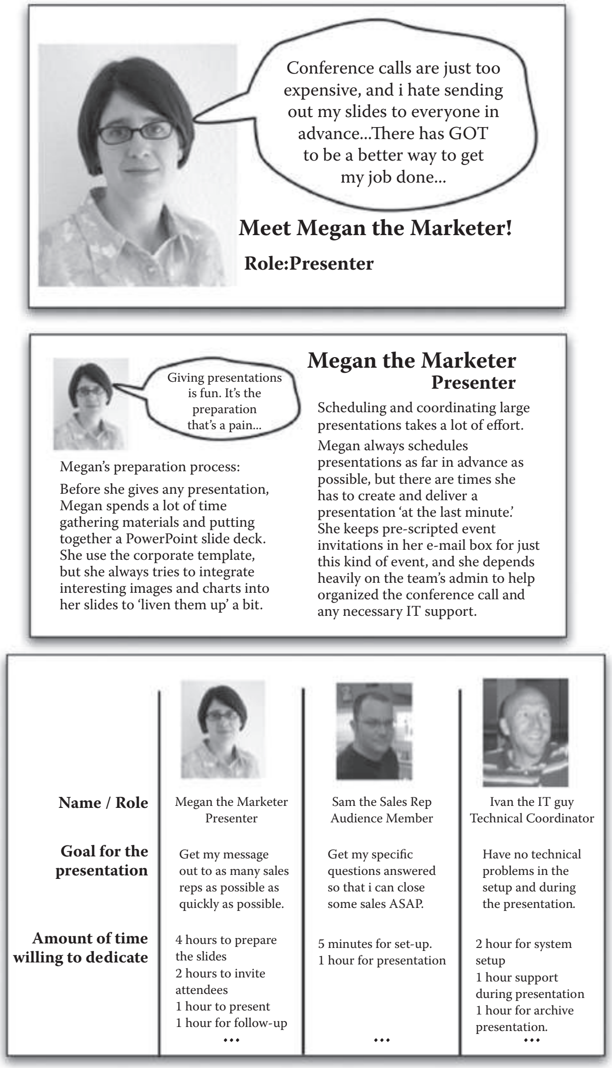
Your persona artifacts should eventually be everywhere around your office (in hallways, coffee room, doors, meeting rooms, stakeholders/leaders' offices, etc.), but they should appear progressively. For every artifact, consider who is going to see it, when (in the development cycle) they are going to see it, and how the environment will affect their ability to digest the information. For example, you might decide to create different "buzz generator" posters (see below for a description) for the developer's hallway versus the marketer's hallway. If you work in place that does not allow posters and such to be displayed around the building, create artifacts that can handed out to individuals, carried around or placed on desk tops.

46.3.3.1.3 Agree on the Information Elements That Should (and Should Not) Be Included on the Artifact

By the time you are ready to create persona artifacts, you will have quite a bit of information about each persona at your disposal. The information you have will all seem highly relevant and deeply interrelated, and it can therefore be difficult to comb out small snippets to include on individual artifacts. Remember that the easiest way to create a useless persona artifact is to overload it with information. For example, you might decide to create "wanted" posters to create buzz and to convey the name, role, and picture for each of your primary personas. It will be tempting to include a quote and maybe a few bulleted details with additional information. Remember your priorities: if you really do want to build buzz and interest, consider limiting the poster to just a photo, a name, and a role. When in doubt, always opt for less information and leave your audience craving more.

46.3.3.1.4 Agree on the Relative Priorities of the Information Elements on the Artifact

Once you decide which information elements should be included on an artifact, prioritize these elements according to how important it is that the element is read and understood. For example, on the "wanted" posters, the photo and name should probably be very large and eye-catching. In contrast, a comparison poster you distribute a few weeks or months later should include names and roles, but these are probably not as important as comparative information about each persona's goals, abilities, desires, and so on. See Figure 46.7, for example, posters in each of the three categories of artifacts.



Conference calls are just too expensive, and i hate sending out my slides to everyone in advance...There has GOT to be a better way to get my job done...

Meet Megan the Marketer!

Role:Presenter

Giving presentations is fun. It's the preparation that's a pain...

Megan the Marketer
Presenter

Scheduling and coordinating large presentations takes a lot of effort.

Megan always schedules presentations as far in advance as possible, but there are times she has to create and deliver a presentation 'at the last minute.' She keeps pre-scripted event invitations in her e-mail box for just this kind of event, and she depends heavily on the team's admin to help organized the conference call and any necessary IT support.

Megan's preparation process:

Before she gives any presentation, Megan spends a lot of time gathering materials and putting together a PowerPoint slide deck. She use the corporate template, but she always tries to integrate interesting images and charts into her slides to 'liven them up' a bit.

Name / Role	Megan the Marketer Presenter	Sam the Sales Rep Audience Member	Ivan the IT guy Technical Coordinator
Goal for the presentation	Get my message out to as many sales reps as possible as quickly as possible.	Get my specific questions answered so that i can close some sales ASAP.	Have no technical problems in the setup and during the presentation.
Amount of time willing to dedicate	4 hours to prepare the slides 2 hours to invite attendees 1 hour to present 1 hour for follow-up ...	5 minutes for set-up. 1 hour for presentation ...	2 hour for system setup 1 hour support during presentation 1 hour for archive presentation. ...

FIGURE 46.7 Examples of a buzz generator, and enricher, and a comparison facilitator poster for the online presentation of software personas.

If you have limited resources (e.g., very little money to use on persona artifacts), think carefully about the artifacts you will need now and try to predict what you will need later. Do not use your entire budget on artifacts you will distribute early; remember that you still face the challenge of keeping the personas alive and useful throughout the Adulthood phase.

46.3.4 Phase 4: Persona Adulthood

Personas are "all grown up" in the adulthood phase and they have a job to do. You have now introduced the personas to the product team and worked to clarify the role and importance of the personas. You have encouraged the product team to embrace the personas and the information they contain, and now it is time to help everyone use the personas to inform the design and development of the product.

Adult personas are ready to be put to work in a variety of ways. Personas can help by answering difficult questions and by focusing activities in a way that takes the guesswork out of making customer-driven decisions. Personas can participate in your product planning, design and development process by

- Being present at your meetings and representing the voice of your customer throughout the development cycle
- Providing consistency by providing a common reference point across your organization, even in a highly chaotic, fast-moving, and ever-changing environment
- Providing a way for all of the product teams to touch base using a common language, and to ensure that everyone is staying focused on creating a good experience on the right audiences

Personas can only be involved and helpful in these ways if they inhabit your workspaces and attend your meetings. Even though they are not real people, personas can become the most powerful voices in the room. Large wall posters, which introduce your personas, should be placed in every meeting room as well as other common spaces where team members discuss product design, features, and overall user experience. The important thing is that the personas' presence is felt. You want your team mates to refer to the personas in their everyday work. Hundreds of tiny decisions are made each day and you want these decisions to be made in consideration of your target audiences.

The more the persona names are used, the more likely it is that everyone in your organization will accept the fact that the personas and the user data they represent are here to stay. The more the persona names replace the word "user" in documents and conversation, the more likely it is that the persona data will shape your product. We suggest that you Ban the word "user" across your organization. Find the owner of each and every document that will help to define or describe your product and encourage them to use the names of the personas instead of the word "user." You have succeeded if you can search the Product Vision Statement, Business Plan, Technical Spec, Marketing and Messaging Plans and find no instance of the word "user."

46.3.4.1 Use Personas for Product Planning, Design, Evaluation, and Release

One obvious way to use personas is to test design ideas by asking questions like: "Will Sally want to use this feature?" We have found that this is only one of the many ways personas can be involved in the product design and development process. The effective persona practitioner must understand the many other ways personas can be involved in existing processes, and ensure that the personas work hard in an organization during the entire development process.

Personas can be used to inform quality assurance test cases, to recruit usability test participants, to make high level and detailed feature priority decisions and to communicate product direction. Personas can also inform marketing, advertising and sales strategy.

46.3.4.1.1 Personas and Product Planning

Personas can help your team envision what your new product should do. Personas can help you understand the context into which you will launch your product and the kinds of problems it needs to solve if it is going to be successful. Now that you have created your personas, you can ask the personas to "tell you their stories"; the needs, goals, and contexts you so carefully included in your persona descriptions will now allow you to generate helpful stories about the way your product will be used and the actions (and reactions) it should elicit.

Personas can help in the product planning process, both by helping you discover important features and by helping you evaluate the relative values of each feature. You can use personas to help you understand and capture your user and system requirements through

- Persona narratives and storytelling
- Persona-focused competitive reviews
- Persona-focused feature brainstorming
- Persona-focused evaluation of proposed features

All of these involve taking on the perspective of your personas to review the competition, your ideas for features, and so on. For example, you can do a persona-focused competitive review by finding out which existing products your new product will compete with. Your marketing team has probably already done this and they are a good source for help with this exercise. If you can, buy a copy of each competing product. (If the products are prohibitively expensive, you can do this exercise using the marketing or collateral materials instead of the actual products; this will give you insight into the reaction of your potential customers to the messages your competitors have deemed to be important.) Once you have access to the products, it is relatively easy to look at them from your personas' perspectives.

Gather the core team and ask one member to "walk through" the competitive products from the perspective of one of you personas. As you observe your "persona" walking through the product, you will find aspects of the product that work well and some that do not work well. If members of your product design team are present, they will come up with ideas for functionality that you must address in your product and ideas for brand new features.

46.3.4.1.2 Personas and Product Design

Once your organization has a vision and overall development plan in place, it is time to design the elements of your product. Your personas helped you understand the big picture, and now they can help you make decisions about specific features and design elements. That is, your personas can show you what these features look and behave like.

There is one process we have found particularly helpful in translating insights derived from personas into ideas for product designs: Design Mapping. We will describe this method in depth in the Section 46.3.4.2 of this chapter so that you can try it out for yourself.

46.3.4.1.3 Personas and Product Design Evaluation

As your team settles in on the features and specific solutions that it needs to embrace to create a successful product, your personas can help in honing the implementation of these features toward the very best design.

You can use your personas to help with evaluation of your features and solutions through

- Cognitive walkthroughs and design reviews with personas
- User testing and ongoing user research with persona profiles
- Quality assurance (QA) testing and bug bashes

The best way to incorporate personas into the above processes is to involve the owner of each process (e.g., the QA manager) to meet with the persona core team. As a rule, meet with process owners earlier than you think is necessary. This will give you time to figure out ways to incorporate personas into the various evaluation processes your company uses before it releases any product.

46.3.4.1.4 Personas and Product Release

Now that your product is getting close to being complete, it is time to turn your attention toward details that are not directly related to product development. You have put a great deal of effort into creating and using your personas to design and build your product. Now that the product is almost complete, your personas (and all of the persona-related materials and tools you have created) can be extremely helpful to those responsible for documenting, supporting, and selling your product.

If you have used the personas throughout the design and development process, you will have many documents that talk about how the product is supposed to work from the point of view of the personas. These documents will be invaluable to the documentation, training, and support professionals in your organization. Marketing and sales professionals will also be able to use the personas (and related deliverables) to help craft materials to support their own work.

Many persona practitioners have told us that the personas seem to "move out" of the design and development offices and "move in" to the documentation, support, and sales offices during product release.

46.3.4.2 A Great Tool for Persona Adulthood: Using Design Maps to Get from Personas to Product Designs

Design Mapping is a process that results in a large flowchart created out of sticky notes, and depicts an individual's end-to-end experience of using a tool or accomplishing a goal. They are artifacts that help you understand and communicate information about the ways people achieve their goals and the ways they could achieve their goals with new tools. Maps are similar to other participatory design tools, but are useful in ways that we have not found other tools to be; Design Maps tell stories about the experiences of personas in the future.

Maps are helpful information gathering and design tools because they are easy to create, iterate, and read. If they are kept in public spaces, they can become an accessible source of insights into user experiences (either as they exist today or as they are envisioned to become). Unlike prose documents or complex flowcharts, Maps make it easy to quickly extract and understand the end-to-end user experience and/or focus on details of interest.

Design Maps can help you test new experiences before you build a new product. Moreover, Design Maps will help you translate what you know about your personas into designs for new experiences that your product could support. Once you design the experience you want to create, it is relatively easy to create features to support that experience.

46.3.4.2.1 What Are Design Maps?

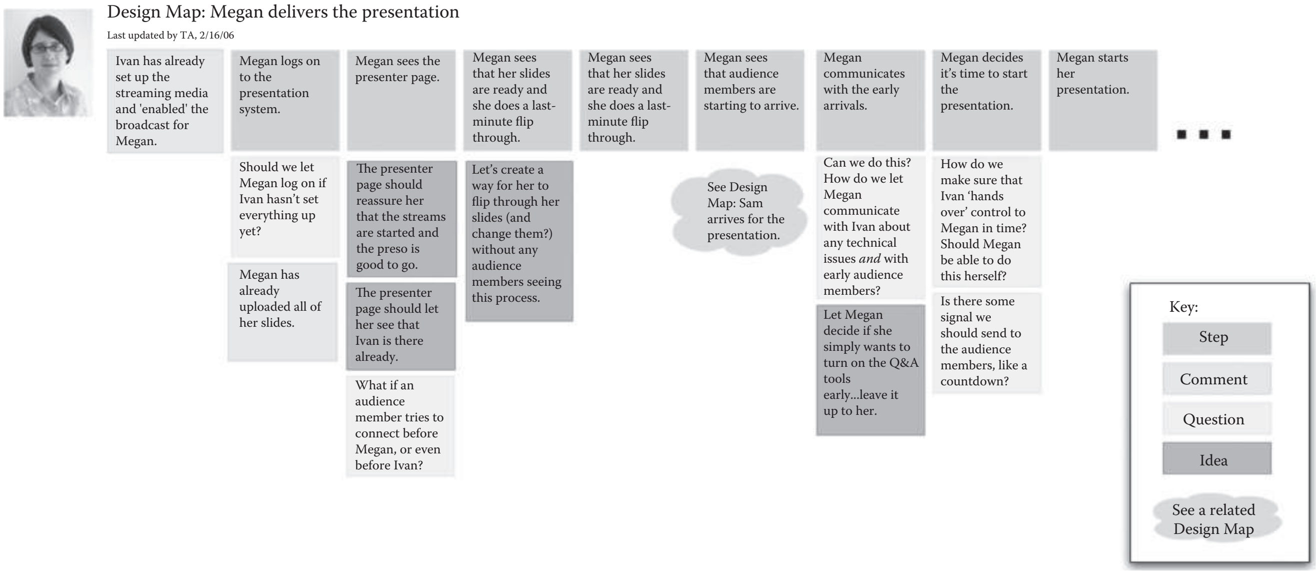
Design Maps tell stories that look into the future; these stories describe how your personas will behave once your new product is built. Those familiar with scenario-based design will recognize that Design Maps have a distinct similarity to scenarios (see Carroll [1995]). Scenarios are short prose stories that describe how aspects of your product will be—or should be—used. Design Maps are both a special type of scenario and a process by which to create scenarios and modify them. Design Maps are flowchart version of many scenarios "strung together" to create a big picture of the experience your product will support. Design Maps are inexpensive (both in terms of time and materials) and they are most helpful when built before paper prototypes and certainly before any code is written.

46.3.4.2.2 Which Processes Should I Design Map?

Design Maps depict end-to-end experiences (not specific features or widgets); you can create Design Maps to explore any experience you want to create as it relates to any aspect of your new product's design. The Design Maps you create should explore the ways that your personas achieve the goals that you have established for them. Remember that their roles and goals may change in your new designs.

46.3.4.2.2.1 Design Map for the "Big Picture" This Map shows the entire experience end-to-end and therefore describes activities in very broad terms. Think of this "overview" Design Map as analogous to a map of the United States with a line drawn on it to show the route of a cross-country driving trip; the overview Map should give the reader a general sense of direction and the order of progression, but should not contain details.

46.3.4.2.2.2 Design Maps for Achieving Major Milestones These Maps should "fit into" the overall Map, but should explore individual goals and tasks more specifically. In the



Design Map: Megan delivers the presentation

Last updated by TA, 2/16/06

Ivan has already set up the streaming media and 'enabled' the broadcast for Megan.

Megan logs on to the presentation system.

Should we let Megan log on if Ivan hasn't set everything up yet?

Megan has already uploaded all of her slides.

Megan sees the presenter page.

The presenter page should reassure her that the streams are started and the preso is good to go.

The presenter page should let her see that Ivan is there already.

What if an audience member tries to connect before Megan, or even before Ivan?

Megan sees that her slides are ready and she does a last-minute flip through.

Let's create a way for her to flip through her slides (and change them?) without any audience members seeing this process.

Megan sees that her slides are ready and she does a last-minute flip through.

Megan sees that audience members are starting to arrive.

See Design Map: Sam arrives for the presentation.

Megan communicates with the early arrivals.

Can we do this? How do we let Megan communicate with Ivan about any technical issues *and* with early audience members?

Let Megan decide if she simply wants to turn on the Q&A tools early...leave it up to her.

Megan decides it's time to start the presentation.

How do we make sure that Ivan 'hands over' control to Megan in time? Should Megan be able to do this herself?

Is there some signal we should send to the audience members, like a countdown?

Megan starts her presentation.

■ ■ ■

FIGURE 46.8 A Design Map exploring how Megan starts an online presentation. Design Maps are created by your team and explore the new experiences you are going to build into your product.

cross-country trip example, a "major milestone" Map would be the equivalent of a highway map showing the roads you used to traverse a single state.

46.3.4.2.2.3 Design Maps for Critical Details These Maps should fit into the milestones Maps much as the milestones fit into the big picture. These Maps explore very specific details of particular tasks, the way an enlargement of a downtown area shows the specific details of the ways streets crisscross a city (Figure 46.8).

46.3.4.2.3 How to Create a Design Map

Maps show steps in a process or experience sequentially, with any questions, comments, or ideas regarding these steps arrayed underneath. Finished Design Maps are large sheets of paper covered with color-coded Post-It™ (or "sticky") notes that describe the user experiences related to your product. Design Maps are created by the design team without the participation of users.

46.3.4.2.3.1 The Elements of a Map: Steps, Questions, Comments, and Design Ideas All Maps have four basic building blocks: steps, questions, comments, and design ideas. Steps should be arrayed horizontally, with related comments, questions, and design ideas arranged under the steps they reference. You can read across the row of steps to get a sense of the process from end to end (i.e., the steps in a task taken to reach a goal), or you can focus on a subset of the steps and read down the columns to understand related questions and ideas (see Figure 46.9).

Steps ("blue" sticky notes): These are the "verbs" or the "backbone" of the process. The facilitator of the Mapping exercise places steps horizontally across the Map. A good way to elicit steps is to ask "What will the persona do next?" Steps are the building blocks of tasks.

Comments ("green" sticky notes): Comments are qualifying statements about steps; they are the most flexible elements on a Map. Comments can describe behaviors, habits, awareness or lack of awareness of features or alternative actions, or even qualities of objects. If you hear an important piece of information, but it is not a step, question or design idea, record it as a green comment.

For example, in our Megan Delivers the Presentation Map (Figure 46.8), the comment "Megan has already uploaded all of her slides" is a note about her actions that could be significant with respect to the rest of the experience. The comment is not a step, but it relates to the step listed above: "Megan logs on to the presentation system." The comment, in this example, serves to remind the facilitator and Map readers that we are assuming that the slides are uploaded in a separate, previous series of actions in this particular Design Map. If this comment were to change (in this example, if we were to change or design the process so that the slides are uploaded immediately before the presentation), it could affect all of the steps, comments, questions, and ideas in the remainder of the Map.

Questions ("yellow" sticky notes): Yellow "questions" are the most useful interview management tool of the Mapper. When you first start Mapping any process, you will identify many questions, some indicating areas where you need clarification and some that express your Mapping participants' issues. In fact, you will probably encounter so many questions that the

sheer volume and importance of them will threaten to derail your attempt to Map the entire process. Listing the questions on the Map allows you to record and move past them quickly so that you can capture as much of the process as possible without being derailed. Once you create a Map that captures most of an end-to-end process, you can loop back and track down answers to the questions you have identified.

Create a yellow question when

- You have questions about the process
- You are not quite sure what will, should, or could happen next
- Anyone participating in the Mapping session begins to belabor a point

Design Ideas ("pink" sticky notes): As you create your Map, you will inevitably think of, or be presented with, an assortment of ideas for specific features, widgets, or even things like marketing messages. Your Mapping goal is to create a solid picture of the end-to-end experience you want to create for your persona. While you do not want to allow your Mapping session to turn into a discussion of specific new features, you also should not discard good ideas just because they come up at the "wrong time." For example, in Figure 46.8, there is a pink sticky note that says "Let's create a way for her to flip through her slides (and change them?) without any audience members seeing this process." This is an interesting idea and worth capturing. Ask anyone who comes up with a design idea to record it on a pink sticky note, place it on the Map, and move on.

46.3.4.2.3.2 Facilitating a Design Mapping Session Encourage mapping participants to focus on the *experience*, not on the *tool*. The goal is not to have a Map that tells you "the serial number registration tracking database will feed the score records to the page via ASP," but one that says "Megan can see that Ivan is already logged on."

During Design Mapping sessions, remind your team to consider:

- Do the tasks assigned to personas in the Design Map correspond to your personas' skills? For example, if Sam the Sales Rep is expected to spend an hour doing technical preparation so that he can attend the presentation, he is not being well served by the new design. If Megan's Design Map allows her to answer questions by presenting new content on the fly, you are on the right track.
- Does this new process being constructed in the Map offer undeniable advantages to the personas over the old way of doing things?
- Are we assuming things have to be done a certain way just because that is the way they are done now?

As you move through a Mapping session, remember to table questions that might sidetrack your work by providing everyone with yellow sticky notes and encouraging participants to write down difficult questions and issues and post them on the map. During your Design Mapping session, you might hear a comment like: "Well, if we are assuming Sam can access the Internet using a broadband connection from wherever he is, even if he is on the road, we can assume he will not have any trouble viewing the presentation. It would also be great if we could assume he has all the media players installed, and the latest version of the browsers. This makes things easier for us." This is a good opportunity to refer to your personas. Do you have information about Sam's technical setup? How likely is it that his computer will have the latest media players? Is this likely to be something that is done for him, or something he has to figure out for himself? Your personas will be able to immediately answer some of these questions; others will have to go onto to the Map to be answered later. In this particular example, you might decide to create another Map that assumes that Sam does not have everything he needs loaded on his machine. What process are you going to design to make it easy for him to prepare for and attend a presentation in this case?

Sometimes you will want to move fairly quickly, placing blue steps across the top of the Map, and filling in details later. Other times your team might find it most effective to hash out the details under each step, before moving to the next one. In either case, you will want to limit mapping sessions to 2–3 hours each.

After each session, follow-up on any questions or issues raised and add answers to the Map. It can be useful to convert the sticky notes paper versions of your Maps into electronic versions in Microsoft Visio or a similar tool. This makes it easy for participants to review progress and quickly scan for new material. The electronic versions are useful for printing in various formats and sending to stakeholders for review at a distance.

46.3.4.2.4 Use Design Maps to Create Wireframes

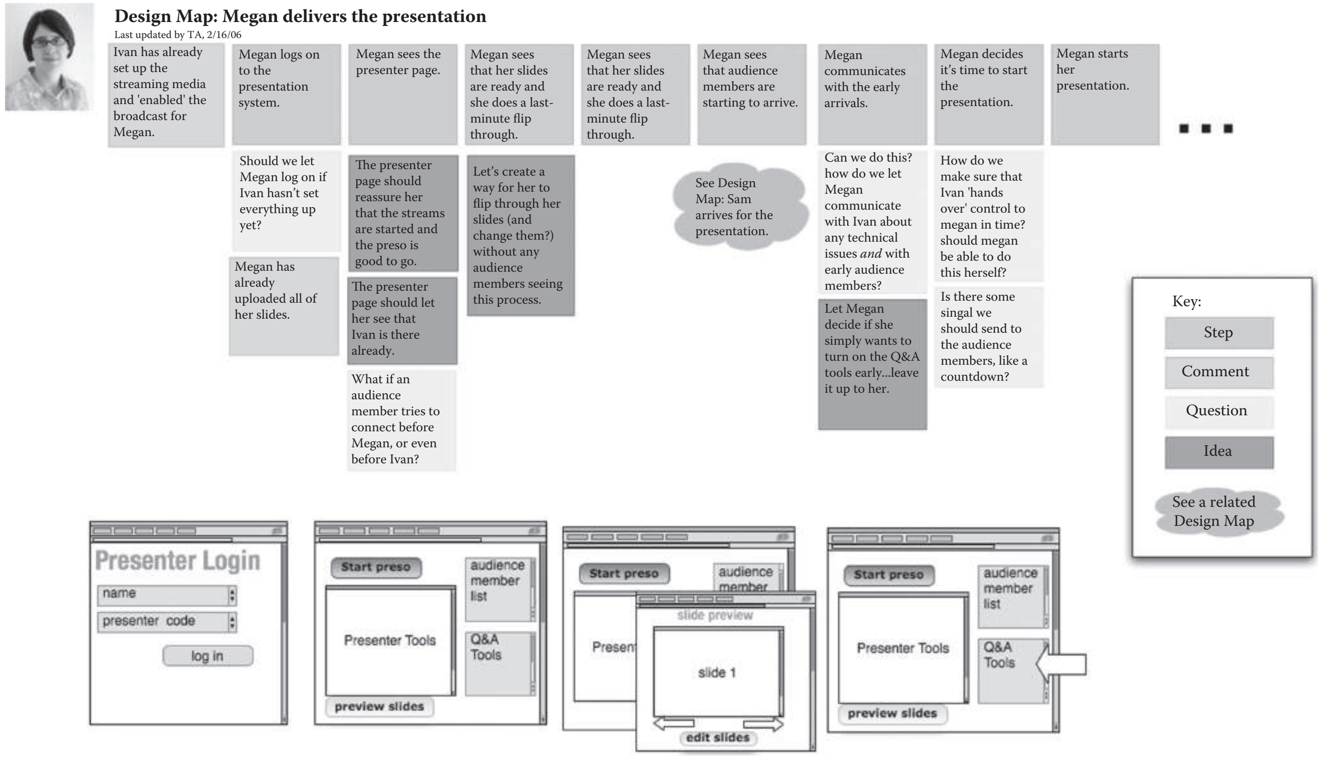
Wireframes tend to evolve naturally from Design Maps. Once you and your team have agreed on the experience you want to facilitate for your personas, it is relatively easy to use the steps, assumptions, questions, and design ideas in the Maps to create wireframes of the product's UI.

With your team, identify the columns of the Design Map that "go together" and should be grouped on a single interface (see Figure 46.10). At this point, the UI designer or graphic designer should be heavily involved. Consider what information you are collecting from the personas and when you are collecting it so that you can plan to display it on the UI at the right times (e.g., if you have not asked the persona for their name yet, you cannot create a wireframe for a personalized interface).

46.3.4.2.5 The Benefits of Design Maps

Perhaps the most important benefit of Design Maps (and wireframes) is that they hold and communicate a shared vision of the project for your entire team. Seeing the "big picture" early on in the project helps motivate everyone toward the common goal of making it real. Design Maps enable your entire team to "see" the product from the personas' point of view, giving the architects of the product the opportunity to understand and empathize with users. A deeper understanding of the planned product and personas early on in the development process can enhance each team member's work on your product—whether they are coding, marketing, managing, testing, funding or selling it.

Design Maps (and their associated wireframes) are a perfect document to work from when communicating project plans to stakeholders. Once your Design Maps are completed, you can use them to perform design walk-throughs of your product with other team members. Have someone read through the map and another person check the prototype or



Design Map: Megan delivers the presentation

Last updated by TA, 2/16/06

Ivan has already set up the streaming media and 'enabled' the broadcast for Megan.

Megan logs on to the presentation system.

Should we let Megan log on if Ivan hasn't set everything up yet?

Megan has already uploaded all of her slides.

Megan sees the presenter page.

The presenter page should reassure her that the streams are started and the preso is good to go.

The presenter page should let her see that Ivan is there already.

What if an audience member tries to connect before Megan, or even before Ivan?

Megan sees that her slides are ready and she does a last-minute flip through.

Let's create a way for her to flip through her slides (and change them?) without any audience members seeing this process.

Megan sees that her slides are ready and she does a last-minute flip through.

Megan sees that audience members are starting to arrive.

See Design Map: Sam arrives for the presentation.

Megan communicates with the early arrivals.

Can we do this? how do we let Megan communicate with Ivan about any technical issues *and* with early audience members?

Let Megan decide if she simply wants to turn on the Q&A tools early...leave it up to her.

Megan decides it's time to start the presentation.

How do we make sure that Ivan 'hands over' control to megan in time? should megan be able to do this herself?

Is there some singal we should send to the audience members, like a countdown?

Megan starts her presentation.

FIGURE 46.10 Wireframes evolve naturally from design maps. You and your mapping team can evaluate which process steps belong together and design the interface flow accordingly.

the product to make sure the Mapped process is supported by the products' design.

As your development team begins coding your new product, check in frequently to evaluate what they are building against what you *thought* they were going to build. Use the Design Maps to "test" the emerging product: Does the product being built actually support the experience you have designed? The Design Maps you created define a task flow; when the product changes during development, use the Maps to evaluate whether or not the changes support the tasks you identified.

SIDEBAR 46.6 Design Mapping Illuminates—and Fixes!—Holes in Other Kinds of Specification Documents

Raina Brody and Sylvia Olveda

Usability Specialists, Amazon.com

The Amazon usability team works with many different project teams from all over the company. For one of our projects, we were working with a team that was designing and developing a new feature for the website. The team had already created three primary personas and a very large document full of use cases, which specified many features and UI elements. The use cases and UI specifications all referred to their personas by name. In short, it looked like they had done a lot of good, user-centered work and were pretty far along the path toward creating a good solution. We asked the designer and the design manager why they felt they needed our help.

They replied "all of this stuff looks really good, but there are enormous holes in the use cases when it comes to the actual UI, the experience flow, and the technical implementation/specifications. Some of the technical services and features these use cases call for do not exist and simply cannot be built—and the rest of the team does not seem to get this." We decided to lead a few Design Mapping Sessions to help them identify and document the holes and to communicate their concerns to the rest of the team.

We set up a meeting with the project team (including members of the business team, design and development teams) and asked them to pick a couple of the most important use cases. They were a bit hesitant at first, because some members felt that they had already done all of this work in the use case document. After describing their primary use cases, we started the Design Mapping exercise. Very soon, it became clear that there were holes in the existing documentation. For example, some of the original use cases assumed the existence of data types and search services that simply did not exist, and that were not scoped as part of the project schedule. The Design Map helped us discover that very important elements in their use cases had not yet been thought about.

The Design Mapping process really started going well when the project team members realized that we, the usability team, were not trying to design their product for them. Instead, we were serving as facilitators to help them come up with and discuss their ideas from a customer experience and technical feasibility perspective. Of course, it was our job to ask (and sometimes answer) some difficult questions about whether customers would be able to discover and/or understand some of the UI elements the team came up with.

The Mapping process generated excitement from the project team and some of the best ideas came from developers. After our first meetings, the Mapping sessions went well and went very fast. The team agreed that the Design Mapping process helped them identify what was hard, what was easy, and what they could really do. The team also realized that while the original use case document contained a lot of good ideas, the complexities of the actual implementation were not made as apparent as they were with the Mapping session.

At the end of the project, we asked the team how the Design Mapping and personas helped with the project. The answers we got were very encouraging:

From a key developer: "Design mapping helped everyone on the team to really focus on the project from our customer's point of view. It took a lot of disparate opinions and ideas about what we wanted to build and provided a common focus. It was responsible for some very productive brainstorming."

From the Technical Program Manager: "The personas and Mapping process are invaluable tools designing a product that is customer-centric; together they have the power to overcome designs driven by emotion and bias: two things commonly found in every product design cycle."

From the Product Manager: "The Design Mapping we did at the beginning of our project has proven to be an invaluable tool to keep the team focused on what is best for our target customers. It was also an extremely helpful team-building exercise."

From the team Manager: "The Design Mapping process helps us develop the right features for the right customers. Project teams are hesitant at first because it seems like a significant time investment, but once they go through the process, they find it invaluable. It actually saves time in the long run by making sure teams make better decisions up front."

WE LEARNED SOME VALUABLE LESSONS FROM THIS MAPPING EXERCISE

If you are Mapping with a team that has never tried it before, do not start by Mapping a controversial feature or experience. Instead, start with one of the features or experiences that seems well defined and clear. This will help them team understand the Mapping process and will show them that you do not intend to take over the design of their product.

Encourage teams to do use cases after they do Design Maps. Design Maps generate lots of use cases, and they have the added benefit of clearly illustrating how use cases fit together in an end to end customer or user experience.

Present Design Mapping as a technique to facilitate the product team's design process. It is important that the team still feel in control, even in a situation where you are leading a Mapping exercise.

Create a Mapping plan after your first Mapping meeting. After you do one Map, it will be easy to identify other user experiences you want to Map. Revisit your Mapping schedule after you do the first two or three Maps to integrate new ideas for Maps and a new perspective on how long the Mapping process will take.

Think about who you want to invite and who you need to invite to Mapping sessions. We always facilitated, and invited at least one designer, the technical program or project manager, between one and three members of the technical/development team, and the product manager.

Word is spreading fast, and now we have so many requests to facilitate Design Mapping sessions we can hardly keep up with them.

46.3.5 Phase 5: Persona Lifetime Achievement and Retirement

Once the project or product is completed, it is time to think about what has been accomplished and prepare for the next project. You will want to assess how effective the persona method was for your team and product development process. If you are beginning to think about the next product (or next version of the product you have just released) you will need to decide whether, and how, you will reuse your existing personas and the information they contain.

The end of a product cycle is a good time to assess the effectiveness of personas for the team and to take stock of lessons learned for the next time. How did the development team accept the method? Were your personas useful? To what extent were they accurate and precise? We will provide suggestions and tools you can use to validate the use of personas in the development process and to determine if the persona effort was worth the effort and resources it required. Did personas change the product? Did they change your design and development process? User-centered designers are constantly under pressure to validate the worth and ROI of their activities and personas can be useful tools for measuring the success of both the product and of the UCD activities as a whole.

Recall the questions we recommended you answer in Phase 1, Family Planning, related to "organizational introspection." Assessing ROI is, in simple terms, working to answer those original questions (listed in the left column of Figure 46.11) in terms that are meaningful now that you are done with the effort (i.e., those questions listed in the right column of Figure 46.11).

46.3.5.1 Retirement

Depending on the nature of your products, you might be able to reuse the personas or "reincarnate" some of your persona data in new personas. That is, you will need to decide what to do with your "old" personas as you prepare for your next project. Do your personas retire, do they change over time? Do they buy your product and start using it? Can other product teams utilize your personas or some portion of the information in them (i.e., are they reincarnated)?

In most cases, you will decide to use some combination of direct reuse (using them again without alteration), reincarnation (reusing some their content and related data) or retirement (discarding or completely replacing some of the personas). Note that, if your persona effort has been a success, retirement and reincarnation can be a bit tricky; to have "room" for the next set of personas, you will need to help your organization let go of the personas they have come to know so well.

Questions You Should Ask During Family Planning	Questions You Will Ask During Lifetime Achievement
What resources do we have for personas and other UCD activities?	How much did the persona effort actually cost?
What product problems do we want to solve with personas?	Has the product improved? How much, and in what ways?
What process problems do we want to solve with personas?	Has the process improved? In what ways?
How can we ensure that the personas will be accepted and used by our colleagues?	Were personas perceived as helpful? Has the company's focus on users improved? In what ways?

FIGURE 46.11 The work you did during family planning is highly related to what you will need to do in lifetime achievement.

Before you decide what to do with your personas, you need to revisit the data sources you used to create them. If you are about to start work on the next version of the product you have just released, it is likely that many (but probably not all) of your data sources are still relevant and you can reuse entire personas or some of the information in the personas. If you are moving on to create a completely different product or if there have been major shifts in strategy, then perhaps only a few of the data sources (e.g., those that relate to your company or to the general product space in which you work) may still be relevant.

46.3.5.2 Reusing Your Personas

If you are building a new version of your product, or a new product for the same audience, you might find that many of your personas can be reused. Your personas could be reused by the same team that used them originally, by a new design and development team, or perhaps by a team in some other part of your company, like marketing, sales, or product support.

When you created your personas, you assimilated your data, created persona skeletons, prioritized the skeletons, and built some or all of the skeletons into full personas. When you move on to the next version of your product, you can reevaluate the primary versus secondary classification for each of your original personas. You might decide to demote one of your primary personas and promote one of your secondary personas; this promotion/demotion is especially useful if you are building a new version of the same project but your company has decided to focus on a slightly different user base. Additionally, you can revisit some of the persona skeletons you created but never developed for the first project; it is possible that one of these sketches would be just right for the new project. If so, you have a tremendous head start and can simply build up the sketch into a full persona.

46.3.5.3 Reincarnating Personas

If some of the data in your personas is still relevant, but the personas you originally created are not, you can create "reincarnated" personas by reusing "old" data in new personas. If the products you develop serve users in a specific market segment or industry, you will find many data sources that stay relevant no matter what project you are working on. If the data sources are still relevant, but the particular personas you have created are not, it is important to do some research and find some additional sources.

Once you have collected the appropriate set of data (which will include sources you have already used), you can revisit the processes described in the Conception & Gestation section and reassimilate data points according to the issues you are finding related to your new project.

46.3.5.4 Retiring Your Personas

You might decide that you do not want to reuse or reincarnate your personas or their underlying data at all. There are many reasons to retire personas before moving on to the next project, such as the following:

- The current project is significantly different than the last project.
- The users' goals have changed.
- Your company adopted a new strategy or are targeting a different user base.
- There are significant changes to the environment in which your product will be used, such as new technologies or new competitive products that have "changed the landscape?" (e.g., the advent of streaming media and broadband in the home, or Bluetooth technology for computing).

When you determine that a persona or set of personas is no longer relevant, it is a good idea to *officially* retire the persona(s) before moving on.

Why "officially?" Why not just take down the posters and start working on a new set of personas? Because if you have done your job well, you have made the personas incredibly memorable and all your work has paid off; people in your organization have absorbed various amounts of information about the primary personas and are accustomed to thinking about them. If you try to introduce a new set of personas on top of an old set, you run the risk of confusing your team—which will destroy the clarity that personas are supposed to provide.

You cannot reach into your colleagues' heads and erase everything they know about the personas you have been using, but you have to find a way to help them move past the old personas and let go of the (no longer relevant) information they contain. This can be as simple as an e-mail announcement that the old set of personas is retiring and why. If you are moving on to a totally different product or a new strategy, most of your colleagues would know about the switch and the retirement announcement will make sense to them. Use this as an opportunity to invite feedback from the team on the ways personas helped or did not help them do their jobs; you can use this feedback to tweak your customized persona lifecycle the next time around.

46.3.5.5 Moving on to the Next Persona Effort

Finally, it is worth noting that the activities we recommend at the end of one persona project function to prepare you for the next persona project; regaining control over the personas and evaluating the success of the effort will help you be even more successful in your next effort. The lifetime achievement, reuse, and retirement phase provides an excellent opportunity to touch base with your core team members and with other stakeholders to talk about how things went. As you dive back into Family Planning you will want to predict the new issues you will encounter. This final lifecycle phase is a great time to have a postmortem to talk about what improved, stayed the same, or worsened during or due to your persona effort.

46.4 SUMMARY

Personas can be an invaluable asset to product design and development teams, but they must be created and used with care. The best advice we can give you as you embark on your own persona efforts is to keep in mind the following axioms that are at the heart of the persona lifecycle approach:

- Building personas from assumptions is good; building personas from data is much, much better.
- Personas are a highly memorable, inherently usable communication tool *if* they are communicated well.
- Personas can be initiated by executives or first used as part of a bottom-up, grass roots experiment but eventually need support at all levels of an organization.
- Personas are not a stand-alone UCD process but should be integrated into existing processes and used to augment existing tools.
- Personas can help bring a user-centered focus into even a stubbornly technology-focused organization.
- Effective persona efforts requires organizational introspection and strategic thinking.
- Personas *can* be created fast and show their value quickly, but if you want to get the full value of personas, you will have to commit to a significant investment of time and resources.

In short, the "devil is in the details" when it comes to launching a persona effort within an organization. Perhaps this is the reason that persona efforts are inevitably more work than you think they are going to be. If you can dedicate some time, and can get some help from at least one colleague, the persona lifecycle will enable you to integrate persona creation and use methods into your existing processes. Equally importantly, it will provide you with data-driven, user-focused reasons to change aspects of existing processes that are not working well for the team and are resulting in problematic products.

SIDEBAR 46.7 Personas in the Present—and Looking toward the Future

Kim Goodwin

Vice President and General Manager, Cooper

As for the future of personas, I have heard a number of people say that personas are just the latest fad, and no one will care about them in a few years. It is true that some people are using things they call "personas" just because they are the latest craze, and no doubt the popularity of personas will fade quickly with those people who find that a photo, a name, and a collection of personal tidbits do not accomplish much. People who look to personas to solve all of their problems will also be disappointed. However, those practitioners who take the time to master personas—which are easy to understand but not so easy to develop and use—will find that personas are one tool they will never put down.

In the last few years, Cooper designers have been using personas for more than product definition and interaction design guidance. We find that experience goals (how a persona wants to feel, as opposed to the end goals we usually focus on with personas) are invaluable in guiding the aesthetic aspects of the visual, auditory, and physical design. Does your online banking persona want to feel her money is secure? A lime green background and Comic Sans typeface probably are not the best choices. Does a critically ill person want to be reminded of his condition? No, so perhaps his home healthcare device should not look as if it belongs in a hospital. We have used them for designing business processes, organizations, and training curricula, as well.

Personas have been adopted by certain parts of companies, but not yet by others. In many cases, we see companies that use personas for one product but not others, or who rely heavily on personas to design their websites, but do not yet use them to inform the design of other customer-facing systems. I believe the lack of adoption is not due to a failing of the method, but to a common failing of organizations: silos. The website or product design teams are generally isolated from other parts of a company, so those other groups are unaware of the advances those teams are making. In addition, there is seldom anyone with overall responsibility for a customer's or user's experience with that company. To realize the true potential of their investment in personas, companies will need to look for other opportunities to use them, even outside of electronic systems. For example, a couple of years ago, I spoke with a human resources publication interested in applying employee personas to benefits plans.

There is no question in my mind: personas are here to stay, and we will see them showing up in more and more places. After all, personas are about understanding our fellow human beings, and that will never go out of style.

46.4.1 Areas for Further Investigation

While we are clearly fans of the persona approach, we know that personas are not foolproof. In fact, our own experiences with them have proven to us that personas have their limits—personas are not a panacea and they are not right for every situation or organization. The details of these shortcomings are not well understood at this time, though as noted earlier, some discussion, case studies and research does exist to lead the way (e.g., Blomquist and Arvola 2002; Chapman and Milham 2006; Chapman et al. 2008; Rönkkö et al. 2004). Clearly, personas do not help a development team build better products merely by their presence. As we argue here (and in our books, *The Persona Lifecycle*, 2006; *The Essential Persona Lifecycle*, 2010), personas must be assimilated by the product team and explicitly used in design and development activities. But, what uses of personas have the most value? What characteristics of personas are the most critical? We have provided some process and guidance to help practitioners employ the persona approach successfully, but at present, this is based more on practice and experience than science. In addition to the research and case studies cited previously, we need more rigorous evaluations of the method to better understand its benefits and limitations. Some reasonable suggested directions for research are provided by Chapman and Milham (2006) and Miaskiewicz and Kozar (2006).

The process we recommend for persona creation, while accomplishable and generally effective, is not particularly precise. Given the same data as input, different groups of people will likely create different personas. Many practitioners (e.g., Miaskiewicz, Sumner, and Kozar 2008; McGinn and Kotamraju 2008; Mulder and Yaar 2007; Sinha 2003; including us) have proposed quantitative analysis methods as the basis for persona creation to enhance repeatability and accuracy. And while this is certainly a reasonable move in the right direction, it is the thoughtful application of qualitative data that helps make a persona into a persona. Thus, we do not believe a quantitative approach could ever appropriately solve the problem alone. For similar reasons, the notion that personas can be abstracted into reusable elemental characteristics or directly repurposed across multiple product lines seems imprudent. Again, more investigation along these lines is needed.

Finally, there are some cases where development teams have attempted to create representations of things other than people (e.g., organizational archetypes—a persona of a company) to be used, like personas, in the development of products or services. We believe that such representations, while potentially useful, do not have the power and impact that representations of people have. They are not as memorable or provocative as personas—we relate to personas in ways that we cannot relate to other abstractions. Thus, we suggest this as another interesting line of research.

47 Prototyping Tools and Techniques

Michel Beaudouin-Lafon and Wendy E. Mackay

CONTENTS

47.1 INTRODUCTION

“A good design is better than you think.”

Heftman
as cited in Raskin 2000

Design is about making choices. In many fields that require creativity and engineering skill, such as architecture and automobile design, prototypes both inform the design process and help designers select the best solution.

This chapter describes tools and techniques for using prototypes to design interactive systems. The goal is to illustrate how they can help designers generate and share new ideas, get feedback from users or customers, choose among design alternatives, and articulate reasons for their final choices.

We begin with our definition of a prototype and then discuss prototypes as design artifacts, introducing four dimensions for analyzing them. We then discuss the role of prototyping within the design process, in particular the concept of a design space and how it is expanded and contracted by generating and selecting design ideas. The following sections describe specific prototyping approaches: rapid prototyping, both offline and online, for early stages of design, and iterative and evolutionary prototyping, which use online development tools. Finally, we address the specific issue of prototyping mixed with reality and pervasive computing systems.

47.1.1 What Is a Prototype?

We define a *prototype* as a concrete representation of part or all of an interactive system. A prototype is a tangible artifact, not an abstract description that requires interpretation. Designers, as well as managers, developers, customers, and end users, can use these artifacts to envision and to reflect upon the final system.

Note that other fields may define prototype differently. For example, an architectural prototype is a scaled-down model of the final building. This is not possible for prototypes of interactive systems: The designer may limit the amount of information the prototype can handle, but the actual user interface must be presented at full scale. Thus, a prototype interface to a database may handle only a small subset of the final database but must still present a full-size display and interaction techniques. Fashion designers create another type of prototype, a full-scale, one-of-a-kind model, such as a handmade dress sample. Although in haute couture this prototype may also be the final product, the ready-to-wear market requires additional design phases to create a design that can be mass-produced in a range of sizes. Some interactive system prototypes begin as one-of-a-kind models that are then distributed widely (since the cost of duplicating software is so low). However, most successful software prototypes evolve into the final product and then continue to evolve as new versions of the software are released.

Hardware and software engineers often create prototypes to study the feasibility of a technical process. They conduct systematic, scientific evaluations with respect to predefined benchmarks and, by systematically varying parameters, fine tune the system. Designers in creative fields, such as typography or graphic design, create prototypes to express ideas and reflect on them. This approach is intuitive, oriented more to discovery and generation of new ideas than to evaluation of existing ideas.

HCI is a multidisciplinary field that combines elements of science, engineering, and design (Mackay and Fayard 1997; Dijkstra-Erikson, Mackay, and Arnowitz 2001). Prototyping is primarily a design activity, although we use software engineering to ensure that software prototypes evolve into technically sound working systems and we use scientific methods to study the effectiveness of particular designs.

47.2 PROTOTYPES AS DESIGN ARTIFACTS

We can look at prototypes as both concrete artifacts in their own right or as important components of the design process. When viewed as artifacts, successful prototypes have several characteristics: They support creativity, helping the developer to capture and generate ideas, facilitate the exploration of a design space, and uncover relevant information about users and their work practices. They encourage communication, helping designers, engineers, managers, software developers, customers, and users to discuss options and interact with each other. They also permit early evaluation since they can be tested in various ways, including traditional usability studies and informal user feedback, throughout the design process.

We can analyze prototypes and prototyping techniques along the following four dimensions:

- *Representation* describes the form of the prototype, such as sets of paper sketches or computer simulations.
- *Precision* describes the level of detail at which the prototype is to be evaluated, such as informal and rough or highly polished.
- *Interactivity* describes the extent to which the user can actually interact with the prototype, such as “watch only” or fully interactive.
- *Evolution* describes the expected lifecycle of the prototype, such as throwaway or iterative.

47.2.1 Representation

Prototypes serve different purposes and thus take different forms. A series of quick sketches on paper can be considered a prototype; so can a detailed computer simulation. Both are useful; both help the designer in different ways. We distinguish between two basic forms of representation: offline and online.

Offline prototypes (also called “paper prototypes”) do not require a computer. They include paper sketches, illustrated storyboards, cardboard mock-ups, and videos. The most salient characteristics of offline prototypes (of interactive systems) is that they are created quickly, usually in the early stages of design, and they are usually thrown away when they have served their purposes.

Online prototypes (also called “software prototypes”) run on a computer. They include computer animations, interactive video presentations, programs written with scripting languages, and applications developed with interface builders. The cost of producing online prototypes is usually higher, and may require skilled programmers to implement advanced interaction and visualization techniques or to meet tight performance constraints. Software prototypes are usually more effective in the later stages of design, when the basic design strategy has been decided.

In our experience, programmers often argue in favor of software prototypes even at the earliest stages of design. Because they are already familiar with a programming language, these programmers believe it will be faster and more useful to write code than to “waste time” creating paper prototypes. In 20 years of prototyping, in both research and industrial settings, we have yet to find a situation in which this is true.

First, offline prototypes are very inexpensive and quick. These permit a very rapid iteration cycle and help prevent the designer from becoming overly attached to the first possible solution. Offline prototypes make it easier to explore the design space, examining a variety of design alternatives and choosing the most effective solution. Online prototypes introduce an intermediary between the idea and the implementation, slowing down the design cycle.

Second, offline prototypes are less likely to constrain how the designer thinks. Every programming language or development environment imposes constraints on the interface, limiting creativity and restricting the number of ideas considered. If a particular tool makes it easy to create scrollbars and pull-down menus and difficult to create a zoomable interface, the designer is likely to limit the interface accordingly. Considering a wider range of alternatives, even if the developer ends up using a standard set of interface widgets, usually results in a more effective design.

Finally, and perhaps most importantly, offline prototypes can be created by a wide range of people, not just programmers. Thus all types of designers, technical or otherwise, as well as users, managers, and other interested parties, can all contribute on an equal basis. Unlike programming software, modifying a storyboard or cardboard mockup requires no particular technical skill. Collaborating on paper prototypes not only increases participation in the design process, but also improves communication among team members and increases the likelihood that the final design solution will be well accepted.

Although we believe strongly in offline prototypes, they are not a panacea. In some situations, they are insufficient to evaluate fully a particular design idea. For example, interfaces requiring rapid feedback to users or complex, dynamic visualizations usually require software prototypes. However, particularly when using video and Wizard of Oz techniques, offline prototypes can be used to create very sophisticated representations of the system.

Prototyping is an iterative process and all prototypes provide information about some aspects while ignoring others. The designer must consider the purpose of the prototype (Houde and Hill 1997) at each stage of the design process and choose the representation that is best suited to the current design question.

47.2.2 Precision

Prototypes are explicit representations that help designers, engineers and users reason about the system being built. By their nature, prototypes require details. A verbal description such as "the user opens the file" or "the system displays the results" provides no information about what the user actually does or sees. Prototypes force designers to show the interaction: just how does the user open the file and what are the specific results that appear on the screen?

Precision refers to the relevance of details with respect to the purpose of the prototype.* For example, when sketching a dialog box, the designer specifies its size, the positions of each field and the titles of each label. However not all these details are relevant to the goal of the prototype: it may be necessary to show where the labels are, but too early to choose the text. The designer can convey this by writing nonsense words or drawing squiggles, which shows the need for labels without specifying their actual content.

Although it may seem contradictory, a detailed representation need not be precise. This is an important characteristic of prototypes: those parts of the prototype that are not precise are those open for future discussion or for exploration of the design space. Yet they need to be incarnated in some form so the prototype can be evaluated and iterated.

The level of precision usually increases as successive prototypes are developed and more and more details are set. The forms of the prototypes reflect their level of precision: sketches tend not to be precise, whereas computer simulations are usually very precise. Graphic designers often prefer using hand sketches for early prototypes because the drawing style can directly reflect what is precise and what is not: the wiggly shape of an object or a squiggle that represents a label are directly perceived as imprecise. This is more difficult to achieve with an online drawing tool or a user interface builder.

The form of the prototype must be adapted to the desired level of precision. Precision defines the tension between what the prototype states (relevant details) and what the prototype leaves open (irrelevant details). What the prototype states is subject to evaluation; what the prototype leaves open is subject to more discussion and design space exploration.

47.2.3 Interactivity

An important characteristic of HCI systems is that they are interactive: users both respond to them and act upon them. Unfortunately, designing effective interaction is difficult: many interactive systems (including many websites) have a good look but a poor feel. HCI designers can draw from a long tradition in visual design for the former, but have relatively little experience with how interactive software systems should be used: personal computers have only been commonplace for a couple decades. Another problem is that the quality of interaction is tightly linked to the end users and a deep understanding of their work practices: a word processor designed for a professional typographer requires a different interaction design than one designed for secretaries, even though ostensibly they serve similar purposes. Designers must take the context of use into account when designing the details of the interaction (Beaudouin-Lafon 2004).

A critical role for an interactive system prototype is to illustrate how the user will interact with the system. While this may seem more natural with online prototypes, in fact it is often easier to explore different interaction strategies with offline prototypes. Note that interactivity and precision are orthogonal dimensions. One can create an imprecise prototype that is highly interactive, such as a series of paper screen images in which one person acts as the user and the other

* Note that the terms low-fidelity and high-fidelity prototypes are often used in the literature. We prefer the term precision because it refers to the content of the prototype itself, not its relationship to the final, as-yet-undefined system.

plays the system. One may create a very precise but noninteractive prototype, such as a detailed animation that shows feedback from a specific action by a user.

Prototypes can support interaction in various ways. For off-line prototypes, one person (often with help from others) plays the role of the interactive system, presenting information and responding to the actions of another person playing the role of the user. For online prototypes, parts of the software are implemented, while others are played by a person. (This approach, called the "Wizard of Oz" after the character in the 1939 movie of the same name, is explained in a later section.) The key is that the prototype feels interactive to the user.

Prototypes can support different levels of interaction. Fixed prototypes, such as video clips or precomputed animations, are noninteractive: the user cannot interact, or pretend to interact, with it. Fixed prototypes are often used to illustrate or test scenarios. Fixed-path prototypes support limited interaction. The extreme case is a fixed prototype in which each step is triggered by a prespecified user action. For example, the person controlling the prototype might present the user with a screen containing a menu. When the user points to the desired item, he or she presents the corresponding screen showing a dialogue box. When the user points to the word "OK," he or she presents the screen that shows the effect of the command. Even though the position of the click is irrelevant (it is used as a trigger), the person playing the role of the user gets the feel of the interaction. Of course, this type of prototype can be much more sophisticated, with multiple options at each step. Fixed-path prototypes are very effective with scenarios and can be used for horizontal and task-based prototypes (see section on prototyping strategies below).

Open prototypes support large sets of interactions. Such prototypes work like the real system, with some limitations. They usually cover only part of the system (see vertical prototypes) and often have limited error handling or reduced performance relative to that of the final system.

Prototypes may thus illustrate or test different levels of interactivity. Fixed prototypes simply illustrate what the interaction might look like. Fixed-path prototypes provide designers and users with the experience of what the interaction might feel like, but only in prespecified situations. Open prototypes allow designers and users to explore a wide range of possible forms of interaction with the system.

47.2.4 Evolution

Prototypes have different life spans: Rapid prototypes are created for a specific purpose and then thrown away, iterative prototypes evolve, either to work out some details (increasing their precision) or to explore various alternatives, and evolutionary prototypes are designed to become part of the final system.

Rapid prototypes are especially important in the early stages of design. They must be inexpensive and easy to produce, since the goal is to quickly explore a wide variety of possible types of interaction and then throw them away. Note that rapid prototypes may be offline or online. Creating precise software prototypes, even if they must be reimplemented in the final version of the system, is important for detecting and fixing interaction problems. A later section presents specific prototyping techniques, both offline and online.

Iterative prototypes are developed as a reflection of a design in progress, with the explicit goal of evolving through several design iterations. Designing prototypes that support evolution is sometimes difficult. There is a tension between evolving toward the final solution and exploring an unexpected design direction, which may be adopted or thrown away completely. Each iteration should inform some aspect of the design. Some iterations explore different variations of the same theme. Others may systematically increase precision, working out the finer details of the interaction. A later section describes tools and techniques for creating iterative prototypes.

Evolutionary prototypes are a special case of iterative prototypes in which the prototype evolves into part or all of the final system (Figure 47.1). Obviously, this only applies to software prototypes. Extreme Programming (Beck 2000) advocates this approach, tightly coupling design and implementation

and building the system through constant evolution of its components. Evolutionary prototypes require more planning and practice than the approaches above because the prototypes are both representations of the final system and the final system itself, making it more difficult to explore alternative designs. We advocate a combined approach, beginning with rapid prototypes and then using iterative or evolutionary prototypes according to the needs of the project. A later section describes how to create iterative and evolutionary prototypes, using appropriate development tools.

47.3 PROTOTYPES AND THE DESIGN PROCESS

In the previous section, we looked at prototypes as artifacts, that is, the results of a design process. Prototypes can also be seen as artifacts for design, as an integral part of the design process. Prototyping helps designers think: prototypes are the tools they use to solve design problems. In this section, we focus on prototyping as a process and its relationship to the overall design process.

47.3.1 User-Centered Design

The field of HCI is both user centered (Norman and Draper 1986) and iterative. User-centered design places the user at the center of the design process, from the initial analysis of user requirements to testing and evaluation. Prototypes support this goal by allowing users to see and experience the final system long before it is built. Designers can identify functional requirements, usability problems, and performance issues early and improve the design accordingly.

Iterative design involves multiple design-implement-test loops,* enabling the designer to generate different ideas and successively improve upon them. Prototypes support this goal by allowing designers to evaluate concrete representations of design ideas and select the best.

Prototypes reveal the strengths as well as the weaknesses of a design. Unlike pure ideas, abstract models, or other representations, they can be contextualized to help understand how the real system would be used in a real setting. Because prototypes are concrete and detailed, designers can explore different real-world scenarios and users can evaluate them with respect to their current needs. Prototypes can be compared directly with other, existing systems, and designers can learn about the context of use and the work practices of the end users. Prototypes can help designers reanalyze the user's needs during the design process: not abstractly, as with traditional requirements analysis, but in the context of the system being built.

47.3.2 Participatory Design

Participatory design is a form of user-centered design that actively involves the user in all phases of the design process (see Greenbaum and Kyng 1991). Users are not simply consulted at the beginning and called in to evaluate the system at the end; they are treated as partners throughout. This early and active involvement of users helps designers avoid unpromising design paths and develop a deeper understanding of the actual design problem. Obtaining user feedback at each phase of the process also changes the nature of the final evaluation, which is used to fine tune the interface rather than discover major usability problems.

A common misconception about participatory design is that designers are expected to abdicate their responsibilities as designers, leaving the design to the end user. In fact, the goal is for designers and users to work together, each contributing their strengths to clarify the design problem as well as explore design solutions. Designers must understand what users can and cannot contribute. Usually, users are best at understanding the context in which the system will be used and subtle aspects of the problems that must be solved. Innovative ideas can come from both users and designers, but the designer is responsible for considering a wide range of options that might not be known to the user and balancing the trade-offs among them.

Because prototypes are shared, concrete artifacts, they serve as an effective medium for communication within the design team as well as with users. We have found that collaborating on prototype design is an effective way to involve users in participatory design. Prototypes help users articulate their needs and reflect on the efficacy of design solutions proposed by designers.

47.3.3 Exploring the Design Space

Design is not a natural science: the goal is not to describe and understand existing phenomena but to create something new. Of course, designers benefit from scientific research findings, and they may use scientific methods to evaluate interactive systems. However, designers also require specific techniques for generating new ideas and balancing complex sets of trade-offs to help them develop and refine design ideas.

Designers from fields such as architecture and graphic design have developed the concept of a design space, which constrains design possibilities along some dimensions, while leaving others open for creative exploration. Ideas for the design space come from many sources: existing systems, other designs, other designers, external inspiration, and accidents that prompt new ideas. Designers are responsible for creating a design space specific to a particular design problem. They explore this design space, expanding and contracting it as they add and eliminate ideas. The process is iterative: more cyclic than reductionist. That is, the designer does not begin with a rough idea and successively add more details that are precise until the final solution is reached. Instead, he or she begins with a design problem, which imposes a set of constraints, and then generates a set of ideas to form the initial design space. He or she then explores this design space, preferably with the user, and selects a particular design direction to pursue. This closes

* Software engineers refer to this as the Spiral model (Boehm 1988).

off part of the design space, but opens up new dimensions that can be explored. The designer generates additional ideas along these dimensions, explores the expanded design space, and then makes new design choices. Design principles (e.g., Beaudouin-Lafon and Mackay 2000) help this process by guiding it both in the exploration and choice phases. The process continues, in a cyclic expansion and contraction of the design space, until a satisfying solution is reached or time has run out.

All designers work with constraints: not just limited budgets and programming resources, but also design constraints. These are not necessarily bad: one cannot be creative along all dimensions at once. However, some constraints are unnecessary, derived from poor framing of the original design problem. If we consider a design space as a set of ideas and a set of constraints, the designer has two options. She can modify ideas within the specified constraints or modify the constraints to enable new sets of ideas. Unlike traditional engineering, which treats the design problem as a given, designers are encouraged to challenge, and if necessary, change the initial design problem. If she reaches an impasse, the designer can either generate new ideas or redefine the problem (and thus change the constraints). Some of the most effective design solutions derive from a more careful understanding and reframing of the design brief.

Note that all members of the design team, including users, may contribute ideas to the design space and help select design directions from within it. However, it is essential that these two activities are kept separate. Expanding the design space requires creativity and openness to new ideas. During this phase, everyone should avoid criticizing ideas and concentrate on generating as many as possible. Clever ideas, half-finished ideas, silly ideas, and impractical ideas all contribute to the richness of the design space and improve the quality of the final solution. In contrast, contracting the design space requires critical evaluation of ideas. During this phase, everyone should consider the constraints and weigh the trade-offs. Each major design decision must eliminate part of the design space: rejecting ideas is necessary in order to experiment and refine others and make progress in the design process. Choosing a particular design direction should spark new sets of ideas, and those new ideas are likely to pose new design problems. In summary, exploring a design space is the process of moving back and forth between creativity and choice.

Prototypes aid designers in both aspects of working with a design space: generating concrete representations of new ideas and clarifying specific design directions. The next two sections describe techniques that have proven most useful in our own prototyping work, both for research and product development.

47.3.4 Expanding the Design Space: Generating Ideas

The most well-known idea generation technique is brainstorming, introduced by Osborn (1957). His goal was to create synergy within the members of a group: ideas suggested by one participant would spark ideas in other participants. Subsequent studies (Collaros and Anderson 1969; Diehl and Stroebe 1987) challenged the effectiveness of group brainstorming, finding that aggregates of individuals could produce the same number of ideas as groups. They found certain effects, such as production blocking, free riding, and evaluation apprehension, were sufficient to outweigh the benefits of synergy in brainstorming groups. Since then, many researchers have explored different strategies for addressing these limitations. For our purpose, the quantity of ideas is not the only important measure: the relationships among members of the group are also important. As de Vreede et al. (2000) pointed out, one should also consider elaboration of ideas, as group members react to each other's ideas.

We have found that brainstorming, including a number of variants, is an important group-building exercise for participatory design. Of course, designers may brainstorm ideas by themselves. However, brainstorming in a group is more enjoyable and, if it is a recurring part of the design process, plays an important role in helping group members share and develop ideas together.

The simplest form of brainstorming involves a small group of people. The goal is to generate as many ideas as possible on a prespecified topic: quantity, not quality, is important. Brainstorming sessions have two phases: the first for generating ideas and the second for reflecting upon them. The initial phase should last no more than an hour. One person should moderate the session, keeping time, ensuring that everyone participates, and preventing people from critiquing each other's ideas. Discussion should be limited to clarifying the meaning of a particular idea. A second person records every idea, usually on a flipchart or transparency on an overhead projector. After a short break, participants are asked to reread all the ideas and each person marks their three favorite ideas.

One variation is designed to ensure that everyone contributes, not just those who are verbally dominant. Participants write their ideas on individual cards or Post-it notes for a prespecified period. The moderator then reads each idea aloud. Authors are encouraged to elaborate (but not justify) their ideas, which are then posted on a whiteboard or flipchart. Group members may continue to generate new ideas, inspired by the others they hear.

We use a variant of brainstorming, called "video brainstorming" (Mackay 2000), as a very fast technique for prototyping interaction: instead of simply writing or drawing their ideas, participants act them out in front of a video camera (Figure 47.2). The goal is the same as other brainstorming exercises, that is, to create as many new ideas as possible, without critiquing them. However, the use of video, combined with paper or cardboard mock-ups, encourages participants to experience the details of the interaction and to understand each idea from the perspective of the user, while preserving a tangible record of the idea.

Each video brainstorming idea should take two to five minutes to generate and capture, allowing participants to simulate a wide variety of ideas very quickly. The resulting video clips

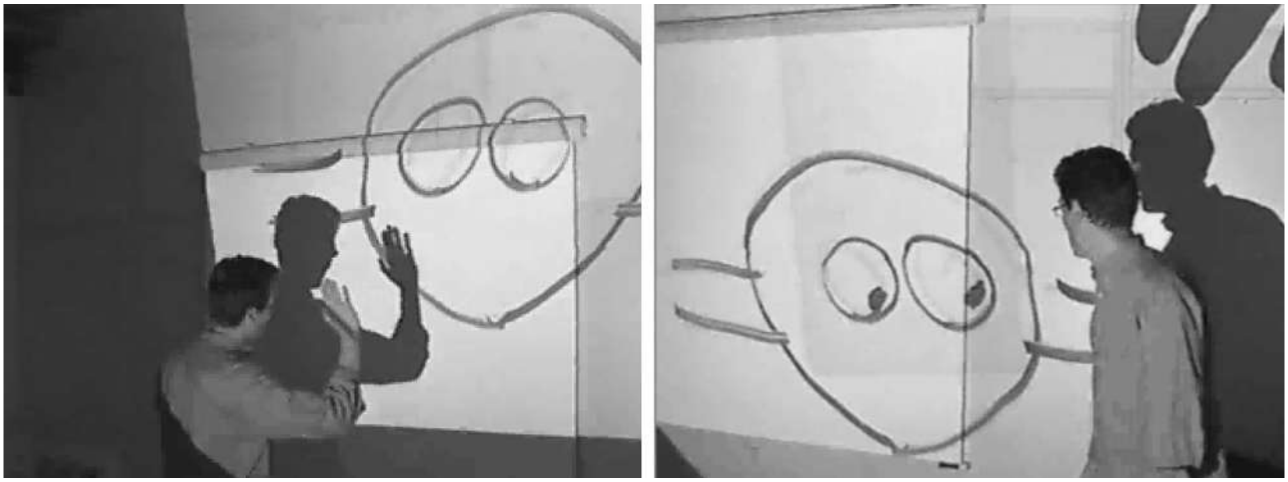

FIGURE 47.2 Video brainstorming an animated character. One participant uses an overhead projector to project an image on the wall and responds to the actions of a second participant, who plays the role of the user. Here, the animated character, a very rough sketch on a transparency, reponds when the user waves and moves its eyes to follow the user.

provide illustrations of each idea that are easier to understand (and remember) than hand-written notes. (We find that raw notes from brainstorming sessions are not very useful after a few weeks because the participants no longer remember the context in which the ideas were created, whereas video brainstorming clips are useful years later.)

Video brainstorming requires thinking more deeply about each idea than in traditional oral brainstorming. It is possible to stay vague and general when describing an interaction in words or even with a sketch, but acting out the interaction in front of the camera forces the author of the idea (and the other participants) to consider seriously the details of how a real user would actually interact with the idea. Video brainstorming also encourages designers and users to think about new ideas in the context in which they will be used. We also find that video clips from a video brainstorming session, even though rough, are much easier for the design team to interpret than written ideas from a standard brainstorming session.

We generally run a standard brainstorming session, either orally or with cards, prior to a video brainstorming session, in order to maximize the number of ideas to be explored. Participants then take their favorite ideas from the previous session and develop them further as video brainstorms. Each person is asked to direct at least two ideas, incorporating the hands or voices of other members of the group. We find that, unlike standard brainstorming, video brainstorming encourages even the quietest team members to participate.

47.3.5 Contracting the Design Space: Selecting Alternatives

After expanding the design space by creating new ideas, designers must stop and reflect upon the choices available to them. After exploring the design space, designers must evaluate their options and make concrete design decisions: choosing some ideas, specifically rejecting others, and leaving other aspects of the design open to further idea generation activities. Rejecting good, potentially effective ideas is difficult, but necessary to make progress.

Prototypes often make it easier to evaluate design ideas from the user's perspective. They provide concrete representations that can be compared. Many of the evaluation techniques described elsewhere in this book could be applied to prototypes, to help focus the design space. The simplest situation is when the designer must choose among several discrete, independent options. Running a simple experiment, using techniques borrowed from psychology, allows the designer to compare how users respond to each of the alternatives. The designer builds a prototype, with either fully implemented or simulated versions of each option. The next step is to construct tasks or activities that are typical of how the system would be used, and ask people from the user population to try each of the options under controlled conditions. It is important to keep everything the same, except for the options being tested.

Designers should base their evaluations on both quantitative measures, such as speed or error rate, and qualitative measures, such as the user's subjective impressions of each option. Ideally, of course, one design alternative will be clearly faster, prone to fewer errors, and preferred by the majority of users. More often, the results are ambiguous, and the designer must consider other factors when making the design choice. (Interestingly, running small experiments often highlights other design problems and may help the designer reformulate the design problem or change the design space.)

The more difficult (and common) situation is when the designer faces a complex, interacting set of design alternatives, in which each design decision affects a number of others. Designers can use heuristic evaluation techniques, which rely on our understanding of human cognition, memory, and sensory-perception. They can also evaluate their designs with respect to ergonomic criteria or design principles (Beaudouin-Lafon and Mackay 2000).

Another strategy is to create one or more scenarios that illustrate how the combined set of features will be used in a realistic setting. The scenario must identify who is involved, where the activities take place, and what the user does over a specified period. Good scenarios involve more than a string of independent tasks; they should incorporate real-world activities, including common or repeated tasks, successful activities, breakdowns, and errors, with both typical and unusual events. The designer then creates a prototype that simulates or implements the aspects of the system necessary to illustrate each set of design alternatives. Such prototypes can be tested by asking users to walk through the same scenario several times, once for each design alternative. As with experiments and usability studies, designers can record both quantitative and qualitative data, depending on the level of the prototypes being tested.

The previous section described an idea-generation technique called "video brainstorming," which allows designers to generate a variety of ideas about how to interact with the future system. We call the corresponding technique for focusing in on a design "video prototyping." Video prototyping can incorporate any of the rapid-prototyping techniques (offline or online) described in a later section. Video prototypes are quick to build, force designers to consider the details of how users will react to the design in the context in which it will be used, and provide an inexpensive method of comparing complex sets of design decisions.

To an outside observer, video brainstorming and video prototyping techniques look very similar: both involve small design groups working together, creating rapid prototypes, and interacting with them in front of a video camera. Both result in video illustrations that make abstract ideas concrete and help team members communicate with each other. The critical difference is that video brainstorming expands the design space, by creating a number of unconnected collections of individual ideas, whereas video prototyping contracts the design space, by showing how a specific collection of design choices work together in a single design proposal.

47.3.6 Prototyping Strategies

Designers must decide what role prototypes should play with respect to the final system and in which order to create different aspects of the prototype. The next section presents four strategies: horizontal, vertical, task oriented, and scenario based, which focus on different design concerns. These strategies can use any of the prototyping techniques covered in the following sections.

47.3.6.1 Horizontal Prototypes

The purpose of a horizontal prototype is to develop one entire layer of the design at the same time. This type of prototyping is most common with large software development teams, where designers with different skill sets address different layers of the software architecture. Horizontal prototypes of the user interface are useful to get an overall picture of the system from the user's perspective and address issues such as consistency (similar functions are accessible through similar user commands), coverage (all required functions are supported), and redundancy (the same function is/is not accessible through different user commands).

User interface horizontal prototypes can begin with rapid prototypes and progress through to working code. Software prototypes can be built with an interface builder without creating any of the underlying functionality, making it possible to test how the user will interact with the user interface without worrying about how the rest of the architecture works. However, some level of scaffolding or simulation of the rest of the application is often necessary; otherwise, the prototype cannot be evaluated properly. Consequently, software horizontal prototypes tend to be evolutionary, that is, they are progressively transformed into the final system.

47.3.6.2 Vertical Prototypes

The purpose of a vertical prototype is to ensure that the designer can implement the full, working system, from the user interface layer down to the underlying system layer. Vertical prototypes are often built to assess the feasibility of a feature described in a horizontal, task-oriented, or scenario-based prototype. For example, when we developed the notion of magnetic guidelines in the CPN2000 system to facilitate the alignment of graphical objects (Beaudouin-Lafon and Mackay 2000, Beaudouin-Lafon and Lassen 2000), we implemented a vertical prototype to test not only the interaction technique but also the layout algorithm and the performance. We knew that we could only include the particular interaction technique if we could implement a sufficiently fast response.

Vertical prototypes are generally high precision software prototypes because their goals are to validate ideas at the system level. They are often thrown away because they are generally created early in the project, before the overall architecture has been decided, and they focus on only one design question. For example, a vertical prototype of a spelling checker for a text editor does not require text-editing functions to be implemented and tested. However, the final version will need to be integrated into the rest of the system, which may involve considerable architectural or interface changes.

47.3.6.3 Task-Oriented Prototypes

Many user interface designers begin with a task analysis to identify the individual tasks that the user must accomplish with the system. Each task requires a corresponding set of functionality from the system. Task-based prototypes are organized as a series of tasks, which allows both designers and users to test each task independently, systematically working through the entire system.

Task-oriented prototypes include only the functions necessary to implement the specified set of tasks. They combine the breadth of horizontal prototypes, to cover the functions required by those tasks, with the depth of vertical prototypes, enabling detailed analysis of how the tasks can be supported. Depending on the goal of the prototype, both offline and online representations can be used for task-oriented prototypes.

47.3.6.4 Scenario-Based Prototypes

Scenario-based prototypes are similar to task-oriented ones, except that they do not stress individual, independent tasks, but rather follow a more realistic scenario of how the system would be used in a real-world setting. Scenarios are stories that describe a sequence of events and how the user reacts. A good scenario includes both common and unusual situations, and should explore patterns of activity over time. Bødker (1999) developed a checklist to ensure that no important issues have been left out.

We find it useful to begin with anecdotes derived from observations of our interviews with real users. Ideally, some of those users should participate in the creation of specific use and other users should critique them based on how realistic they are. Use scenarios are then turned into design scenarios, in which the same situations are described but with the functionality of the proposed system. Design scenarios are used, among other things, to create scenario-based video prototypes or software prototypes. Like task-based prototypes, the developer needs to write only the software necessary to illustrate the components of the design scenario. The goal is to create a situation in which the user can experience what the system would be like in a realistic use context, even if it addresses only a subset of the planned functionality.

The following section describes a variety of rapid prototyping techniques that can be used in any of these four prototyping strategies. We begin with offline rapid prototyping techniques, followed by online prototyping techniques.

47.4 RAPID PROTOTYPING

The goal of rapid prototyping is to develop prototypes very quickly, in a fraction of the time it would take to develop a working system. By shortening the prototype-evaluation cycle, the design team can evaluate more alternatives and iterate the design several times, improving the likelihood of finding a solution that successfully meets the user's needs. Rapid prototypes also serve to cut off unpromising design directions, saving time, and money. It is far easier to reject an idea based on a rapid prototype than a more fully developed one, and one reduces the chance of spending a great deal of time and effort on a design that ultimately does not work.

How rapid is rapid depends on the context of the particular project and the stage in the design process. Early prototypes, such as sketches, can be created in a few minutes. Later in the design cycle, a prototype produced in less than a week may still be considered rapid if the final system is expected to take months or years to build. Precision, interactivity, and evolution all affect the time it takes to create a prototype. Not surprisingly, a precise and interactive prototype takes more time to build than an imprecise or fixed one.

The techniques presented in this section are organized from most rapid to least rapid, according to the representation dimension previously introduced. Offline techniques are generally more rapid than online techniques. However, creating successive iterations of an online prototype may end up being faster than creating new offline prototypes.

47.4.1 Offline Rapid Prototyping Techniques

Offline prototyping techniques range from simple to very elaborate. Because they do not involve software, they are usually considered a tool for thinking through the design issues, to be thrown away when they are no longer needed. This section describes simple paper and pencil sketches, three-dimensional mock-ups, Wizard of Oz simulations, and video prototypes.

47.4.1.1 Paper and Pencil

The fastest form of prototyping involves paper, transparencies and Post-it notes to represent aspects of an interactive system (e.g., Muller 1991). By playing the roles of both the user and the system, designers can get a quick idea of a wide variety of different layout and interaction alternatives, in a very short period of time (Rettig 1994; Snyder 2003).

Designers can create a variety of low-cost special effects. For example, a tiny triangle drawn at the end of a long strip cut from an overhead transparency makes a handy mouse pointer, which can be moved by a colleague in response to the user's actions. Post-it notes, with prepared lists, can provide pop-up menus. An overhead projector pointed at a whiteboard makes it easy to project transparencies (hand drawn or preprinted, overlaid on each other as necessary) to create an interactive display on the wall. The user can interact by pointing (Figure 47.3) or drawing on the whiteboard. One or more people can watch the user and move the transparencies in response to her actions. Everyone in the room gets an immediate impression of how the eventual interface might look and feel.

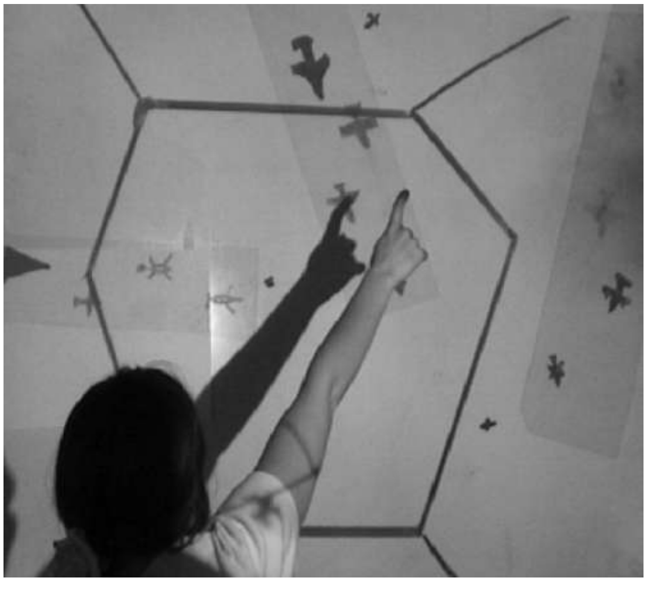

FIGURE 47.3 Hand-drawn transparencies can be projected onto a wall, creating an interface a user can respond to.

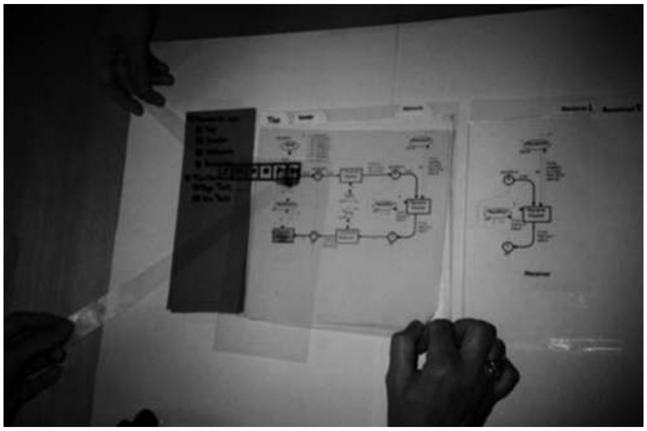

FIGURE 47.4 Several people work together to simulate interacting with this paper prototype. One person moves a transparency with a mouse pointer while another moves the diagram accordingly.

Note that most paper prototypes begin with quick sketches on paper, then progress to more carefully drawn screen images made with a computer (Figure 47.4). In the early stages, the goal is to generate a wide range of ideas and expand the design space, not to determine the final solution. Paper and pencil prototypes are an excellent starting point for horizontal, task-based, and scenario-based prototyping strategies.

47.4.1.2 Mock-Ups

Architects use mock-ups or scaled prototypes to provide three-dimensional illustrations of future buildings. Mock-ups are also useful for interactive system designers, helping them move beyond two-dimensional images drawn on paper or transparencies (see Bødker et al. 1988). Generally made of cardboard, foamcore, or other found materials (Frishberg 2006), mock-ups are physical prototypes of the new system. Figure 47.5 shows an example of a handheld mock-up showing the interface to a new handheld device. The mock-up provides a deeper understanding of how the interaction will work in real-world situations than a set of screen images.

Mock-ups allow the designer to concentrate on the physical design of the device, such as the position of buttons or the screen. The designer can also create several mock-ups and compare input or output options, such as buttons versus trackballs. Designers and users should run through different scenarios, identifying potential problems with the interface or generating ideas for new functionality. Mock-ups can also help the designer envision how an interactive system will be incorporated into a physical space (Figure 47.6).

47.4.1.3 Wizard of Oz

Sometimes it is useful to give users the impression that they are working with a real system, even before it exists. Kelley (1983) dubbed this technique the *Wizard of Oz*, based on the scene in the 1939 movie of the same name. The heroine, Dorothy, and her companions ask the mysterious Wizard of Oz for help. When they enter the room, they see an enormous green human head breathing smoke and speaking with a deep, impressive voice. When they return later, they again see the Wizard. This time, Dorothy's small dog pulls back a curtain, revealing a frail old man pulling levers and making the mechanical Wizard of Oz speak. They realize that the impressive being before them is not a wizard at all, but simply an interactive illusion created by the old man.

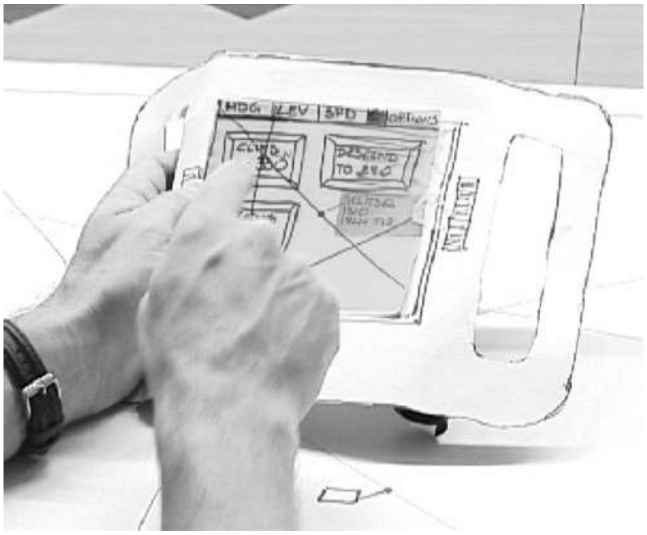

FIGURE 47.5 Mock-up of a hand-held display with carrying handle.

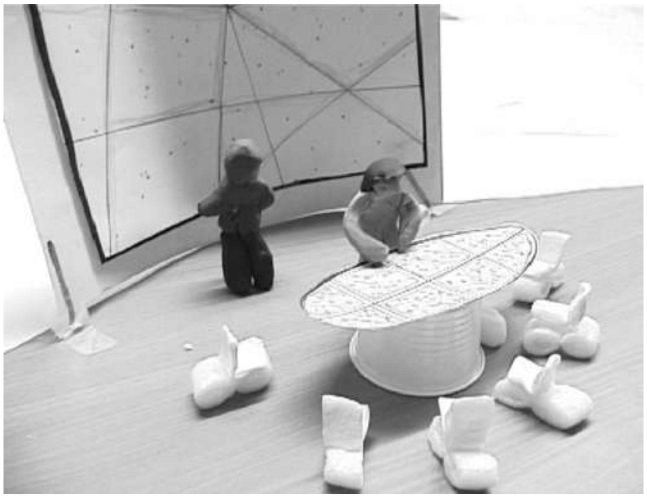

FIGURE 47.6 Scaled mock-up of an air traffic control table, connected to a wall display.

The software version of the Wizard of Oz operates on the same principle. A user sits at a screen and interacts with what appears to be a working program. Hidden elsewhere, the software designer (the Wizard) watches what the user does and, by responding to different user actions, creates the illusion of a working software program. In some cases, the user is unaware that a person, rather than a computer, is operating the system.

The Wizard of Oz technique lets users interact with partially functional computer systems. Whenever they encounter

something that has not been implemented (or there is a bug), a human developer who is watching the interaction overrides the prototype system and plays the role destined to eventually be played by the computer. A combination of video and software can work well, depending upon what needs to be simulated.

The Wizard of Oz technique was initially used to develop natural language interfaces (e.g., Chapanis 1982; Good et al. 1984). Since then, the technique has been used in a wide variety of situations, particularly those in which rapid responses from users are not critical. Wizard of Oz simulations may consist of paper prototypes, fully implemented systems, and everything in between.

47.4.1.4 Video Prototyping

Video prototypes (Mackay 1988) use video to illustrate how users will interact with the new system. As explained in an earlier section, they differ from video brainstorming in that the goal is to refine a single design, not generate new ideas. Video prototypes may build upon paper and pencil prototypes and cardboard mock-ups and can use existing software and images of real-world settings.

We begin our video prototyping exercises by reviewing relevant data about users and their work practices, and then review ideas we video brainstormed. The next step is to create a use scenario, describing the user at work. Once the scenario is described in words, the designer develops a storyboard. Similar to a comic book, the storyboard shows a sequence of rough sketches of each action or event, with accompanying actions and/or dialogue (or subtitles), with related annotations that explain what is happening in the scene or the type of shot (Figure 47.7). A paragraph of text in a scenario corresponds to about a page of a storyboard.

Storyboards help designers refine their ideas, generate "what-if" scenarios for different approaches to a story, and communicate with the other people who are involved in the design process. Some storyboards may be informal sketches of ideas, with only partial information. Others follow a predefined format and are used to direct the production and editing of a video prototype. Designers should jot down notes on storyboards as they think through the details of the interaction.

Paper storyboards can be used as is to communicate with other members of the design team. Designers and users can discuss the proposed system and alternative ideas for interacting with it (Figure 47.8). Simple videos of each successive frame, with a voice over to explain what happens, can also be

FIGURE 47.8 Video prototyping. The CPN design team reviews their observations of CPN developers and then discusses several design alternatives. They work out a scenario and storyboard it, then shoot a video prototype that reflects their design.

effective. We usually use storyboards to help us shoot video prototypes, which illustrate how a new system will look to a user in a real-world setting. We find that placing the elements of a storyboard on separate cards and arranging them (Mackay and Pagani 1994) helps the designer experiment with different linear sequences and insert or delete video clips. Continuing to the next step, that is, creating a video prototype based on the storyboard, forces designers to consider the design details in even greater depth.

Storyboards, even very informal ones, are essential guides for shooting video prototypes. To avoid spending time in postproduction, we use a technique called "editing-in-the-camera" (see Mackay 2000) in which each video clip, guided by the storyboard, is shot in the order that it will be viewed. With a well-designed storyboard, this is just as easy and results in a finished video prototype at the end of a one-hour session. Note that today's digital video cameras include editing features in the camera, which introduces the temptation to make editing changes on the fly. Our students who do this consistently take more time than their colleagues who do not, usually with worse results. In general, we recommend avoiding post hoc editing and just following the storyboard.

We use title cards, as in a silent movie, to separate the clips. This both simplifies shooting and makes it easier for the viewer to follow the story. Title cards also provide the only acceptable way to edit while you are shooting: if you make an error, you should address it immediately by rewinding to the last title card and continue shooting from there.

Video prototypes take several forms. In some, a narrator explains each event and several people on the sidelines may be necessary to move images and illustrate the interaction. In others, actors simply perform the movements and the viewer is expected to understand the interaction without a voice over. You can easily create simple special effects. For example, time-lapse photography allows you to have images appear and disappear based on the user's interaction. For example, record a clip of a user pressing a button, press "pause" on the camera, add a pop-up menu, then restart the camera, to create the illusion of immediate system feedback.

Video prototypes should begin with a title, followed by an establishing shot that shows the user in the context defined by the scenario. Next, create a series of close-up and midrange shots, interspersed with title cards to explain the story. Place a final title card with credits at the end. We print blank title cards on colored paper to make it easier to search for the sections of the video later: When you fast-forward through video, a solid blue or red frame clearly stands out (for detailed examples of video-based prototyping techniques, see Mackay 2002).

Video prototypes are fixed prototypes. However, it is also possible to use video as an open prototype, in which users can interact with the prototype in an open-ended way. Video thus becomes a tool for sketching and visualizing interactions. For example, we sometimes use a live video camera as a Wizard of Oz tool and capture the interaction with a second video camera. The Wizard should have access to a set of prototyping materials representing screen objects. Other team members stand by ready to help move objects as needed. The live camera is pointed at the Wizard's work area, with either a paper prototype or a partially working software simulation. The resulting image is projected onto a screen or monitor in front of the user. One or more people should be situated so that they can observe the actions of the user and manipulate the projected video image accordingly. This is most effective if the Wizard is well prepared for a variety of events and can present semiautomated information. The user interacts with the objects he or she sees on the screen and the Wizard moves the relevant materials in direct response to each user action. The other camera records the interaction between the user and the simulated software system on the screen, to create either a video brainstorm (for a quick idea) or a fully storyboarded video prototype.

Figure 47.9 shows a Wizard of Oz simulation with a live video camera, video projector, whiteboard, overhead projector, and transparencies. The setup allows two people to experience how they would communicate via a new interactive communication system. One video camera films the blond woman, who can see and talk to the brunette woman. Her image is projected live onto the left side of the wall. An overhead projector displays hand drawn transparencies, manipulated by two other people, in response to gestures made by the brunette woman. The entire interaction is videotaped by a second video camera. Note that participants at a workshop on user interfaces for air-traffic control created this video: none of the participants had ever used video prototyping techniques but they were able to set up this Wizard of Oz style environment and use it to generate new interaction ideas in less than 30 minutes.

Combining Wizard of Oz and video is a particularly powerful prototyping technique because it gives the person playing the user a real sense of what it might actually feel like to interact with the proposed tool, long before it has been implemented. Seeing a video clip of someone else interacting with a simulated tool is more effective than simply hearing about

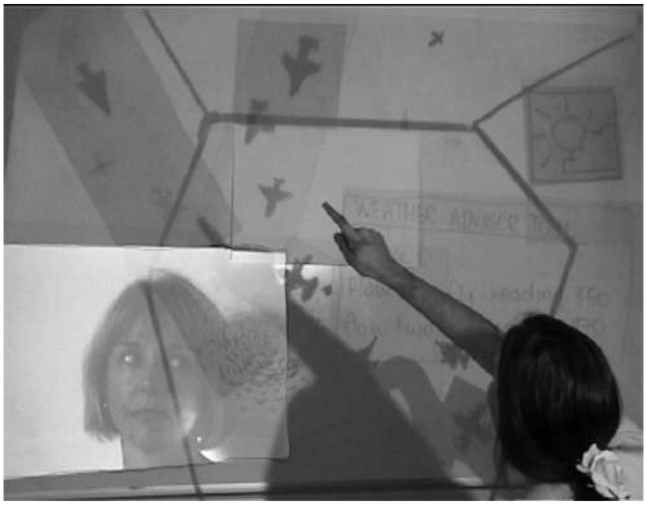

FIGURE 47.9 Complex Wizard of Oz simulation, with projected image from a live video camera and transparencies projected from an overhead projector.

it, but interacting with it directly is more powerful still. Note that video should be used with caution, particularly when video prototypes are taken out of their original design setting (for a more detailed discussion of the ethical issues involved, see Mackay 1995).

Video prototyping may act as a form of specification for developers, enabling them to build the precise interface, both visually and interactively, created by the design team. This is particularly useful when moving from offline to online prototypes, which we now describe.

47.4.2 Online Rapid Prototyping Techniques

The goal of online rapid prototyping is to create higher precision prototypes than can be achieved with offline techniques. Such prototypes may prove useful to better communicate ideas to clients, managers, developers and end users. They are also useful for the design team to fine tune the details of a layout or an interaction. They may exhibit problems in the design that were not apparent in less precise prototypes. Finally, they may be used early on in the design process for low precision prototypes that would be difficult to create offline, such as when very dynamic interactions or visualizations are needed.

The techniques presented in this section are sorted by interactivity. We start with noninteractive simulations, such as animations, followed by interactive simulations that provide fixed or multiple-path interactions. We finish with scripting languages, which support open interactions.

47.4.2.1 Noninteractive Simulations

A noninteractive simulation is a computer-generated animation that represents what a person would see of the system if he or she were watching over the user's shoulder. Noninteractive simulations are usually created when offline prototypes, including video, fail to capture a particular aspect of the interaction and it is important to have a quick prototype to evaluate the idea. It is usually best to start by creating a storyboard to describe the animation, especially if the developer of the prototype is not a member of the design team.

One of the most widely used tools for noninteractive simulations is Macromedia Director™. The designer defines graphical objects called "sprites," and defines paths along which to animate them. The succession of events, such as when sprites appear and disappear, is determined with a time line. Sprites are usually created with drawing tools, such as Adobe Illustrator or Deneba Canvas, painting tools, such as Adobe Photoshop, or even scanned images. Director is a very powerful tool and experienced developers use it quickly to create sophisticated interactive simulations. (However, it is still faster to create noninteractive simulations.) Other similar tools exist on the market such as Adobe AfterEffects and Macromedia Flash (Figure 47.10).

Future work

The DPI model:

– an abstract model
– a simplified and tested implementation: CPN2000

Next steps:

– define a concrete interface model
– implement the DPI model
– extend DPI to:
* groupware
* augmented reality
* mobile systems

FIGURE 47.10 A noninteractive simulation of a desktop interface created with Macromedia Flash. The time-line (top) displays the active sprites while the main window (bottom) shows the animation. (© O. Beaudoux, with permission)

Figure 47.11 shows a set of animation movies created by Curbow to explore the notion of accountability in computer systems (Dourish 1997). These prototypes explore new ways to inform the user of the progress of a file copy operation. They were created with Macromind Director by combining custom-made sprites with sprites extracted from snapshots of the Macintosh Finder. The simulation features cursor motion, icons being dragged, windows opening and closing, and so forth. The result is a realistic prototype that shows how the interface looks and behaves, that was created in just a few hours. Note that the simulation also features text annotations to explain each step, which helps document the prototype.

Noninteractive animations can be created with any tool that generates images. For example, many web designers use Adobe Photoshop to create simulations of their websites. Photoshop images are composed of various layers that overlap like transparencies. The visibility and relative position of each layer can be controlled independently. Designers can quickly add or delete visual elements, simply by changing the characteristics of the relevant layer. This permits quick comparisons of alternative designs and helps visualize multiple pages that share a common layout or banner. Skilled Photoshop users find this approach much faster than most web-authoring tools.

We used this technique in the CPN2000 project (Mackay, Ratzer, and Janecek 2000) to prototype the use of transparency. After several prototyping sessions with transparencies and overhead projectors, we moved to the computer to understand the differences between the physical transparencies and the transparent effect as it would be rendered on a computer screen. We later developed an interactive prototype with OpenGL, which required an order of magnitude more time to implement than the Photoshop mock-up.

Even a spreadsheet program can be used for prototyping: Berger (2006) described the use of Microsoft Excel to prototype form-based interfaces. First, a template is created that contains a number of reusable elements by taking advantage

of the workbook feature of Excel, where multiple pages can be presented with a tabbed interface. Then, prototypes are created by copying and pasting items from the template into a blank page, taking advantage of the table structure of the spreadsheet to create grid layouts.

47.4.2.2 Interactive Simulations

Designers can also use tools such as Adobe Photoshop to create Wizard of Oz simulations. For example, the effect of dragging an icon with the mouse can be obtained by placing the icon of a file in one layer and the icon of the cursor in another layer and by moving either or both layers. The visibility of layers, as well as other attributes, can also create more complex effects. Like Wizard of Oz and other paper prototyping techniques, the behavior of the interface is generated by the user who is operating the Photoshop interface.

More specialized tools, such as Hypercard and Macromedia Director, can be used to create simulations with which the user can directly interact. Hypercard (Goodman 1987) was one of the most successful early prototyping tools. It was an authoring environment based on a stack metaphor: a stack contains a set of cards that share a background, including fields and buttons. Each card can also have its own unique contents, including fields and buttons (Figure 47.12). Using a scripting language, stacks, cards, fields, and buttons can react to user events, such as clicking a button, as well as system events, for example, when a new card is displayed or about to disappear.

Interfaces can be prototyped quickly with this approach, by drawing different states in successive cards and using buttons to switch from one card to the next. Multiple-path interactions can be programmed by using several buttons on each card. Interactions that are more open require advanced use of the scripting language, but are easy to master with a little practice.

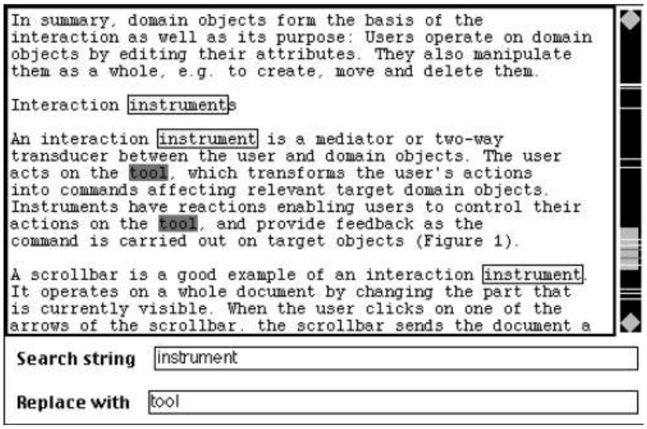
Macromind Director uses a different metaphor, attaching behaviors to sprites and to frames of the animation. For example, a button can be defined by attaching a behavior to the sprite representing that button. When the sprite is clicked, the animation jumps to a different sequence. This is usually coupled with a behavior attached to the frame containing the button that loops the animation on the same frame. As a result, nothing happens until the user clicks the button, at which point the animation skips to a sequence where, for example, a dialogue box opens. The same technique can be used to make the OK and Cancel buttons of the dialogue box interactive. Typically, the Cancel button would skip to the original frame while the OK button would skip to a third sequence. Director comes with a large library of behaviors to describe such interactions, so that prototypes can be created completely interactively. New behaviors can also be defined with a scripting language called Lingo.

47.4.2.3 Scripting Languages

Scripting languages are the most advanced rapid prototyping tools. As with the interactive-simulation tools described above, the distinction between rapid prototyping tools and development tools is not always clear. Scripting languages make it easy to quickly develop throwaway prototypes (a few hours to a few days), which may or may not be used in the final system, for performance or other technical reasons.

A scripting language is a programming language that is both lightweight and easy to learn. Most scripting languages are interpreted or semicompiled; for example, the user does not need to go through a compile-link-run cycle each time the script (program) is changed. Scripting languages can be forbidding: they are not strongly typed and nonfatal errors are ignored unless explicitly trapped by the programmer. Scripting languages are often used to write small applications for specific purposes and can serve as glue between preexisting applications or software components.

Tcl (Ousterhout 1994) is particularly suitable to develop user interface prototypes (or small to medium-size applications) because of its Tk user interface toolkit. Tcl was inspired by the syntax of the Unix shell and makes it very easy to interface existing applications by turning the application programming interface (API) into a set of commands that can be called directly from a Tcl script. Tk features all the traditional interactive objects (called "widgets") of a UI toolkit: buttons, menus, scrollbars, lists, dialogue boxes, and so forth. A widget is typically created with only one line. For example,



In summary, domain objects form the basis of the
interaction as well as its purpose: Users operate on domain
objects by editing their attributes. They also manipulate
them as a whole, e.g. to create, move and delete them.

Interaction instruments

An interaction instrument is a mediator or two-way
transducer between the user and domain objects. The user
acts on the tool, which transforms the user's actions
into commands affecting relevant target domain objects.
Instruments have reactions enabling users to control their
actions on the tool, and provide feedback as the
command is carried out on target objects (Figure 1).

A scrollbar is a good example of an interaction instrument.
It operates on a whole document by changing the part that
is currently visible. When the user clicks on one of the

```
button .dialogbox.ok -text OK -command {destroy
.dialogbox}.
```

This command creates a button, called ".dialogbox.ok," whose label is "OK." It deletes its parent window ".dialogbox" when the button is pressed. A traditional programming language and toolkit would take 5 to 20 lines to create the same button.

Tcl also has two advanced, heavily parameterized widgets: the text widget and the canvas widget. The text widget can be used to prototype text-based interfaces. Any character in the text can react to user input using tags. For example, it is possible to turn a string of characters into a hypertext link. In Beaudouin-Lafon (2000), the text widget was used to prototype a new method for finding and replacing text. When entering the search string, all occurrences of the string are highlighted in the text (Figure 47.13). Once a replace string has been entered, clicking an occurrence replaces it (the highlighting changes from yellow to red). Clicking a replaced occurrence returns it to its original value. This example also uses the canvas widget to create a custom scrollbar that displays the positions and status of the occurrences.

The Tk canvas widget is a drawing surface that can contain arbitrary objects: lines, rectangles, ovals, polygons, text strings, and widgets. Tags allow behaviors (e.g., scripts) that are called when the user acts on these objects. For example, an object that can be dragged will be assigned a tag with three behaviors: button-press, mouse-move, and button-up. Because of the flexibility of the canvas, advanced visualization and interaction techniques can be implemented more quickly and easily than with other tools. For example, Figure 47.14 shows a prototype exploring new ideas to manage overlapping windows on the screen (Beaudouin-Lafon 2001). Windows can be stacked and slightly rotated so that

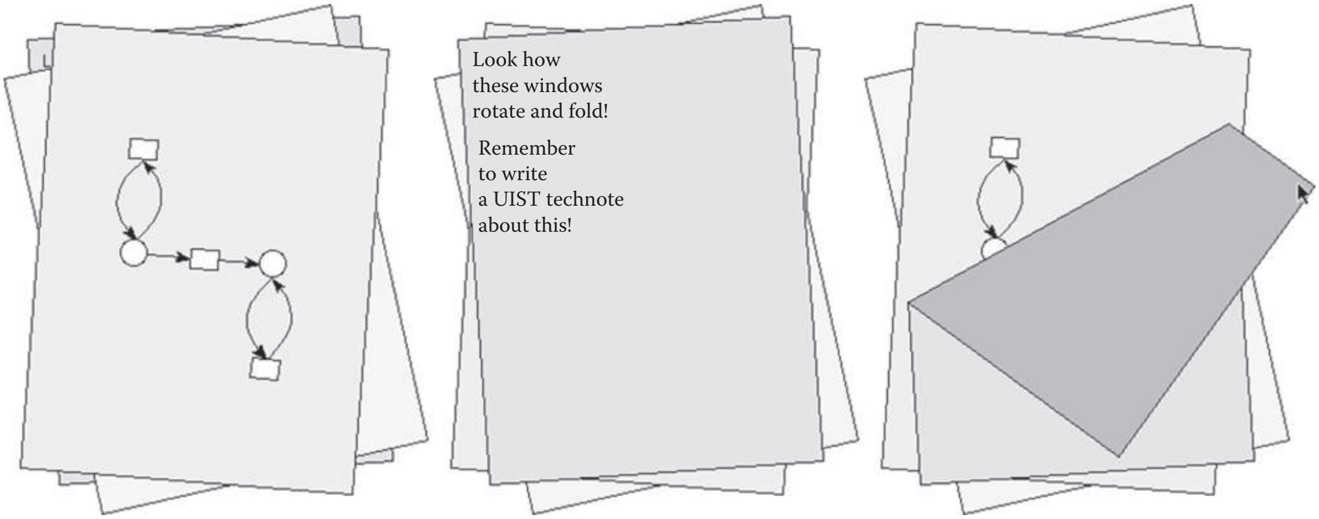

FIGURE 47.14 Using the Tk canvas widget to prototype a novel window manager. (From Beaudouin-Lafon, M. 2001. Novel interaction techniques for overlapping Windows. In *Proceedings of ACM Symposium on User Interface Software and Technology, UIST 2001*, Orlando, Florida. *CHI Letters* 3(2):153–4.)

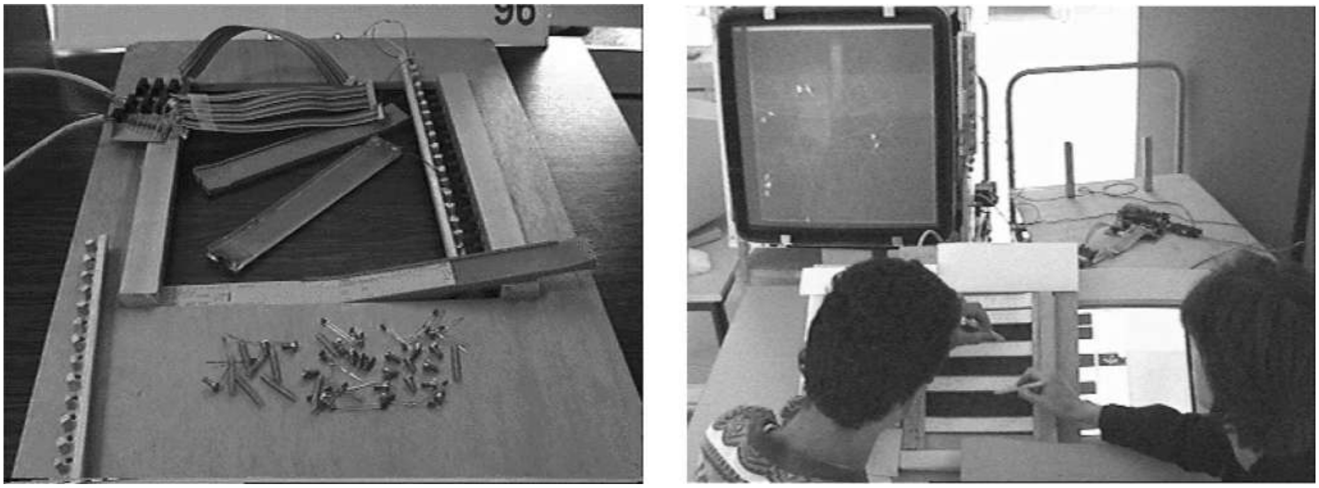

FIGURE 47.15 Caméléon's augmented stripboard (left) is a working hardware prototype that identifies and captures hand-writing from paper flight strips. Members of the design team test the system (right), which combines both hardware and software prototypes into a single interactive simulation.

it is easier to recognize them, and they can be folded so it is possible to see what is underneath without having to move the window. Even though the prototype is not perfect, that is, folding a window that contains text is not properly supported, it was instrumental in identifying a number of problems with the interaction techniques and finding appropriate solutions through iterative design.

Tcl and Tk can also be used with other programming languages. For example, Pad++ (Bederson and Meyer 1998) is implemented as an extension to Tcl/Tk: the zoomable interface is implemented in C for performance and is accessible from Tk as a new widget. This makes it easy to prototype interfaces that use zooming. It is also a way to develop evolutionary prototypes: a first prototype is implemented completely in Tcl, then parts of it are reimplemented in a compiled language to performance. Ultimately, the complete system may be implemented in another language, although it is more likely that some parts will remain in Tcl.

Software prototypes can also be used in conjunction with hardware prototypes. Figure 47.15 shows an example of a hardware prototype that captures handwritten text from a paper flight strip (using a combination of a graphics tablet and a custom-designed system for detecting the position of the paper strip holder). We used Tcl/Tk, in conjunction with C11, to present information on a RADAR screen (tied to an existing air traffic control simulator) and to provide feedback on a touch-sensitive display next to the paper flight strips (Caméléon, Mackay, et al. 1998). The user can write in the ordinary way on the paper flight strip, and the system interprets the gestures according to the location of the writing on the strip. For example, a change in flight level is automatically sent to another controller for confirmation and a physical tap on the strip's ID lights up the corresponding aircraft on the RADAR screen. A later section of this chapter expands this approach to the development of prototypes of mixed reality and pervasive computing systems.

47.5 ITERATIVE AND EVOLUTIONARY PROTOTYPES

Prototypes may also be developed with traditional software development tools. In particular, high-precision prototypes usually require a level of performance that cannot be achieved with the rapid online prototyping techniques previously described. Similarly, evolutionary prototypes intended to evolve into the final product require more traditional software development tools. Finally, even shipped products are not final, since subsequent releases can be viewed as initial designs for prototyping the next release.

Development tools for interactive systems have been in use for over 20 years and are constantly being refined. Several studies have shown that the part of the development cost of an application spent on the user interface is 50% to 80% of the total cost of the project (Myers and Rosson 1992). The goal of development tools is to shift this balance by reducing production and maintenance costs. Another goal of development tools is to anticipate the evolution of the system over successive releases and support iterative design.

The lowest level tools are graphical libraries, which provide hardware independence for painting pixels on a screen and handling user input and window systems that provide an abstraction (the window) to structure the screen into several virtual terminals. User interface toolkits structure an interface as a tree of interactive objects called "widgets," while user interface builders provide an interactive application to create and edit those widget trees. Application frameworks build on toolkits and UI builders to facilitate the creation of typical functions such as cut/copy/paste, undo, help, and interfaces based on editing multiple documents in separate windows. Model-based tools semiautomatically derive an interface from a specification of the domain objects and functions to be supported. Finally, user interface development environments (UIDEs) provide an integrated collection of tools for the development of interactive software.

Before we describe some of these categories in more detail, it is important to understand how they can be used for prototyping. It is not always best to use the highest level available tool for prototyping. High-level tools are most valuable in the long term because they make it easier to maintain the system, port it to various platforms, or localize it to different languages. These issues are irrelevant for vertical and throwaway prototypes, so a high-level tool may prove less effective than a lower level one.

The main disadvantage of higher level tools is that they constrain or stereotype the types of interfaces they can implement. User interface toolkits usually contain a limited set of widgets, and it is expensive to create new ones. If the design must incorporate new interaction techniques, such as bimanual interaction (Kurtenbach et al. 1993) or zoomable interfaces (Bederson and Hollan 1994), a user interface toolkit will hinder rather than help prototype development. Similarly, application frameworks assume a stereotyped application with a menu bar, several toolbars, a set of windows holding documents, and so forth. Such a framework would be inappropriate for developing a game or a multimedia educational CD-ROM that requires a fluid, dynamic, and original user interface.

Finally, developers need to truly master these tools, especially when prototyping in support of a design team. Success depends on the programmer's ability to change the details quickly as well as the overall structure of the prototype. A developer will be more productive when using a familiar tool than if forced to use a more powerful but unknown tool.

Since a complete tour of development tools for interactive systems is beyond the scope of this chapter, we focus on those tools that can be used most effectively for prototyping: user interface toolkits, user interface builders, and user interface development environments.

47.5.1 User Interface Toolkits

User interface toolkits are probably the most widely used tool nowadays to implement applications. All three major platforms (Unix/Linux, MacOS, and Windows) come with at least one standard UI toolkit. The main abstraction provided by a UI toolkit is the widget. A widget is a software object that has three facets that closely match the MVC model (Krasner and Pope 1988): a presentation, a behavior, and an application interface.

The presentation defines the graphical aspect of the widget. The overall presentation of an interface is created by assembling widgets into a tree. Widgets such as buttons are the leaves of the tree. Composite widgets constitute the nodes of the tree and control the layout of their children. The behavior of a widget defines the interaction methods it supports: a button can be pressed, a scrollbar can be scrolled, and a text field can be edited. The application interface defines how a widget communicates the results of the user interaction to the rest of the application. It is usually based on a notification mechanism.

One limitation of widgets is that their behaviors are limited to the widget itself. Interaction techniques that involve multiple widgets, such as drag-and-drop, cannot be supported by the widgets' behaviors alone and require separate support in the UI toolkit. Some interaction techniques, such as toolglasses or magic lenses (Bier et al. 1993), break the widget model both with respect to the presentation and the behavior and cannot be supported by traditional toolkits. In general, prototyping new interaction techniques requires either implementing them within new widget classes, which is not always possible, or not using a toolkit at all. Implementing a new widget class is typically more complicated than implementing the new technique outside the toolkit, for example, with a graphical library, and is rarely justified for prototyping. Many toolkits provide a blank widget, such as the Canvas in Tk or JFrame in Java Swing (Eckstein, Loy, and Wood 1998), which can be used by the application to implement its own presentation and behavior. This is usually a good alternative to implementing a new widget class, even for production code.

User interface toolkits have been an active area of research over the past 15 years. InterViews (Linton, Vlissides, and Calder 1989) inspired many modern toolkits and user interface builders. Some recent research toolkits that can be used for prototyping include SubArctic (Hudson, Mankoff, and Smith 2005) and Satin (Hong and Landay 2000). The latter is dedicated to ink-based interaction and is used with the Silk and Denim UIDEs described below.

A number of toolkits have also shifted away from the widget model to address other aspects of user interaction. For example, GroupKit (Roseman and Greenberg 1996, 1999) was designed for groupware, Jazz (Bederson, Meyer, and Good 2000) for zoomable interfaces, the Visualization (Schroeder, Martin, and Lorensen 1997) and InfoVis (Fekete 2004) toolkits for visualization, Inventor (Strass 1993) for 3D graphics, and Metisse (Chapuis and Roussel 2005) for window management (Figure 47.16).

Creating an application or a prototype with a UI toolkit requires solid knowledge of the toolkit and experience with programming interactive applications. In order to control the complexity of the interrelations between independent pieces of code (creation of widgets, callbacks, global variables, etc.), it is important to use well-known design patterns (Gamma et al. 1995) such as Command, Chain of Responsibility, Mediator, and Observer. Otherwise the code quickly becomes unmanageable and, in the case of a prototype, unsuitable to design space exploration.

47.5.2 User Interface Builders

User interface builders leverage user interface toolkits by allowing the developer of an interactive system to create the presentation of the user interface, such as the tree of widgets, interactively with a graphical editor. The editor typically features a palette of widgets that the user can use to draw the interface in the same way as a graphical editor is used to create diagrams with lines, circles, and rectangles. The presentation attributes of each widget can be edited interactively as well as the overall layout. This saves a lot of time that would otherwise be spent writing and fine tuning rather dull code that creates widgets and specifies their attributes. It also makes it extremely easy to explore and test design alternatives.

Apple's Interface Builder (Figure 47.17) is a descendant of the NeXT interface builder (NeXT Corporation 1991). The palette to the right contains the available widgets. The user interface of the application was created by dragging these widgets into the application window at the top left. The bottom left window contains icons representing the application objects. By dragging connectors between widgets and these objects, a significant part of the behavior of the interface can be created interactively. The user interface can be tested at any time by switching the builder to test mode, making it easy to verify that it behaves as expected. The same application built directly with the underlying toolkit would require dozens of lines of code and significant debugging.

User interface builders are widely used to develop prototypes, as well as final applications. They are easy to use, they make it easy to change the look of the interface, and they hide a lot of the complexity of creating user interfaces with UI toolkits. However, despite their name, they do not cover the whole user interface. Therefore they still require a significant amount of programming, a good knowledge of the underlying toolkit and an understanding of their limits, especially when prototyping novel visualization and interaction techniques.

47.5.3 User Interface Development Environments

A number of high-level tools exist for creating interactive applications. They are often based on user interface toolkits, and they sometimes include an interface builder. These

With permission.)

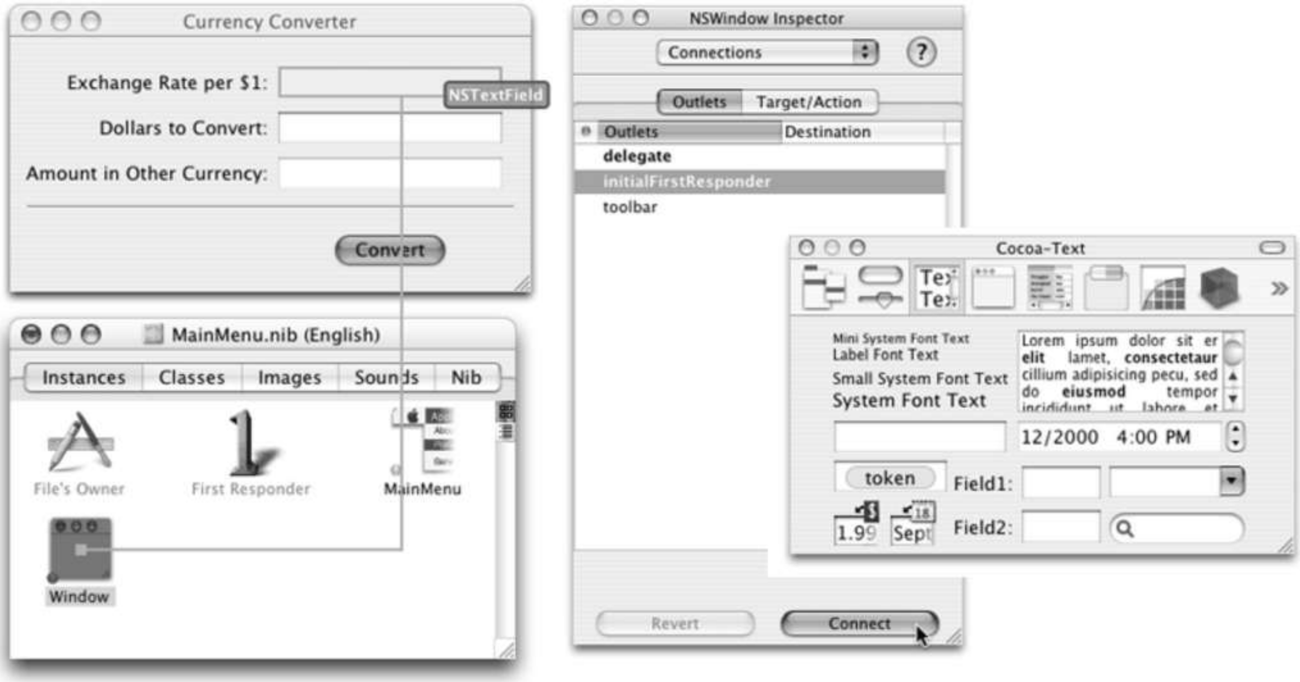

FIGURE 47.17 Interface Builder with the window being built (top-left), application objects (bottom-left), inspector (center), and widget palette (right).

tools are often referred to as "user interface development environments."

The simplest of these tools are application frameworks, which address stereotyped applications. For example, many applications have a standard form where windows represent documents that can be edited with menu commands and tools from palettes; each document may be saved into a disk file; standard functions such as copy/paste, undo, and help are supported. Implementing such stereotyped applications with a UI toolkit or UI builder requires replicating a significant amount of code to implement the general logic of the application and the basics of the standard functions. Application frameworks address this issue by providing a shell that the developer fills in with the functional core and the actual presentation of the nonstandard parts of the interface. Most frameworks have been inspired by MacApp, a framework developed in the 1980s to develop applications for the Macintosh (Apple Computer 1996). Some frameworks are more specialized than MacApp. For example, Unidraw (Vlissides and Linton 1990) is a framework for creating graphical editors in domains, such as technical and artistic drawing, music composition, or circuit design. By addressing a smaller set of applications, such a framework can provide more support and significantly reduce implementation time.

Mastering an application framework takes time. It requires knowledge of the underlying toolkit and the design patterns used in the framework, and a good understanding of the design philosophy of the framework. A framework is useful because it provides a number of functions "for free," but at the same time it constrains the design space that can be explored. Frameworks can prove effective for prototyping if their limits are well understood by the design team.

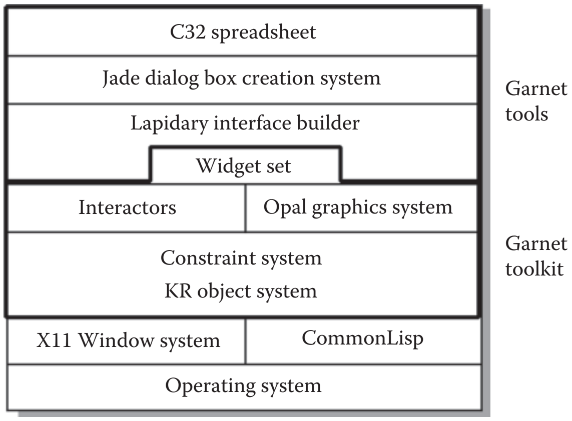

FIGURE 47.18 The Garnet toolkit and tools. (From Myers, B. A., D. A. Giuse, R. B. Dannenberg, B. Vander Zander, D. S. Kosbie, E. Pervin, A. Mickish, and P. Marchal. 1990. Garnet: Comprehensive support for graphical, highly-interactive user interfaces. *IEEE Comput* 23(11):71–85.)

UIDEs consist in assembling a set of tools into an environment where different aspects of an interactive system can be specified and generated separately. For example, Garnet (Figure 47.18) and its successor Amulet (Myers et al. 1990; Myers et al. 1997) provide a comprehensive set of tools, including a traditional user interface builder, a semi-automatic tool for generating dialogue boxes, a user interface builder based on a demonstration approach, and so forth.

Some UIDEs include tools that are specifically designed for prototyping. For example, Silk (Landay and Myers 2001) is

FIGURE 47.19 A sketch created with Silk (top left) and its automatic transformation into a Motif user interface (top right). A storyboard (bottom) is used to test sequences of interactions, here a button that rotates an object. (From Landay, J., and B. A. Myers. 2001. Sketching interfaces: Toward more human interface design. *IEEE Comput* 34(3):56–64. With permission.)

a tool aimed at the early stages of design, when interfaces are sketched rather than prototyped in software. The user sketches a user interface directly on the screen (Figure 47.19). Using gesture recognition, Silk interprets the marks as widgets, annotations, and so forth. Even in its sketched form, the user interface is functional: buttons can be pressed, tools can be selected in a toolbar, and so on. The sketch can also be turned into an actual interface, that is, using the Motif toolkit. Finally, storyboards can be created to describe and test sequences of interactions. Monet (Li and Landay 2005) expands this approach by supporting the specification of animations and continuous interaction such as drag-and-drop. Silk and Monet therefore combine some aspects of offline and online prototyping techniques, trying to get the best of both worlds. Another example is Denim (Lin et al. 2000), which addresses the prototyping of websites. Like Silk, it uses a sketch-based interface to allow designers to quickly enter ideas about the overall design of the website as well as individual pages and test the navigation. This illustrates a current trend in research where online tools attempt to support not only the development of the final system, but the whole design process. The following section will also illustrate this trend in the new and very active areas of mixed reality and pervasive computing.

47.6 PROTOTYPING MIXED REALITY AND PERVASIVE COMPUTING SYSTEMS

While most examples in the previous sections concerned traditional graphical user interfaces (GUIs), there is an increasing need to address the design and prototyping of systems that combine the physical and online worlds. The current trend towards pervasive computing and mixed reality started with Weiser's (1991) seminal article on ubiquitous computing and was carried on by augmented reality (Wellner, Mackay, and Gold 1993) and tangible interfaces (Holmquist, Schmidt, and Ullmer 2004). A common theme of these approaches is to combine interaction with the real world and interaction with online information, taking advantage of humans' abilities to interact with physical artifacts.

While mixed reality emphasizes the role of physical objects, pervasive computing emphasizes the role of the physical space. Both raise new and difficult issues when

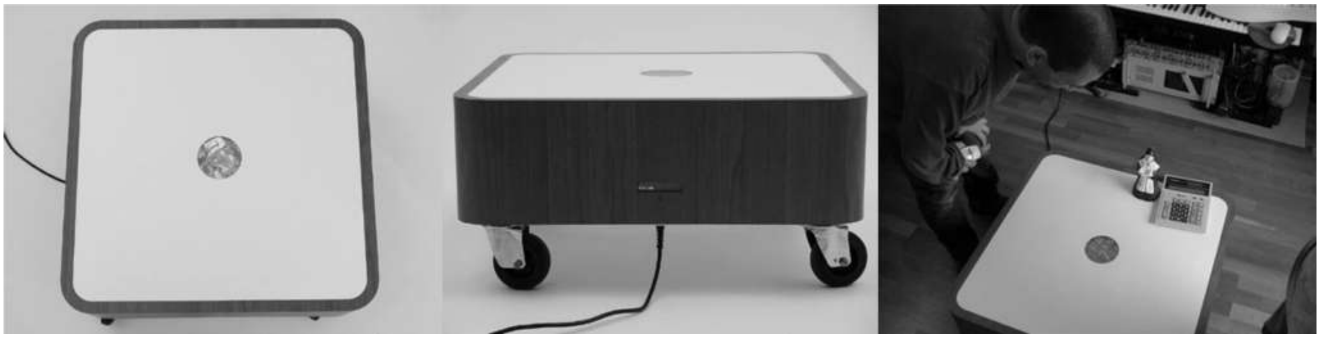

FIGURE 47.20 The drift table. (From Gaver, W., J. Bowers, A. Boucher, H. Gellerson, S. Pennington, A. Schmidt, A. Steed, N. Villar, and B. Walker. 2004. The drift table: Designing for ludic engagement. In *Proc. CHI '04 Design Expo*. New York: ACM Press. With permission.)

trying to actually design and build such systems. At the prototyping stage, they typically require a larger effort than when designing a GUI. First, the range of possible interactions is much broader and typically includes gesture, eye-gaze, or speech. These techniques are already difficult to incorporate into traditional interfaces: in a mixed reality or pervasive computing environment, the user is much less constrained, making recognition and interpretation of users' actions much harder. Designers must then address recognition errors and more generally the effects of context on the sensing techniques. Second, the range of artifacts to design is larger than with desktop interfaces, as it includes the physical artifacts that the users may manipulate; in pervasive computing, the role of user location, the issues of wireless network coverage and sensor range, the difficulty of providing feedback where needed are all new challenges that need to be addressed. Finally, these systems are not necessarily used for tasks where speed of execution and productivity are the primary measures of success. Whether they are used in the home, for tourism, such as tour guides, for assisted living or plain entertainment, the wider and less well-mapped design space typically requires extensive prototyping work.

For example, Boucher and Gaver (2006) described their experiences in designing the drift table, a coffee table with a small screen in the center displaying an aerial view of England and load sensors measuring the weight of objects on the table. According to the measured weight and its estimated location, the aerial view slowly drifts in that direction, as if navigating with a hot air balloon. While the resulting design is conceptually simple, it required many prototypes, both to explore what it should do and how it could be built. The final prototype (Figure 47.20) had to be aesthetically pleasing as well as fully functional for testing in people's homes. This example shows that the higher precision prototypes had to address interaction, function, and looks simultaneously. This proved particularly challenging but is common when prototyping these types of systems.

The prototyping strategies that we have described, such as horizontal, vertical, and scenario-based prototypes, are still valid for prototyping mixed reality and pervasive computing systems, as well as some of the prototyping techniques, such as offline prototyping with mock-ups and video prototyping. Online prototyping, however, requires specific tools and iterative and incremental prototyping, even more so. The rest of this section explores some of the existing tools.

Phidgets (Greenberg and Fitchett 2001) are physical sensors and actuators that can be controlled from a computer through a USB connection. A wide range of sensors is available (light, motion, distance, pressure, humidity, etc.), as well as input devices (buttons, sliders), LEDs, LCD displays, motors, and RFID tag readers. By hiding their implementations and exposing their functionalities through a standard software interface, phidgets can greatly facilitate the design and prototyping of tangible interfaces. For example, they can be embedded into a physical artifact and programmed from the computer to prototype a mobile device. Since all phidgets can be represented on the computer screen, they can also be used for Wizard of Oz settings, where the Wizard can directly control the output phidgets such as LEDs and motors.

Papier-Mâché (Klemmer et al. 2004) is a toolkit for creating tangible interfaces based on vision, RFID tags, and barcodes. It is more adapted to the development of augmented paper applications than Phidgets and provides a richer development environment. The DART toolkit (MacIntyre et al. 2005) takes a similar approach, but targets augmented and mixed reality applications. The development environment is based on Macromedia Director, with the explicit goal of being familiar to designers. In the context of prototyping, both toolkits can be used for applications other than those that they explicitly target. For example, DART can superimpose a computer-generated model with live or recorded video, which can be used to put an image or 3D model of a device being designed in the real world.

Topiary (Li, Hong, and Landay 2004) is a tool for prototyping pervasive applications that use the locations of people, places, and objects. Unlike the above tool, its goal is not to create real-world prototypes allowing to test a system in situ. Rather, it is an online tool that allows to create and test scenarios on the screen, using maps representing the environment and icons representing the people, places, and objects of interest. Once a scenario has been created, the tool allows the user to experience it either from a bird's eye view or from the perspective of a particular user by displaying the user's PDA. Such scenario-based prototyping can be very useful in the early stages of design, when exploring ideas.

Finally, a CAPpella (Dey et al. 2004), is a tool to help end users create or customize context-aware applications. It uses programming by demonstration so that users only have to show examples of sensor data and the system's reaction. While the system targets end users, it can also be used by designers to create prototypes of context-aware applications. By hiding the complexity of programming recognizers, it allows for a fast exploration of alternatives.

In summary, while mixed reality and pervasive computing create new challenges for designers, a number of tools are starting to appear to help with the design process in general and prototyping in particular. Interestingly, these tools can also be used to prototype more traditional applications. For example, phidgets can be used to control an online application in a Wizard of Oz setting, DART can be used to create scenarios that mix videos with models of future artifacts, and a CAPpella can be used to experiment with recognition-based applications. As mixed reality and pervasive computing systems become more widely available, they will no doubt provide more tools to be used by designers in unexpected ways to help with the prototyping of interactive systems at large.

47.7 CONCLUSION

Prototyping is an essential component of interactive system design. Prototypes may take many forms, from rough sketches to detailed working prototypes. They provide concrete representations of design ideas and give designers, users, developers and managers an early glimpse into how the new system will look and feel. Prototypes increase creativity, allow early evaluation of design ideas, help designers think through and solve design problems, and support communication within multidisciplinary design teams.

Prototypes, because they are concrete and not abstract, provide a rich medium for exploring a design space. They suggest alternate design paths and reveal important details about particular design decisions. They force designers to be creative and to articulate their design decisions. Prototypes embody design ideas and encourage designers to confront their differences of opinion. The precise aspects of a prototype offer specific design solutions: designers can then decide to generate and compare alternatives. The imprecise or incomplete aspects of a prototype highlight the areas that must be refined or require additional ideas.

We defined prototypes and then discussed them as design artifacts. We introduced four dimensions by which they can be analyzed: representation, precision, interactivity, and evolution. We then discussed the role of prototyping within the design process and explained the concept of creating, exploring, and modifying a design space. We briefly described techniques for generating new ideas to expand the design space and techniques for choosing among design alternatives to contract the design space.

We described a variety of rapid prototyping techniques for exploring ideas quickly and inexpensively in the early stages of design, including offline techniques (from paper and pencil to video) and online techniques (from fixed to interactive simulations). We then described iterative and evolutionary prototyping techniques for working out the details of the online interaction, including development tools and software environments. Finally, we addressed the emerging fields of mixed reality and pervasive computing and described the new challenges they raise for interactive systems design, as well as some of the tools available for prototyping them.

We view design as an active process of working with a design space, expanding it by generating new ideas and contracting as design choices are made. Prototypes are flexible tools that help designers envision this design space, reflect upon it, and test their design decisions. Prototypes are diverse and can fit within any part of the design process, from the earliest ideas to the final details of the design. Perhaps most important, prototypes provide one of the most effective means for designers to communicate with each other, as well as with users, developers, and managers, throughout the design process.

48 Scenario-Based Design

Mary Beth Rosson and John M. Carroll

CONTENTS

48.1 INTRODUCTION

Scenario-based design (SBD) is a family of techniques in which the *use* of a future system is concretely described at an early point in the development process. Narrative descriptions of envisioned usage episodes—user interaction scenarios—are then used in various ways to guide the development of the system that will enable these use experiences.

Like other user-centered approaches, SBD changes the focus of design work from defining system operations (i.e., functional specification) to describing how people will use a system to accomplish work tasks and other activities. However, unlike approaches that analyze and address human behavior and experience through the formal analysis and modeling of well-specified tasks, SBD offers relatively lightweight methods for envisioning future use possibilities.

A user interaction scenario is a *sketch of use*. It is intended to vividly capture the essence of an interaction design, much as a two-dimension paper-and-pencil sketch captures the essence of a physical design. Like any story, a scenario consists of a setting, or situation state, one or more actors with personal motivations, knowledge and capabilities, and various tools and objects that the actors encounter and manipulate. The narrative describes a sequence of actions and events that lead to an outcome. These actions and events are related in a usage context that includes the goals, plans, and reactions of the people taking part in the episode.

Table 48.1 presents a brief scenario in which Jerry, an internal business training professional, is preparing for an upcoming 1-week training session with colleagues at another company location. In the scenario, Jerry has the goal to update his knowledge about the software professionals he will be working with; in the narrative, he uses their microblogs to gather recent updates about these individuals in a relatively unobtrusive fashion (Zhao and Rosson 2009). The scenario describes one way that microblogging might support Jerry's goals. In this sense, it is one potential "solution" to his desire to re-acquaint himself with these remote colleagues; it might be contrasted to other scenarios, for example, more direct information exchanges based on individual e-mails that request updates from everyone or a group update request e-mailed out by the managers.

Designers can quickly construct scenarios like these to make envisioned possibilities more concrete. The example conveys how the social media paradigm of microblogging might be applied to the management of business relationships in distributed work settings. Importantly, the scenario does not propose options as an abstract model or even as a list of features or functions. Instead, it presents

TABLE 48.1
Potential Design Scenario Meeting the Needs of Business Trip Preparation

Jerry Visits a Remote Company Site to Carry Out a Training Session
Jerry works as a trainer in the Human Resources Department of VisionWay, a high-tech software development firm. Next week he will visit the company's Seattle lab to conduct training sessions on a new version management tool recently mandated by upper management for all sites. He has prepared a standard training presentation but wants to refresh his memory of the 30 or so staff members he will be working with; he last visited about 6 months ago.
Jerry knows that many of the tech-savvy staff members in Seattle microblog on a regular basis, so he decides to spend some time every day reviewing their posts. By doing this, he discovers that one group is struggling with a color matcher module in their visual analytics package; by following the link in the code, he is able to grab and insert example modules and method calls from this part of their code library into his training materials. Along the way, he also learns that several of the team members have just joined a softball team and that Susan (one of the managers) has recently had a baby.
During his visit, the training sessions go very well, as the developers discuss how the new version management features will help them manage their current updates. In fact, they get so caught up in their discussion that they turn his training session into an impromptu problem-solving session for three of the most problematic methods.

TABLE 48.2
Concerns Stemming from the Solution-First Approach to Design and Aspects of Scenario-Based Design That Address Each Concern

Hazards of Solution-First Approach	How SBD Can Help
Designers want to select a solution approach quickly, which may lead to premature commitment to their first design ideas.	Because they are concrete but rough, scenarios support visible progress, but relax commitment to the ideas expressed in the scenarios.
Designers attempt to quickly simplify the problem space with external constraints, such as the reuse of familiar solutions.	Because they emphasize people and their experiences, scenarios direct attention to the use-appropriateness of design ideas.
Designers are intent on elaborating their current design proposal, resulting in inadequate analysis of other ideas or alternatives.	Because they are evocative and by nature are incomplete, scenarios promote empathy and raise usage questions at many levels.

these ideas implicitly, embeded within a concrete episode of human–computer interaction (HCI) and personal experience.

User interaction scenarios can be successively detailed to discover and address finer-grained design issues. The scenario in Table 48.1 narrates a story about Jerry's experiences, but does so at a relatively high level of abstraction, focusing on his goals and general behavior, rather than details of user interaction. But even when narrated in this general fashion, scenarios serve as grist for group brainstorming to develop further alternatives or to raise questions about the assumptions behind the scenarios. They can be used to analyze software requirements, as a partial specification of functionality, and can be refined to consider and guide the design of user interface layouts and controls. They can also be used to identify and plan evaluation tasks for usability tests.

48.2 WHY SCENARIO-BASED DESIGN?

One reason that scenarios have become so popular in interactive system design is that they enable rapid communication about usage possibilities and concerns among many different stakeholders. It is easy to write a simple text scenario and takes only a little more effort to enrich it with a rough sketch or storyboard. When designers are working through ideas, they want to make progress quickly, so that they can obtain feedback and continue to refine their ideas. Scenarios are one way to do this.

The design of an interactive system is an ill-defined problem. Such problems tend to evoke a problem-solving strategy termed *solution-first* (Cross 2001). In the solution-first strategy, designers generate and analyze a candidate solution as a means of clarifying the problem state, the allowable moves, and the goal. They exploit the concreteness of their own solution proposals to evoke further requirements for analysis.

A solution-first approach to design is energizing, effective, and efficient; it explains the popularity of contemporary system development approaches like rapid prototyping (Wasserman and Shewmaker 1982) and extreme programming (Beck 1999). But this general strategy also entrains well-known hazards (Cross 2001): Designers tend to generate solutions too quickly, before they analyze what is already known about the problem and possible moves. Once an approach is envisioned, they may have trouble abandoning it when it is no longer appropriate. Designers may too readily reuse pieces of a solution they have used earlier, one that is familiar and accessible, but perhaps not appropriate. They may not analyze their own solutions very well or they may consider too few alternatives when exploring the problem space. In the next three sections, we consider how SBD may help to minimize these hazards of solution-first problem solving (see Table 48.2).

48.2.1 Scenarios Are Concrete but Rough

Design analysis is always indeterminate, because the act of design changes the world within which people act and experience. Requirements always change (Brooks 1995). When designs incorporate technologies that are evolving rapidly, requirements change even more rapidly. The more successful, the more widely adopted a design is, and the more impact it has, the less possible it would have been to determine its correct design requirements. And in any case, refinements in software technology and new perceived opportunities and requirements propel a new generation of designs every 2–3 years.

Design representations that are at once concrete but flexible help to manage ambiguous and dynamic situations. Analysts must be concrete to avoid being swallowed by indeterminacy; they must be flexible to avoid being captured by false steps. Systematic decomposition is a traditional approach to managing ambiguity, but it does not promote flexibility. Instead, designers end up with a set of concrete sub-solutions, each of which is fully specified. Unfortunately, by the time the set of sub-solutions is specified, the requirements often would have changed.

User interaction scenarios reconcile concreteness and flexibility. A scenario envisions a concrete design solution, but it can be couched at many levels of detail. Initially, a scenario may be extremely rough. It specifies a possible design by indicating the tasks users may carry out, but without committing to lower-level details describing *how* the tasks will be carried out or *how* the system will present the functionality for the tasks. The scenario in Table 48.1 is at an intermediate level, with some sense of task flow, but few details about specific user–system interactions.

Concrete material is interpreted more easily and more thoroughly than abstract material. For example, people remember a prototypical example far better than they remember the abstract category to which it belongs (Medin and Schaffer 1978; Rosch et al. 1976). Incomplete material tends to be elaborated with respect to personal knowledge when it is encountered. This process of elaboration creates more robust and accessible memories, relative to memories for more complete material (Wertheimer 1938). The combination of concreteness and incompleteness in scenarios engages a powerful variety of constructive cognitive processes.

The fluidity of design situations demands provisional solutions, tentative commitments. Yet, if every design decision is suspended, the result will be a design space, not a design. A scenario is a concrete design proposal that a designer can evaluate and refine, but it is also rough, so that it can be easily altered, and many details can be deferred.

48.2.2 Scenarios Maintain an Orientation to People and Their Needs

Designers need constraints; there are just too many things that might be designed. The current state of technology development makes some solutions impossible and others irresistible: On the one hand, designers cannot use technology that does not yet exist. On the other hand, designers are caught up in a technological zeitgeist that biases them toward making use of the latest gadgets and gizmos. They are likely to be biased toward familiar technologies, even when they are aware of limitations in these technologies.

Scenarios are work-oriented design objects. They describe systems in terms of the work that users will try to do when they use those systems, ensuring that design will remain focused on the needs and concerns of users (Carroll and Rosson 1990). Scenarios address what has been called the "representational bias" in human cognition—people overestimate the relevance of things that are familiar to them (Kahneman and Tversky 1972; Tversky and Kahneman 1974). For instance, designers who have years of experience with general-purpose e-mail communication mechanisms might see update requests sent out over e-mail listservs as a solution to Jerry's visit preparation needs, even though the stakeholders might be better served by emerging social media like Twitter (http://twitter.com). It is difficult to move beyond the familiar, but generating and sharing a vivid representation of exceptions to the status quo can promote innovative thinking. Scenarios that describe unusual but critical circumstances can provide such a perspective.

The reuse of familiar ideas is just one type of constraint that designers may apply in their solution-first problem solving. Other constraints may arise from the organizational structures within which the design work is embedded. Design projects are often chartered with a priori commitments to follow a systematic decomposition process. This makes them easy to manage, but unlikely to succeed with respect to discovering the real requirements of users and clients. Schedules and resources are often assigned in ways that create on-going conflicts between system designers and usability engineers. Usability engineers need to evaluate scenarios and prototypes at every stage of system development, but if schedules and resources do not provide for this, this work can conflict with software construction and refinement.

Constraints such as these can distract designers with ancillary factors so that they lose sight of what is essential in the design project, namely, the needs and concerns of users. The designer can become "unsituated" with respect to the real design situation, which is not the marketing manager's projections, or the instructional designer's list of steps, or the software engineer's system decomposition. The real design situation is the situation that will be experienced by the user, and the designers need to stay focused on that.

Scenarios can be made even more effective as work-oriented design objects when users are directly involved in creating them. Ackoff (1979) argues that the indeterminacy of design situations makes it imperative that *all* stakeholders participate directly. Scenarios support a simple and natural process of participatory design, where prospective users begin by enacting or relating episodes of current activities, then work iteratively with designers to transform and enrich these scenarios with the opportunities provided by new technologies (Carroll et al. 2000; Chin, Rosson, and Carroll 1997).

48.2.3 Scenarios Are Evocative, Raising Questions at Many Levels

There is a fundamental tension between thinking and doing: thinking impedes progress in doing, and doing obstructs thinking. Sometimes this conflict is quite sharp, as when one must stop and think before taking another step. But frequently it is more a matter of trading off priorities. Designers are intelligent people performing complex and open-ended tasks. They want to reflect on their activities, and they routinely do reflect on their activities. However, people take pride not only in what they know and learn, but in what they can do and in what they actually produce.

Donald Schön (1983, 1987) discusses this conflict extensively in his books on reflective practice. For example, he analyzes a coach reacting to an architecture student's design concept for a school building, which included a spiral ramp intended to maintain openness while breaking up lines of sight (she calls the idea "a Guggenheim"):

> … when I visited open schools, the one thing they complained about was the warehouse quality—of being able to see for miles. It [the ramp] would visually and acoustically break up the volume. (Schön 1987, page 129)

In this episode, the coach feels that the student needs to explore and develop her concept more thoroughly, noting that a ramp has thickness and that this will limit her plans to use the space underneath the ramp; he urges her to draw sections. However, he does not justify this advice; as Schön puts it, he does not reveal "the meanings underlying his questions" (Schön 1987, page 132). Schön regards this as a hopeless confrontation in which no progress can be made on the particular design project or on the larger project of understanding how to design. Both the student and the coach are willing to act publicly and to share actions, but they do not reflect enough on their own and one another's values and objectives and on their interpersonal dynamics.

Reflection is not always comfortable; it entails consideration of one's own competence, thereby opening up the possibility of recognizing one's inadequacies or mistakes. Nonetheless, designers regularly create many opportunities for reflection, for example, organizing design, reviewing meetings, or building prototypes that are used in formative evaluations. Such activities promote identification and integration of different perspectives; they raise concrete and detailed design issues to guide further work. In this way they help designers to reflect on the work they have already done. But they do not evoke reflection *in the context of doing design*. Design reviews and formative evaluations are ancillary activities that must be coordinated with the design itself.

Scenarios help designers to reflect about their ideas in the context of doing design. The narrative is written to evoke an image of people doing things, pursuing goals, using technology in support of these goals. The story enables author and readers to empathize with the people in the situation; this in turn provokes questions about motivations, intentions, reactions, and satisfaction. For example, in the example scenario from Table 48.1, is it valuable for Jerry to discover a specific code issue of concern to the employees? What is the effect of reviewing the discussion of visual analytics in the midst of other unrelated posts? How important is it to also discover the more personal information, for example, regarding the company softball team or the manager's new baby?

Scenarios promote reflection and analysis in part because the human mind is adept at overloading meaning in narrative structures, both in generation and interpretation, as illustrated by the remarkable examples of dreams (Freud 1900), myths (Lévi-Strauss 1967), and folktales (Propp 1958). It is well known that when people communicate, they rely on the *given-new contract* (Haviland and Clark 1974): they assume or allude to relevant background information, then present what is novel. This normative structure eases both the generation and interpretation of narratives.

Schön (1983) describes design as a "conversation" with a situation comprised of many interdependent elements. The designer makes moves and then "listens" to the design situation to understand their consequences:

> "In the designer's conversation with the materials of his design, he can never make a move that has only the effects intended for it. His materials are continually talking back to him, causing him to apprehend unanticipated problems and potentials." (page 101)

When a move produces unexpected consequences, and particularly when it produces undesirable consequences, the designer articulates "the theory implicit in the move, criticizes it, restructures it, and tests the new theory by inventing a move consistent with it" (page 155).

Scenarios often include implicit information about design consequences. Considering again the scenario in Table 48.1, if the microblog solution will rely on a popular social media service like Twitter, the participating employees would need to do no additional work to create information useful to Jerry. At the same time, the use of Twitter also means that Jerry will be able to see whatever a given employee chooses to tweet, whether related to work activities or not. If instead a new tool is created (e.g., a company-hosted microblog), employees may feel they are being asked to do extra work to share their updates; the posts are more likely to provide useful information about current project activity; and Jerry is less likely to encounter personal or social updates. Furthermore, microblogging in general can introduce less positive consequences; with 30 employees to visit, Jerry may find it too tedious to scan the many posts that they have generated. These tradeoffs are important to the scenarios, but often it is enough to imply them (this is an aspect of the roughness property discussed earlier).

There are times, however, when it is useful to reflect more systematically on such tradeoffs by making them explicit. If Jerry finds that Twitter logs for the 30 people are simply too long or diverse to browse and he gives up on his goal, the scenario ends in failure. As a designer, it is important to consider when and how such failure scenarios may occur. In SBD, designers analyze and record the important tradeoffs in each scenario under development, so that they can understand, address, and monitor both the desirable and the undesirable consequences of proposed design moves.

Table 48.3 illustrates how the tradeoffs implied by a scenario (including those that arise through "what if?" reasoning)

TABLE 48.3
Tradeoff Analysis of the Scenario from Table 48.1

Browsing remote colleagues' microblogs prior to making a business visit...
+ Increases the common ground between the visitor and the remote colleagues
+ Leverages any current blogging practices of the employees who are to be visited, along with the microblog reviewing practices of the person planning the visit
− But employees who do not like to microblog, or who do so infrequently, may be ignored
− But the number of posts may be large, with considerable content that is irrelevant

can be captured through *claims analysis*. Features of a scenario are extracted and analyzed with respect to hypothesized positive consequences (upsides, shown in the table with a +) and negative consequences (downsides, shown with a –). Each feature and its upsides and downsides constitutes a *claim*. Depending on the level of specification in the scenario, the features that are analyzed may be either general in nature (e.g., mentioning microblogs as a general technique) or more specific (e.g., emphasizing the formatting of Twitter feed displays). As the analysis takes place, it is important to consider variations of the scenario to develop as balanced a view as possible of the consequences for users. For instance, while the upsides in Table 48.3 capture some of the basic motivation for reviewing microblogs, the downsides are revealed by asking questions like "what if some of the employees never participate in blogging?" and "what if all employees blog many times each day?".

Scenarios and the tradeoffs they imply can help designers move within a design space along a more deliberated path, namely away from or toward specific user consequences (Carroll and Rosson 1991). For example, a design team might decide to leverage employees' pre-existing Twitter practices rather than building a new tool, and instead design a mechanism for summarization to address the information overload that comes from digesting the many small and diverse personal posts. Alternatively, the team may decide that a better solution will be to design a private company-specific microblog service, because it will be more effective at evoking detailed and work-relevant posts, while at the same time recognizing that this may minimize posts with personal content.

Scenarios of use are multifarious design objects; they can describe designs at multiple levels of detail and with respect to multiple perspectives. In this way, they can help designers reflect on several aspects of a problem situation simultaneously. The scenario in Table 48.1 offers a high-level task view, but any scenario can be elaborated to include the moment-to-moment thoughts of its actors to provide a detailed account of their cognitive processing or to explore their individual actions and reactions to convey a detailed functional view. They might also be elaborated in terms of the hardware or software components needed for implementing the envisioned functionality (Rosson and Carroll 1995; Wirfs-Brock 1995). Each of these variations in resolution and perspective is a permutation of a single underlying scenario. The permutations are integrated through their roles as complementary views of the same design object.

Using scenarios in this way makes them a more powerful design representation. They allow the designer the flexibility to develop and analyze key usage scenarios in great detail, for example, to describe core application functionality while merely sketching less critical scenarios. At the same time, designers are able to switch among multiple perspectives, for example, directly integrating usability views with software views. Such a flexible and integrative design object can help designers manage the many interdependent consequences implied by design moves (Rosson and Carroll 2000a).

48.2.4 Potential Pitfalls in Scenario-Based Design

While scenario envisionment and analysis can address many of the concerns of solution-first design, a design process centered on scenarios raises its own tradeoffs. The concreteness and work-orientation that make scenarios effective as user-centered design representations may also introduce their own bias into the process, as designers come to identify with and optimize their ideas for particular actors or activity contexts—the very characteristics that make a story realistic and evocative may also lead designers to adopt too narrow a view. The analysis of consequences implied by a scenario (as in Table 48.3) helps to create a more balanced view of current design ideas, but at the same time it may lead to a focus on incremental changes to their ideas (e.g., to address a perceived downside) rather than to consider more innovative or transformational ideas. Also, like any design process that focuses on largely textual representations, a scenario-based process (with its associated analysis and illustration) can produce an unwelcome documentation burden, as designers may find themselves maintaining and evolving a large set of design scenarios at varying stages of refinement. In the next two sections we consider frameworks, design tools, and other methods that are aimed at reaping the benefits of SBD while also helping to manage costs such as these.

48.3 SCENARIO-BASED DEVELOPMENT

The concrete and work-oriented character of scenarios makes them an effective representation for human-centered design activities, particularly when these activities include participation by end-users or other stakeholders (Carroll et al. 2000; Chin, Rosson, and Carroll 1997; Muller 1992; Muller et al. 1995; Karat 1995; Karat and Bennett 1991; Rosson and Carroll 2002). Scenarios can be quickly developed, shared, and revised; they are easily enriched with sketches, storyboards, or other mock-ups (Erickson 1995; Kyng 1995). A scenario of use can be directed at many concerns in system development, including documentation design and object-oriented software design (Carroll 1995; Carroll 2000). Given these many virtues, it is no surprise that scenarios are pervasive in software design and development (Rosson, Maass, and Kellogg 1988; Weidenhaupt et al. 1998). In this section, we expand on the view that scenarios are a user-centered design representation, introducing a programmatic framework for employing scenarios of use in interactive system design (Carroll 2000; for a comprehensive presentation of these SBD methods, see Rosson and Carroll 2002).

The framework summarized in this section incorporates scenario-based analysis and design into all phases of system development, from problem analysis through usability evaluation and iterative development. We build on the general rationale for SBD described in Section 48.3, but at the same time show how to make the impacts of scenario-based reasoning comprehensive and systematic. The overall process is one of usability engineering, where the scenarios support continual assessment and elaboration of the system's usefulness, ease of use, and user satisfaction. The aim is to develop a rich understanding of current activities and work practices and to use this understanding as a basis for activity transformation.

Figure 48.1 provides an overview of the scenario-based development framework. We assume that system development begins with an initial business case, technology exploration vision or charter, even though the design team's "plan" at this point may be quite sketchy and non-binding. The starting vision motivates a period of intense analysis during which the current situation is examined for problems and opportunities that might be addressed by available technologies. The analysts' understanding of the current situation is synthesized and communicated in problem scenarios and claims. Problem scenarios describe prototypical stakeholders engaged in meaningful activities; the claims enumerate features of the current situation that are understood to have important consequences—both positive and negative—for the scenario actors.

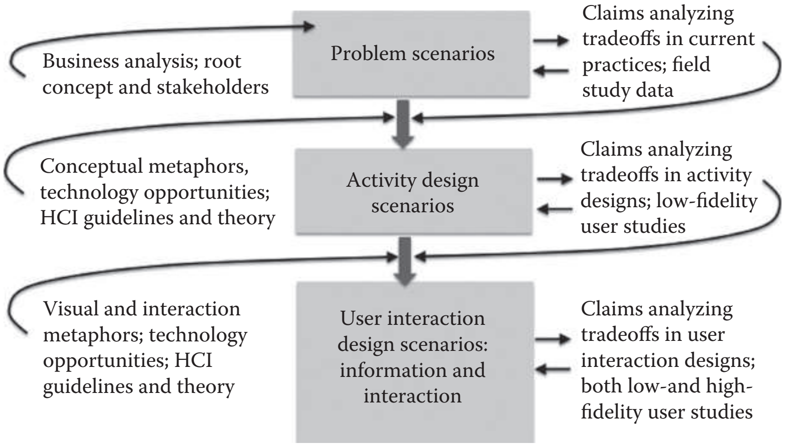
Problem scenarios are transformed and elaborated through several phases of iterative design. Design envisionment is inspired by both metaphors and technology features, while also constrained by knowledge of interactive system design. Each set of scenarios is complemented by claims that analyze the possible positive and negative consequences of key design features. Claims analysis leads designers to reflect on the usage implications of their design ideas while the ideas are being developed.

SBD is mediated by evaluation throughout development. Each narrative serves as a test case for analytic evaluation; each claim hypothesizes usability outcomes for one or more test cases. As they become concrete enough to convey to prospective users, design scenarios are evaluated more directly in empirical usability studies. In these the set of claims are used for mediated evaluation, wherein the hypothesized usage impacts are operationalized and tested explicitly (Scriven 1967). The empirical findings are interpreted with respect to the ongoing claims analysis, refining or redirecting the design efforts. We turn now to a brief example illustrating the key elements of the framework.

48.3.1 Problem Analysis

A challenge for any software development project is identifying the complete and correct set of requirements (Brooks 1995). Many system requirements are functional, addressed by the actual services and information provided by the final system. Other requirements are nonfunctional, for example, the measured quality of the software implementation or user interactions, or pragmatic features of the system development process like schedule, cost, or delivery platform (Rosson and Carroll 2000b; Sommerville 1992; Sutcliffe and Minocha 1998). In SBD, we express an initial high-level view of requirements as a *root concept* (Table 48.4). The root concept enumerates key aspects of the team's starting vision; it is used to guide further analysis and elaboration of system requirements.

Table 48.4 contains a root concept for the business use of microblogs, the design example that we will use to illustrate the SBD framework (Rosson and Carroll 2002). The starting vision and rationale in this case are quite intuitive: there are



Problem scenarios
Business analysis; root concept and stakeholders
Claims analyzing tradeoffs in current practices; field study data
Activity design scenarios
Conceptual metaphors, technology opportunities; HCI guidelines and theory
Claims analyzing tradeoffs in activity designs; low-fidelity user studies
User interaction design scenarios: information and interaction
Visual and interaction metaphors; technology opportunities; HCI guidelines and theory
Claims analyzing tradeoffs in user interaction designs; both low-and high-fidelity user studies

FIGURE 48.1 An overview of the scenario-based design framework. Scenarios serve as a central representation throughout the development cycle, first describing the goals and concerns of current practices in the problem domain that are successively transformed and refined through an iterative design and evaluation process.

TABLE 48.4
Root Concept for a Microblog Service Intended to Support Workgroup Updating

Component	Contribution to Root Concept
High-level vision	Employees microblog regular small updates about work-relevant activities
Basic rationale	Effort of microblog is small; a browsable and shareable activity log is created as a side effect of the posting activity
Stakeholder goals	
Team members	Short messages easy to create, read/post does not distract
Remote colleagues	Easy to "look in on," increase awareness of remote colleagues
Team managers	Monitor reactions, concerns, interactions among employees
Starting assumptions	Leverage existing practices with social media; incremental and participatory development process

advantages to staying aware of colleagues' activities, especially when these are related to one's own business goals, and the cost of creating or reading any single microblog item is relatively small. As a side effect, the blogs are archived over time, potentially creating a long-term record that can be used in support of other tasks.

The root concept also documents the design team's shared beliefs about the project's major stakeholders. A *stakeholder* is any person or organization who will be affected (either positively or negatively) by the system (Checkland 1981; Muller 1991). It is important to take a broad view of stakeholders, particularly early in problem analysis, so that appropriate individuals and groups will be represented in the analysis activities. In the example, we consider several different classes of employees likely to be affected by the microblog, so that we can consider their distinct goals with respect to system use—an employee may enjoy posting successes and failures, particularly if it provokes help or consultation from peers. Remote employees will appreciate an ability to "peek in" on project groups or individuals of interest (as in Jerry's case). Management may find the posts useful in detecting team issues in advance, developing summaries for group efforts, and so on.

Although the emphasis of SBD is on analysis and iterative development of useful and usable functionality, a range of nonfunctional concerns may also constrain development. These are documented as starting assumptions in the root concept. In our example, we assume that the microblog tool will attempt to leverage any existing habits the employees have with social media (e.g., Facebook, Twitter) and that it will be developed through a participatory process that engages all stakeholder groups.

The root concept sets up a framework for the designer to investigate current practices related to workplace updates and ongoing awareness. This might involve fieldwork, for example, observations of a workgroup for some period of time that documents the different forms of informal communication taking place; it might also appeal to existing empirical works that have documented workplace behavior patterns (Kraut et al. 1993). At times the analysis may be quite modest, perhaps a quick survey of several workgroups aimed at eliciting descriptions of information-sharing activities or a series of semi-structured interviews with both co-located and remote team members and their managers. Important complementary sources of information during this process are any tools or other artifacts used in an activity—for instance a form used to document weekly progress, regular e-mails that are sent from manager to team members or vice versa, specific tools used for filing or sharing project information, and so on. Such artifacts are an excellent source of implicit information about stakeholders' current values and activities (Bødker 1991; Norman 1988; Rosson and Carroll 2002).

Field studies of current practices generate rich and diverse data about the specific needs and opportunities associated with the stakeholders identified in the root concept. To direct these data systematically toward design efforts, a more abstract representation of themes and relations is useful. For example, an affinity diagram (the analysis team posts and organizes individual observations; Beyer and Holtzblatt 1998) can be helpful in discovering general themes. Other useful techniques include diagrams of the stakeholder relationships, hierarchical task analysis of central activities, and summaries of how collected artifacts support group activities (Rosson and Carroll 2002; Chapter 2).

In SBD, the prime outcome of problem analysis is a set of problem scenarios and claims. Each problem scenario is a narrative of current practices that offers a synthetic view of the actors, themes, relationships, and artifacts discovered in the fieldwork. These scenarios are not design-neutral, however. Even during early analysis activities, the team holds some vision of how technology might enhance current practice. The fieldwork and related analyses will inevitably be colored by this vision (Carroll et al. 1994). If the team fails to establish a vision or creates inconsistent or contradictory visions, this too will influence requirements analysis, but in a less positive fashion.

An effective technique for generating problem scenarios is to first describe a set of hypothetical stakeholders—individuals who represent a synthesis of the people studied during the fieldwork, perhaps supplemented by demographic or market analysis data. It is important to create a rich but realistic view of these individuals, because they will form the basis for describing and later transforming current activities and experiences (see the discussion section for how these descriptions relate to the use of personas). As we continue the example, we focus on both Jerry, the company employee who is planning a training visit, and Susan, the manager of one of the groups he will be training.

TABLE 48.5
Problem Scenario Describing How Jerry Currently Uses Twitter to Prepare for His Visits

Problem Scenario: Jerry Visits a Remote Company Site to Carry Out a Training Session

Jerry is a training professional who has worked for human resources in VisionWay for 15 years. Over the years, he has met and gotten to know many VisionWay employees distributed at the company's five locations and always looks forward to meeting with them as part of the training sessions he leads. Next week, he will be conducting a session at their northeast lab for three software development groups. One of them is managed by Susan, a hard-working and talented young woman who is quickly moving up the technical management chain.

Before any training session, Jerry likes to find out what the participants have been working on lately, so that he can quickly establish common ground and use their current work as examples in his training. He knows that many VisionWay employees use Twitter on a regular basis, so he decides to review their Twitter feeds instead of sending out a bunch of e-mails. After quite a bit of scanning, he locates a couple of brief posts from two of Susan's group members expressing frustration with some software; he infers that they are managing consistency within their visual analytics tool. Along the way, he also discovers that some of the staff joined a co-ed softball team; he enjoys their light-hearted teasing of other teams. In Susan's blog, he sees that she just had a baby and is now only returning to work; he reads on to hear about her experiences at work-baby balancing and looks at baby pictures. In the end, he has just a vague sense of groups' technical issues, not enough to work up any examples for his training materials.

During his visit, the training sessions go well, because he spends time at the beginning to find out more about the versioning problem as well as problems plaguing the other two groups. He does his best to adapt his examples on the fly; he teases the softball players during the breaks, though he notes that a couple of the players are taken aback when he explains how he knows about this. Like the others in the room, he smiles and nods when Susan jumps up quickly to leave 15 minutes early.

TABLE 48.6
Two Claims Analyzed from the Problem Scenario Presented in Table 48.5

Discovering audience members' recent or ongoing technical concerns prior to organizing and delivering a software training session…

+ Enables the trainer to adapt his or her learning materials to the target audience
+ Conveys to the audience that the trainer is interested in hearing about and addressing their problems

– But the training professional may misunderstand or confuse a specific technical issue in the examples s/he develops

Browsing employees' Twitter feeds for information on their current situations…

+ Leverages well-established microblogging practices at no extra cost to the employees
+ May reveal social or personal information that enhances feelings of connection
+ May include emotional modifiers that help to prioritize issues of most concern

– But employees may be uncomfortable if they learn that their public Twitter feeds are being used for work-related purposes
– But employees' Twitter feeds may convey a variety of updates and pointers intended for a broad and diverse audience, making the work-related posts difficult to find

The scenario in Table 48.5 describes some aspects of maintaining collegial relationships across distance; it describes a typical business visit activity that can be used to communicate findings from fieldwork. Problem scenarios like this may be based directly on a particularly common or critical episode or they may be entirely synthetic. The goal is to introduce and contextualize the themes and relationships that will guide subsequent design work. This particular story combines a view of tech-savvy software developers with issues related to business travel—for example, the fact that visits are scheduled for a particular place at a particular time; there is a protocol for arriving, orienting oneself, being welcomed and integrated into a group, participants' ability to adapt their discussion in real time, and so on.

As for any scenario, the themes and relations implicit in a problem scenario can be made more explicit and open for discussion by analyzing them as claims (Table 48.6). At this point, the claims are analyzed by identifying features of the problem scenarios that have notable consequences for the actors' experiences. This is an instance of analytic evaluation and as such is clearly guided by the expectations and biases of the evaluator. A more systematic evaluation can be obtained by asking questions of the scenario that are guided by cognitive or motivational theories of human behavior (Carroll and Rosson 1992; Polson et al. 1992). The first claim explores the upsides and downsides of gathering the advance information (i.e., independent of the technology used), as this is likely to be a driving claim for the ongoing design work. Although it seems obvious that this advance preparation will be useful, it is important to acknowledge possible downsides, as they may be things that design work can remove or minimize (e.g., are there ways to make it more likely that the browser can grasp the terminology/issues he or she encounters in a post? Are there ways to increase the likelihood that the most important information will be the most obvious or easiest to find?) The second claim focuses more specifically on the discoveries made regarding Twitter use, for example, upsides and downsides of the emotional and personal content that is prevalent in Twitter and the information overload experienced by the task of browsing many feeds (Zhao and Rosson 2009).

An important characteristic of claims analysis is that it includes both positive and negative consequences. During problem analysis, there is a tendency to focus on the difficulties or concerns of current practice, for example, as observed in activity breakdowns or contradictions (Bødker 1991; Kuutti 1995; Kyng 1995; Nardi 1996). In contrast, designers tend to focus on the likely benefits of new features. Claims analysis imposes a balanced view of problems and opportunities. With respect to understanding users' requirements, taking a balanced view like this makes us aware of aspects of the current situation that are already working well. With respect to design envisionment, it forces us to consider side effects or other undesired impacts of changes to a situation.

Problem scenarios and claims are a central outcome of problem analysis in SBD. Note that these scenarios do not convey software requirements in the traditional sense of the term—they are not a specification of software features that are required. Instead, they outline a set of criteria for design requirements; whatever solutions designers propose should address the positive and negative user impacts expressed in the scenarios and claims. For instance, a microblogging solution might be "required" to reinforce the advantages of employees' existing blogging habits, but at the same time address the disadvantages of information overload. This is quite different from specifying that it will use the Twitter system. Specific features of the solution—at many levels of detail—are then identified, elaborated, evaluated, revised, or discarded in an iterative process.

48.3.2 Activity Design

Design requirements emerge and are refined throughout system development (Brooks 1995). But at some point, a team understands enough about project stakeholders and their needs that they can make specific design proposals. Indeed some projects are so over-determined that system functions are specified in advance and problem analysis consists simply of adapting these requirements to users' characteristics, work settings, and preferences. In SBD, the initial step toward specifying a design solution is made by envisioning how current activities might be enhanced or even completely transformed by available technologies. We deliberately minimize attention to the concrete steps of user interaction at this point, emphasizing the basic goals and motivations of the new activities (see also *essential use cases* as described by Constantine and Lockwood 1999).

SBD is *activity*-centered—we analyze current practice at the level of meaningful activities and build from this to new activities (Bertelsen and Bødker 2003; Kuutti and Arvonen 1992; Norman 2005). A danger in this is that the designers will focus too much on how goals are pursued in the current situation and on understanding and responding to people's current expectations about their tasks and about technology. Thus, to encourage consideration of new options and insights, we deliberately expand the "design space" when envisioning new activities. By design space, we mean the array of possible concepts and technologies that might be relevant to the problem domain, along with some analysis of what these options might bring to the design solution (MacLean, Young, and Moran 1989; Moran and Carroll 1996).

Table 48.7 exemplifies two techniques useful for exploring design alternatives. The upper part of the table shows how different conceptual metaphors evoke contrasting views of stakeholder activities. Metaphors are often used deliberately in user interface design with the hope that users will recruit them in reasoning by analogy about what a system does or how it works (Carroll and Thomas 1982; Carroll, Mack, and Kellogg 1988; Madsen 1994). Here we emphasize the role of metaphors in helping designers "think outside the box" (Erickson 1990; VerPlank 1988). Addressing real world activities and concerns is crucial to effective system design, but it is often metaphoric thinking that promotes the insights of truly creative design.

TABLE 48.7
Using Metaphors and Existing ICT Paradigms to Reason about Activities

Activity Design Features Suggested by Metaphors for Workplace Microblogging	
Hallway water cooler	Casual, easily expandable shared space; good visibility; both talk and whispers
File cabinet	Flexible system for adding, ordering, and removing items; labeled containers
Code review	Organized and issue-driven with one or more supporting artifacts; technical content
Public lecture	Content predesigned and rehearsed; multimedia; large audience; one-way channel
Activity Design Features Suggested by Information Technology	
Twitter	Content is public or by subscription; handles used for call-out to individuals; strict length limitation
Telephone	Person to person; real-time communication; utterances are transient with no archival records
E-mail listserv	List owner; hidden audience; browsable archives; posts include meta-data like sender, date, subject
File sharing	Controlled access to content items; hierarchical structure; automatic log of item uploads, downloads, edits, and so on.

An analysis of current information and communication technology (ICT) provides another approach to metaphoric thinking. When thinking about ICT, the analogy is with the classes of software and devices that already exist (e.g., web information systems, e-mail, database packages). At the same time, taking an ICT view helps to direct the design thinking back to the pragmatic concerns of software development, by enumerating possible technologies and how they might play a role in the solution. Of course, the ICT analysis will be very much influenced by starting assumptions about tools and infrastructure (see Table 48.3); for instance, if the client organization already hosts a well-established online discussion system, the designers may be expected to use that as a starting platform.

The exploration of metaphors and technology does not generate a new activity design. Rather it provides a set of lenses for discussion. The team might consider what it would be like to have a company microblog tool that shares some features with a hallway water cooler (e.g., employees can "see" when others are commenting; there is a tendency for small groups to "gather" at the same time) or with a file cabinet (e.g., posts with different content are put into different "containers"; the containers are organized in some way, perhaps using the alphabet or a hierarchy). Similarly, they may contrast the characteristics of Twitter (e.g., the tool invites personal and social content as well as work-related posts) versus e-mail (e.g., posts can be broadcast in listserv fashion, perhaps to organizational entities like a workgroup). These creative and divergent discussions form a backdrop for the convergent process of scenario envisionment.

The writing of activity scenarios is a synthetic process influenced by many factors. In some cases, one or more problem scenarios may serve as a starting point, contributing a realistic context and user goals for the overall activity. The problem scenario claims guide design reasoning; in SBD, a general heuristic is to maintain or enhance the upsides while minimizing or removing the downsides (Carroll and Rosson 1992). The metaphors and technology exploration inspire ideas and comparisons, while the claims offer constraints to be satisfied. The designers' knowledge of HCI and of interactive system design more broadly also provide important guidance; for example, knowing the relative affordances of different computer-mediated communication channels, understanding the motivational differences in discretionary versus organizationally mandated software use, and so on.

An activity design scenario for Jerry's business trip appears in Table 48.8. It reuses the hypothetical stakeholders and activity context from the problem scenario. In fact, the narrative is quite parallel to the problem scenario, but rather than envisioning the use of Twitter, it proposes a new company-hosted service. The effect of different metaphors can be seen: similar to drawers a in file cabinet, posts can be submitted with different "tags" that serve a grouping function; the idea to use a specialized "fun stuff" tag reflects the effort to promote the personal exchanges observed at a water cooler and in Twitter feeds. Other metaphors and technology are likely to affect other scenarios; for instance, we have not yet considered scenarios for the remote employees making the posts or for the managers who both make and perhaps later review the posts. Note that the scenario also addresses the claim documented in Table 48.7, in that it focuses on maintaining the benefits such as unobtrusive review and leveraging of staff microblog habits, while also addressing downsides like finding relevant content, and a way to include pointers to additional information about specialized content.

Even though activity scenarios are intentionally quite abstract, the designers can begin to evaluate them with respect to their usage implications. One way to do this is with participatory design sessions (Carroll et al. 2000; Muller 1992; Kyng 1995) that focus on how well the proposals suit stakeholders' needs. Such sessions can be structured by claims analyzed for the activity designs, asking stakeholders to weigh the pros and cons of the designs through "what if" discussions (Chin, Rosson, and Carroll 1997).

Two sample claims analyzed from the activity scenario appear in Table 48.9. Not surprisingly, they bear some resemblance to those extracted from the problem scenario; just as SBD promotes scenario elaboration and transformation, the corresponding claims often will document an evolution in the underlying design rationale (DR). For instance, the benefits

TABLE 48.8
Possible Activity Design for Jerry's Preparation and Business Visit

Activity Scenario: Jerry Visits a Remote Company Site to Carry Out a Training Session

<Background on Jerry and his upcoming visit…>

Before any training session, Jerry likes to find out what the participants have been working on lately, so that he can quickly establish common ground and use their current work as examples in his training. He decides to review everyone's posts in the new company-specific microblog tool instead of sending out a bunch of e-mails. He quickly locates the microblogs from the Seattle site and within these the three groups he will be visiting. Using the tags created by the employees he is able to grasp a few of the key issues they have been wrestling with, with plenty of evidence for the frustration they are feeling; he even finds links in some of the posts to code examples that he can incorporate into his training talk. Just as he starts to close down, he notices a "fun stuff" tag. Curious, he explores and learns that some of the staff have joined a co-ed softball team and that Susan just had a baby; he reads on to hear about her experiences at work-baby balancing and looks at baby pictures.

During his Seattle visit, the training sessions go well as he is able to introduce and discuss project-relevant examples from the start of his presentation. Like others in the room, he smiles and nods when Susan jumps up quickly to leave 15 minutes early.

TABLE 48.9
Activity Claims That Analyze Open Issues Raised by the Design Scenario

Using a set of tags to browse work-related microblogs when organizing and delivering a training session…

+ Enables the trainer to adapt his or her learning materials to the target audience
+ Conveys to the audience that the trainer is interested in hearing about and addressing their problems
+ Offers a summary view to the reader via the tag name and grouping structure
− But the training professional may misunderstand or confuse the meaning of a tag
− But tag creation or selection may be too costly for microblog authors to adopt

Browsing employees' company-hosted microblogs for information on their current situations…

+ Leverages well-established microblogging practices
+ Increases the likelihood that work-relevant feeds will be discovered
− But the specialized tool adds an extra task for employees to remember and enact
− But these private feeds may focus entirely on work updates, and meaningful social or personal updates may be missed

of unobtrusive preparation for Jerry are still in place, but now some of the downsides noted for weeding through many non-work tweets have been addressed. In place of that downside, we have noted the likelihood that personal posts will be less likely, even though the scenario envisions a "fun stuff" tag to encourage such content. We also note that by introducing a new company-specific social media tool such as this, the company is implicitly introducing a new "reporting" task for employees to consider and manage on an ongoing basis. These downsides play an important role, as they raise issues that should be discussed and either accepted as necessary costs or addressed through additional design ideas as the project continues.

It is important to note how much progress can be made even at this very early level of envisioning activities. The narrative in Table 48.8 is concrete and evocative; designers or their clients can readily understand what is being proposed and begin to consider the relevant pros and cons. Although the influence of the metaphors and information technology can be seen, few details are provided about how posts and tags will be created or presented or how employees will access and interact with this information. At this point, the scenario is "just talk"; indeed if they are shared and discussed over an interactive medium, it might quickly be extended or revised as part of a real-time design review and discussion.

48.3.3 User Interaction Design

As design continues, tentative decisions are made about the design direction, but now starting to explore the options and tradeoffs associated with the details of the user interaction. As for activity design, we begin by exploring useful metaphors and technology. The metaphors applied to user interaction design often overlap with those from activity design, but the emphasis shifts to how users will see, understand, and respond to the system; the concerns of this phase are similar to those in the "gulfs of evaluation and execution" discussed by Norman (1986). For instance, the three metaphors of water cooler, file cabinet, and code review suggest these design ideas:

- *Water cooler*: posts are more available to people who are "there," perhaps because they appear in larger fonts or arrive with an auditory alert; some posts may be unavailable even to those currently online, as in a whisper perhaps there is a mechanism for a temporary "personal/private" tag; individuals can easily arrive or leave the shared posting space but their coming and going is indicated through some sort of alert (e.g., akin to footsteps).
- *File cabinet*: posts that fall into the same group appear under a label that can be seen when adding or reading new content; authors may be allowed to "grab" a post and move it to another labeled group.
- *Code review*: once a sufficient number of colleagues are "listening," a particular person can "take the floor," with the result that attention is directed to his/her posts in lieu of making other comments; this series of posts may refer to one or more secondary artifact that are being "presented"; other attendees can reply or question a specific post or group of posts.

Technology options explored at this phase might include hyperlinks (icons or other controls used to connect to other posts or external documents); auditory cues (earcons that signal the initiation of a "meeting," or the arrival/departure of colleagues as they activate the microblog tool); and a variety of user interaction control widgets (e.g., a gauge used to set a "whisper" level for a post).

Ideas such as these are discussed and synthesized under the general guidance user interaction design experience and guidelines. Information and interaction design possibilities may be "tried out" in the context of various activity design scenarios, with attention directed at claims analyzed in earlier phases as well as new features and consequences. Does the design reduce the cost of creating or browsing tag structures? Does someone who chooses to post about an issue in more depth feel s/he has an audience? Do the privacy controls encourage more informal banter and exchange? Ongoing and creative design inquiry like this—and the scenarios that provide a real world context for the reflective process—is a hallmark of SBD.

One vision of user interaction for the activity design appears in Table 48.10. For simplicity, we elaborate just the tag browsing subtask. The scenario offers a view into a company microblog that includes a hierarchical information display (org chart) as well as a network display (tag cloud) that can be used to access relevant content. It assumes that posts are browsed as normal in a sequential fashion. It also envisions some specific user interaction details that support sensemaking and user action, for instance an overview of the group's blogging activity positioned in a salient "starting" position and the use of font size and shading to convey popularity and recency of tags.

In parallel with the exploration of these or other user interaction details, the design team would use claims analysis to document the pros and cons raised by the more specific proposals. Although we will not elaborate this example any further in the interest of simplicity, it is clear what some of these tradeoffs might be: a header provides an overview but takes space away from the main content, which is the posts; a tag cloud that pops up over the main display can be a visual distraction and adds window management as a subtask; seeing all the tags at once may be overwhelming (e.g., if there are many) and lead to feelings of information overload. These sorts of issues would be tracked and discussed as the scenario elaboration process continues.

Ultimately, user interaction design comprises all aspects of how the activities' objects and actions are rendered and executed during users' activities. In many design projects, this may include special attention to the needs of new or inexperienced users. For instance, suppose that this was Jerry's first use of a microblogging system. How would he know to

TABLE 48.10
Piece of a User Interaction Scenario for Jerry's Use of the Microblogging Tool

User Interaction Scenario: Jerry Visits a Remote Company Site to Carry Out a Training Session

<Background on Jerry and his upcoming visit, goals and decision to review the posts…>

Jerry starts up the company microblog tool, which by default opens to his own workgroup. He calls up an org chart, pans the map to locate the Seattle lab, then finds Susan's group (her name and group title appear when he hovers over her node with his mouse). When he double-clicks to open her group, all posts from her staff appear, with most recent posts at the top of the list. In the header, he can see summary information, including the number of blogs in the past week, the number of staff who have contributed, and the top five tags that have been active over that time.

Jerry knows he can access subsets of tags by selecting any of the top five but instead decides to first get an overview by asking for a tag cloud. This causes a secondary display to pop up, showing all tags used by this group. The size of the tag shows its overall use and its shading (more or less saturated) shows how recently it has been used. He can quickly see that several tags related to graphics transformations and data consistency are a recent popular topic, so he decides to begin with these feeds. He can open each subset by double-clicking its tag in the cloud. This helps him to grasp the key issues they have been wrestling with, with plenty of evidence for the frustration they are feeling; he even finds links to code examples he can incorporate into his training talk. Before closing the group, he takes a bit of time to find and browse a few more personal blog sets, including the "fun stuff" and "family news" tags.

<Ending that conveys the benefits of the microblog browsing Jerry has done, including helpfulness of the personal information>

get an overview via a tag cloud? The header view might need some special indication, perhaps as simple as a "More…" link next to the top five tags, to invite such a goal. It can be useful to create "user help" versions of design scenarios, where an actor(s) is assumed to have little or no experience using the system. In SBD, help prompts and similar guidance for new users may also be inspired by metaphors (e.g., a coach) and technology (e.g., online tutorials, animated demonstrations) (Rosson and Carroll 2002; Chapter 8).

48.3.4 Evaluation-Centered Iterative Design

Like most user-centered design frameworks, SBD assumes that usability evaluation begins early and continues throughout design and development and that a variety of design representations will be evaluated. For instance, the process of creating user interaction design scenarios often includes the creation of user interaction prototypes; these in turn can be used for quite formal usability testing (e.g., representative users carry out representative tasks on early operational prototypes). Formal evaluations require sufficient progress on a design to enable construction of a prototype, though of course user interaction prototypes can be created in special-purpose languages or tools or may be low-fidelity prototypes constructed of cardboard and paper (Muller 1991; Virzi, Sokolov, and Karis 1996).

Starting in the very early phases of design, user feedback may be obtained in informal participatory design sessions (Muller 1992). It is quite possible to include users in discussion and analysis of problem scenarios and in initial envisionment of activity scenarios (Chin, Rosson, and Carroll 1997). The design ideas are also subjected constantly to analytic evaluation through claims analysis and other design review activities (e.g., usability inspections or cognitive walkthrough; Nielsen 1995; Nielsen and Mack 1994; Polson et al. 1992). All these activities yield formative evaluation feedback that guides changes and expansion of the design vision.

SBD builds on Scriven's (1967) concept of *mediated evaluation*. In mediated evaluation, empirical data are collected (Scriven calls this "pay-off" evaluation), but the materials and methods of the empirical tests are guided by prior analytic evaluation. The analytic evaluation may have many different components, for example, an expert-based inspection or perhaps a cognitive model constructed for a particularly complex or critical interaction sequence (Gray, John, and Atwood 1992; Kieras 1997). In SBD, claims analysis is used to mediate empirical evaluations. Claims written during scenario generation and discussion document the usability issues thought to be most likely to influence users' success, failure, and satisfaction; thus, the claims are used as a skeleton for constructing and administering user tests. In fact one view of a claims set is as a series of usability hypotheses that can be assessed empirically; claims also suggest *why* a design feature may have a particular impact on users' experiences.

Rosson and Carroll (2002) describe how to use scenarios and claims in a systematic way to generate *usability specifications*, a set of baseline tasks with performance and user satisfaction targets that can be assessed in an iterative fashion as the system design evolves and stabilizes. Usability specifications like this have two important roles in evaluation. First, they provide concrete usability-centered objectives that serve as a management tool in system development—if a product team accepts the target measures, then a team's usability engineers are able to insist that redesign and improvement continue until they are met (Carroll and Rosson 1985; Good et al. 1986).

Second, the specifications tie the results of empirical evaluation directly to the usability issues raised during design. For instance, the user interaction scenario specified that Jerry grasps an overview of topics under discussion by Susan's team by looking at the tag cloud. This claim might be extracted as a benchmark task and used to evaluate the efficacy of various tag visualization designs, with the goal of optimizing the comprehension impacts for the user.

48.4 APPLICATIONS FOR SCENARIO-BASED DESIGN

As exemplified by books discussing scenario-based methods (e.g., Alexander and Maiden 2004; Carroll 1995, 2000), one strength of design scenarios is the many roles they can play in system development. Scenarios are accessible to many process stakeholders and as such can be a tremendous aid to project communication and coordination. Scenarios can be represented at varying levels of specificity and formality, making them an attractive medium for gradual evolution and specification of a system's functions. They can also capture important aspects of the nonfunctional constraints or requirements for a project. In this section, we briefly survey research and practice that is exploring different applications of scenarios to the problems of software development.

48.4.1 Scenarios in the System Development Lifecycle

Our example has focused on the familiar processes of requirements analysis, design, and usability evaluation, but scenario-based methods support many diverse goals in system development (Carroll 1997; Carroll et al. 1998). Product planners present day-in-the-life scenarios to managers as design visions (Dubberly and Mitsch 1992); requirements engineers gather workplace scenarios through direct observation and interviews and analyze scenarios as primary data (Antón, McCracken, and Potts 1994; Holbrook 1990; Hsia et al. 1994; Kaindl 1997; Kuutti 1995; Potts 1995).

Even if scenarios are not developed and incrementally refined as recommended in the SBD framework, they may be used at many points along the way. For instance, task-based user documentation is often structured by scenarios. Minimalist help and training provide many examples of this, such as a "training wheels" system that blocks functions that are not relevant to a paradigmatic novice-use scenario (Carroll and Carrithers 1983) or a "view matcher" that guides new programmers through a predefined scenario of debugging and modification (Carroll et al. 1990; Carroll and Rosson 1991; Rosson and Carroll 1996).

48.4.1.1 Personas and Envisionment

The concept of a persona—the envisionment and elaboration of a hypothetical target user with her own personality, needs, and preferences—was originally popularized by Alan Cooper and his colleagues (Cooper 1998; Cooper and Reimann 2003). Personas are often developed during the problem analysis or requirements specification phase of a project, as a means for understanding, expressing, and working with the goals and implied requirements of different target users. Prospective users are conveyed through detailed composite user archetypes (often represented visually, including personality characteristics) and with a context scenario that helps to anticipate user needs and expectations, so that the designers working with the personas can have as direct an experience as possible with potential users. Although it is not yet clear exactly what elements of a persona are most important in guiding or inspiring design, research does suggest that software designers find personas to be of use in the early phase of design when they are trying to understand users' needs (Vasara 2003).

An important issue discussed by Turner and Turner (2011) is the impact of stereotypes on designing with personas—that is, to the extent that personas are "concocted" from a variety of diffuse information, will the design team's own biases or wishful thinking have too great an influence? They argue that while stereotypes are often surprisingly accurate, the creation of personas without sound empirical backing should be approached as a sort of design dialectic, where contrasting frames (perhaps even using extreme or marginal stakeholders) are swapped in and out of the reasoning space to keep it lively and provocative. This recommendation is analogous to the use of "what if?" reasoning in SBD to drive the analysis of tradeoffs, in the hopes of expanding the design space beyond what is already familiar to the designers.

Clearly persona-centered design are similar in many ways to SBD, although we prefer to use the phrase "hypothetical stakeholder," emphasizing that these characters are imaginary and that they may include a diverse set of perspectives and roles in the problem situation under consideration. But like personas, SBD encourages designers to become familiar with and empathize with envisioned characters and personal attributes who are used repeatedly in the iterative process of scenario analysis, envisionment, and refinement.

48.4.1.2 Use Cases and Software Engineering

Scenarios have also come to play a central role in object-oriented software engineering (Alexander and Maiden 2004; Jacobson 1995; Jacobson, Booch, and Rumbaugh 1998; Rubin and Goldberg 1992; Wirfs-Brock, Wilkerson, and Wiener 1990). A *use case* is a scenario written from a functional point of view, enumerating all the possible user actions and system reactions that are required to meet a proposed system function (Jacobson et al. 1992). Use cases can then be analyzed with respect to their requirements for system objects and interrelationships. Wirfs-Brock (1995) describes a variant of use case analysis in which she develops a "user-system conversation": using a two-column format, a scenario is decomposed into a linear sequence of inputs from the user and the corresponding processing and/or output generated by the system. Kaindl (2000) extends this analysis by annotating how scenario steps implement required user goals or system functions.

Scenarios are promising as a mediating representation for analyzing interactions between human-centered and software-centered object-oriented design issues (Rosson and Carroll 1993, 1995, 2001). As we have seen, scenarios can be decomposed with respect to the software objects needed to support the narrated user interaction. These software objects can then be further analyzed with respect to their system responsibilities, identifying the information or services that should be contributed by each computational entity (Wirfs-Brock and Wilkerson 1989; Beck and Cunningham 1989; Rosson and Gold 1989). This analysis (often termed *responsibility-driven design*; Wirfs-Brock, Wilkerson, and Wiener 1990) may lead to new ideas about system functionality, for example, initiatives or actions taken by a software object on behalf of the user or another object. Scenarios and claims analysis are useful in describing these new ideas and considering their usability implications *in the context of use* (Rosson 1999; Rosson and Carroll 1995).

Beyond the natural relationship of scenarios to use cases, software engineers working to refine methods for agile development have found that scenarios can play an important role. Of course, agile methods have always included an important role for user stories or other narratives that serve as a flexible and evolving source of user-centered requirements. However, Lee, McCrickard, and Stevens (2009) argue for expanding this general role through more systematic use of scenarios and claims analysis; they propose the more rigorous agile method of eXtreme SBD (XSBD) and demonstrated its usefulness in a case study of a commercial product.

48.4.1.3 Functional and Nonfunctional Requirements

The general accessibility of scenarios and claims makes them an excellent medium for raising and discussing a variety of competing concerns. We have emphasized their role in conceptualizing opportunities and challenges facing the design team and in negotiating among competing options as new ideas emerge and are evaluated. Others have used these methods in a variety of domains, including children's digital libraries (Theng et al. 2002); negotiation support systems (Pommeranz et al. 2009); personal health management (Rogers 2009); and driver support systems (Tideman, van der Voort, and van Arem 2009). Swanson, Sato, and Gregory (2009) show that SBD can be adapted to discover and address the influences of different and partially overlapping cultural contexts in interactive system design. More generally, both McCall (2010) and Sutcliffe (2010) argue that claims analysis (i.e., considering pros and cons for any feature under consideration) can serve as a mechanism to promote creativity in design reasoning.

Beyond their focal concern for specifying appropriate and useful functionality for a system under design, software engineers are concerned about issues such as code reuse, programming language or platform, and so on; management is concerned with project resources, scheduling, and so on; a marketing team focuses on issues such as the existing customer base and the product cost. These diverse concerns are *nonfunctional requirements* on system development—concerns about "how" a system will be developed, fielded, and maintained rather than "what" a system will provide (Sommerville 1992). Usability goals are often specified as nonfunctional requirements, in that they typically focus on the quality of the system rather than its core functions (Mylopoulos, Chung, and Nixon 1992). The low cost of development, content flexibility, and natural language format of scenarios and claims make them excellent candidates for contrasting and discussing a range of such issues throughout the software development lifecycle (Sutcliffe and Minocha 1998). A particularly interesting case study is presented by Maiden and his colleagues (Maiden et al. 2007), wherein scenarios and associated walkthroughs were useful in discovering airport requirements that could minimize environmental impact.

Taking a more formal approach, a scenario can be modeled as a sequence of task steps and this sequence can be analyzed with respect to users' ability to perform the task under different circumstances (Alexander and Maiden 2004). For example, Gregoriades and Sutcliffe (2005) illustrate the use of Bayesian Belief Network models for assessing the reliability of human users to carry out a scenario's steps under varying environmental pressures. By noting when and where the predicted reliability fails to pass a benchmark threshold, the analysts can identify problematic aspects of a proposed scenario and contrast scenarios from alternative designs. The goals of this approach overlaps with tradeoff analysis, but it provides a more systematic and mathematical representation of design issues most likely to need attention in a design.

48.4.1.4 Evaluating Systems in Use

In SBD, a software development process begins with fieldwork that ultimately is summarized through a set of stakeholder profiles and diagrams, themes, scenarios, and claims analysis (Rosson and Carroll 2002; Chapter 2). However, researchers are currently exploring a variant of this approach in which scenarios are used as an elicitation technique for capturing current practices and reactions during the adoption and acceptance phase of a fielded system. Haynes, Purao and Skattebo (2004, 2009) report a field study of a collaborative system for product lifecycle management in the U.S. Marine Corps. They interviewed 26 current users of the system, selecting individuals representing the various organizational roles associated with system use (e.g., engineers, scientists, staff members). Their interview script was scenario-based: after eliciting information about the interviewee's work context, they asked for personal scenarios of system use. Later they transcribed the interviews and coded the scenarios to identify system features and users' apparent concerns about these features (coded as claims with upsides and downsides). The findings were summarized and shared through focus groups to refine the evaluation. The technique allowed them to collect and summarize a number of related concerns, and also to connect (and on occasion illustrate) these concerns with the organizational roles and usage context represented by the user scenarios.

As this example suggests, it is quite possible to leverage the expressive and communicative power of scenarios in various ways, even when a user-centered analyst enters a software development process that is well underway. Because scenarios are focused on the specifics of a usage context and associated user experience, they are a natural medium for "war stories" about how things are or are not working (Orr 1986). In a recent application of scenario-based evaluation, Haynes and his colleagues (Haynes, Spence, and Lenze 2009) showed that university students can write two sorts of learning scenarios at the end of a course—describing both valuable learning experiences and experiences that should be improved. The educators found that the scenario-writing was useful as a reflective activity for the students but also that the narratives were rich representations for reasoning about course improvements or redesign. When complemented by tradeoff analysis (e.g., documented as claims), such scenarios can become a powerful medium for discussing the need for change, whether aimed at the nature of people's goals and activities or to the technology that supports them.

Other researchers have been contrasting the effectiveness of claims analysis as an analytic evaluation method with other task-centered usability methods. For instance, Blandford and Artfield (2010) summarize a series of studies that compared claims analysis against the popular methods of heuristic evaluation and cognitive walkthrough. They found that claims analysis required more skill on the part of the evaluator (i.e., to recognize and document a rich set of tradeoffs for critical features of a design), it revealed issues at a deeper and more conceptual level of analysis than heuristic evaluation or cognitive walkthrough. They also stress the need to embed any evaluation task in scenarios of use that highlight "those aspects of context that will result in ecologically valid task performance" (p. 54). The work of Theng and colleagues (Theng et al. 2002) is consistent with such claims; they showed that SBD with claims analysis could be used in an intergenerational participatory design setting and were effective at directing attention to important theory-based issues.

48.4.2 Scenario-Based Design Rationale and Reuse

To this point, we have focused on the instrumental role of scenarios and tradeoff analyses in supporting the analysis, design, and evaluation activities of interactive software development. However, another potential role for SBD is building and expressing a science base for user-centered design. In this role, a system's scenario-based analyses comprise DR that can be recruited for explanation, generalization, and reuse—contributing to the theory base for user interaction design (Sutcliffe 2002). Software engineers have often used design patterns as containers of such knowledge for reuse, and recent work by Abraham and Atwood (2009) suggests that a combination of patterns with claims may be particularly effective in recognizing and working with design tradeoffs.

Carroll and Rosson (2003) use a community MOO as a design case study that illustrates the three scientific foundations of scenario-based DR: action science, ecological science, and synthetic science. The MOO's scenarios and associated claims supported action science during the envisioning process, when novel usage features were imagined in response to the real world needs and preferences of users. The DR supported ecological science by surveying and documenting salient causal features of real world usage contexts; these surveys can guide design efforts in similar activities or domains in the future. Finally, the contributions to synthetic science came through the association of interdisciplinary evidence and explanations to the claims' upsides and downsides.

A more complete analysis of scenarios and claims as theoretical material can be found in Sutcliffe's volume on Domain Theory (2002). He argues that claims in particular are an ideal abstraction for stating reusable knowledge about interaction design that is grounded in the relevant usage context. He proposes a template for developing and organizing claim-based knowledge and argues through demonstration that such a representation is reusable from one design project to another. This potential for claims as reusable design knowledge has been explored more thoroughly by researchers developing the LINK-UP claims library and scenario-based development tool (Chewar et al. 2005; Payne et al. 2003). These researchers have elaborated the claim format proposed by Sutcliffe and have been using it to collect and organize scientific knowledge about notification system design. They are currently exploring the effectiveness of the tools in teaching usability engineering concepts and skills to undergraduate and graduate students (Chewar and McCrickard 2003).

48.4.3 Teaching Usability with Scenario-Based Design

Another indirect benefit of scenario-based development is that the resulting scenarios, claims, and related design documents can support a variety of case-based learning activities. As a concrete story, even a single scenario can be evocative enough to illustrate and discuss the usage issues raised by its tradeoff analysis. A set of interrelated and successively refined scenarios and tradeoffs presents an open-ended and rich information structure for a variety of active learning experiences (Carroll and Rosson 2005a,b,c).

Over the past few years, we have been collaborating with other HCI faculty and practitioners to build a case library of scenario-based usability engineering projects (ucs.ist.psu.edu) and incorporating case-based learning activities into our graduate and undergraduate teaching. The students carry out a number of in-class or homework assignments that involve case analysis over the course of a semester—for example, analyzing the implications of "perturbing" a case study in specific ways or tracing the impacts of a tradeoff analyzed early in development through the lifecycle. They also analyze, design, and prototype their own interactive projects, documenting their work as a miniature case study. The case-based experiences serve as a sort of surrogate for apprenticeship learning in the real world, as the students are able to explore and question the reasoning and decisions of actual development teams. At the same time, the cases are an excellent vehicle for encountering and weighing the many competing concerns that development teams must address during interactive system development.

48.5 CURRENT CHALLENGES

When we design interactive systems, we make use. We create possibilities for learning, work, and leisure, for interaction and information. Scenarios—descriptions of meaningful usage episodes—are popular representational tools for making use. They help designers to understand and to create computer systems and applications as artifacts of human activity, as things to learn from, as tools to use in one's work, as media for interacting with other people.

SBD offers significant and unique leverage on some of the most characteristic and vexing challenges of design work: Scenarios are at once concrete and flexible, helping developers manage the fluidity of design situations. Scenarios emphasize the context of work in the real world; this ensures that design ideas are constantly evaluated in the context of real world activities, minimizing the risk of introducing features that satisfy other external constraints. The work-oriented character of scenarios also promotes work-oriented communication among stakeholders, helping to make design activities more accessible to many sources of expertise. Finally, scenarios are evocative, raising questions at many levels, not only about the needs of the people in a scenario as written, but also about variants illustrating design tradeoffs.

Scenario-based methods are not a panacea. A project team who complains "We wrote scenarios, but our system still stinks!" must also report how their scenarios were developed, who reviewed them, and what roles they played in system development. If a user interaction scenario is not grounded in what is known about human cognition, social behavior, and work practices, it may well be inspiring and evocative, but it may mislead the team into building the wrong system (Carroll et al. 1998). Scenarios are not a substitute for hard work.

At the same time, *any* work on user interaction scenarios directs a project team to the needs and concerns of the people who will use a system. It is in this sense that scenarios can provide a very lightweight approach to human-centered design. Simply writing down and discussing a few key expectations about users' goals and experiences will enhance a shared vision of the problems and opportunities facing system users. Adopting a more systematic framework such as described here adds control and organization to the creative process of design and at the same time generates work products (scenarios and claims) that can serve as enduring DR during system maintenance and evolution (McKerlie and MacLean 1994; Moran and Carroll 1996).

Where are scenarios taking us? The current state of the art in the design of interactive systems is fragmented. Scenarios are used for particular purposes throughout system development, but there is no comprehensive process (Carroll 1995; Jarke, Bui, and Carroll 1998; Weidenhaupt et al. 1998). Scenario practices have emerged piecemeal, as local innovations, leading to a considerable variety of scenario types specialized for particular purposes (Campbell 1992; Young and Barnard 1987). A detailed textual narrative of observed workplace practices and interactions, a use case analysis of an object-oriented domain model, a day-in-the-life video envisionment of a future product, and the instructions for test subjects in an evaluation experiment could *all* be scenarios. Recognizing this, and cross-leveraging the many different views of scenarios, is a potential strength of SBD. But much work remains in developing overarching frameworks and methods that exploit this potential advantage.

It is important for us to be ambitious, skeptical, and analytic about scenarios and SBD. Almost 50 years ago, Herman Kahn (1962) expressed puzzlement that scenarios were not more widely used in strategic planning. As we write this in 2010, scenarios have become so pervasive in interactive system design that younger designers may wonder what the alternative is to SBD! But there is yet some strangeness to scenarios. We are not much farther than Kahn was in understanding how scenarios work as tools for planning and design or in understanding how to fully exploit their unique strengths as aides to thought.

49 Participatory Design

The Third Space in Human–Computer Interaction

Michael J. Muller and Allison Druin

CONTENTS

49.1 INTRODUCTION: JUST ADD USERS AND STIR?

In a discussion of integrating women's perspectives into a male-dominated curriculum, Bunch (1987) noted that "you can't just added women and stir" (p. 140). It takes work, and new ways of thinking, and new kinds and methods of openness to bring substantively new voices into a conversation. Similarly, to bring users' knowledges and perspectives directly into computer specification and design, it is necessary to do more than "just add users and stir." This chapter surveys methods that go beyond merely adding users—methods to create new settings and experiences that can assist computer professionals to work in partnership with diverse users in improving both computer technology and the understandings that make computer technologies successful in real use.

Participatory design (PD) is a set of theories, practices, and studies related to end users as full participants in activities leading to software and hardware computer products and computer-based activities (Greenbaum and Kyng 1991; Muller and Kuhn 1993; Schuler and Namioka 1993). The field is extraordinarily diverse, drawing on fields such as user-centered design, graphic design, software engineering, architecture, public policy, psychology, anthropology, sociology, labor studies, communication studies, and political science and from localized experiences in diverse national and cultural contexts (Gregory 2003). This diversity has not lent itself to a single theory or paradigm of study or approach to practice (Beck 1996; Bjerknes and Bratteteig 1995; Clement and Van den Besselaar 1993; Kensing and Blomberg 1998a; Slater 1998; Suchman 2002). Researchers and practitioners are brought together—but are not necessarily brought into unity—by a pervasive concern for the knowledges, voices, and/or rights of end users, often within the context of technology design and development, or of other institutional settings (e.g., workers in companies, corporations, universities, hospitals, and governments) (Bødker 1990; Bødker et al. 1988; Gregory 2003) or of other experiences in life (e.g., children, older adults, and people with disabilities) (Druin 2002; Guha and Druin 2008; Hornof 2008; Xie et al. in press; see also Chapter 40). Many researchers and practitioners in PD (but not all) are motivated in part by a belief in the value of democracy to civic, educational, and commercial settings—a value that can be seen in the strengthening of disempowered groups including workers, children, and older adults, in the improvement of internal processes, and in the combination of diverse knowledge to make better services and products (Beyer and Holtzblatt 1998; Béguin 2003; Bjerknes, Ehn, and King 1987; Braa 1996; Briefs, Ciborra, and Schneider 1983; Bødker, Kensing, and Simonsen 2004; Carroll 1995, 2000; Checkland 1981; Clement, Kolm, and Wagner 1994; Docherty et al. 1987; Druin 2002; Ehn 1988, 1993; Floyd 1993; Floyd et al. 1989; Gasson 1995; Gregory 2003; Greenbaum and Kyng 1991; Kensing and Blomberg 1998b; Klær and Madsen 1995; Kyng and Matthiessen 1997; Madsen 1999; McLagan and Nel 1995; Muller and Kuhn 1993; Mumford 1983; Mumford and Henshall 1979/1983; Noro and Imada 1991; Nygaard 1975; Scrivener, Ball, and Woodcock 2000; Schuler and Namioka 1993; Spencer 1989; Suchman 1995, 2002; Van den Besselaar, Clement, and Jaervinen 1991; Xie et al. in press; Wixon and Ramey 1996).

PD began in an explicitly political context, as part of the Scandinavian workplace democracy movement (e.g., Nygaard 1975; Bjerknes, Ehn, and Bratteteig 1987; Ehn and Kyng 1987; Floyd et al. 1989; more recently, see Bjerknes and Bratteteig [1995]; Beck [1996, 2001]; Gregory [2003]; Kyng and Matthiessen [1997]; Winner [1994]). Early work took the form of experiments conducted by university researchers in alliances with organized labor (for historical overviews, see Ehn [1993]; Gregory [2003]; Levinger [1998]). More recent work has more explicitly considered additional social justice issues such as inclusive design (Light and Luckin 2008), women's needs (Balka 1995; Greenbaum 1991; Nisonen 1994), cultural sensitivity (Druin et al. 2009; Kam et al. 2006), disabilities challenges (Hornof 2008), and more general issues of exclusion related to race, age, gender, and/or class (DiSalvo et al. 2010; Druin 2002).

Subsequent work focused on combining complex and distinct knowledges for realistic design problems. Segalowitz and Brereton (2009) described three attributes of new knowledge that could lead to difficulties in participation: novelty, difference, and dependence. Winters and Mor (2008) discussed the need for a methodology of interdisciplinary knowledge exchanges to support participation design. Fowles (2000) wrote of transforming the "symmetry of ignorance" (mutual incomprehension between designers and users) into a complementary "symmetry of knowledge" through symmetries of participation and symmetries of learning. Nielsen and Bødker (2009) recently updated this analysis for the current context of virtual collaborations with users. Similarly, Holmström (1995) analyzed a "gap in rationalities" among developers and users, and Béguin (2003) argued for the need to close this gap through mutual learning among designers and end users. Reymen, Whyte, and Dorst (2005) considered the diverse knowledges that are needed in design (see also Badke-Schaub [2004]), and Louridas (1999) provided an influential analysis of the similar thought patterns that are used with different conceptual vocabularies by professional versus nonprofessional designers. In view of these different conceptual vocabularies, one of us wrote about the need for translations among the coequal worlds of users and software professionals and the need to foster a polyvocal polity in which these various interested parties could coconstruct new concepts, meanings, and alliances (Muller 1997a, 1997b). Suchman (2002) described her historical practice of PD as "working for the presence of multiple voices not only in knowledge production, but in the production of technologies as knowledges objectified in a particular way." Bødker and Buur (2002) noted the need to support the "many-voiced nature of design." These acknowledgments of the integrity and rationality of multiple voices and multiple knowledges (e.g., users and software professionals) are a crucial aspect of the argument of this chapter, concerning the creation of hybrid spaces between and among those diverse perspectives.

However, the integrity of including multiple voices in design has been questioned. Reyman et al. (2005) summarized the problem from the perspective of professional designers, whose newly won strength in systems' design is challenged by the claims of users' knowledge as a crucial component of design. They noted that "designers have their own expertise," and "it is not yet clear which kind of user involvement is most appropriate." Luck (2003) explored issues of disagreement, even among the users. Druin, this chapter's second author, suggested that there are four roles children can play in the design process: user, tester, informant, and design partner (Druin 2002). With each role there is a spectrum of user involvement, at differing points in the design of new technology. Jönsson and colleagues (n.d.) listed a series of design constraints for working with seniors (see also Demirbilek and Demirkan [2004]). Yamauchi (2009) suggested that best role for users was as "peripheral designers," working with assigned detailed problems rather than whole-system design. Light and Luckin called into question a simplified view of involving everyone in design projects without methods and techniques to enfranchise diverse participants:

> "Believing in the potential of everyone to design is more egalitarian than believing in exclusive talents and specialized roles. However, this is not the same as involving every potential user in every design project, or at all stages, or in the same way as the next person." (Light and Luckin 2008, p. 16)

In effect, the observation by Light and Luckin returns us to our opening theme, "you can't just 'add users and stir.'" People's needs differ by work roles and their relationship to the design task, by life stage, by physical or cognitive condition, and by other attributes and dimensions as well. People need different design affordances and degrees of safety, depending on their circumstances, their identities, and their relationship to the design task and its social or organizational setting. These issues help to motivate this chapter's survey of participatory methods, and particularly our focus on new "hybrid" spaces for mutual learning and reciprocal validation of diverse perspectives.

Recently, PD has achieved a status as a useful commercial tool in some settings (e.g., McLagan and Nel 1995), with several major and influential consultancies forming their business identities around participatory methods,* and an increasing number of textbooks for design or IT governance based on participatory principles (Beyer and Holtzblatt 1998; Bødker, Kensing, and Simonsen 2004). This overall corporate and managerial "mainstreaming" of PD has been greeted by some with enthusiasm and by others with dismay. Participatory work in the United States has sometimes been criticized as too friendly to management or too limited by the users' experience. Participatory work on the Pacific Rim (e.g., Noro and Imada 1991) appears to have grown out of the quality movement and focuses much more on solving problems and much less on changing workplace power relations. On the other hand, PD has gained growing acceptance in the world of research, particularly from academic professionals in Europe and North America focused on developing new technologies for children (e.g., Druin 1999/2002; Garzotto 2008; Hornof 2008; Jones et al. 2003; Kam et al. 2006; Large et al. 2007; Mazzone, Read, and Beale 2008; Robertson 2002; Taxén 2004). Adapting the notions of changing the "power structures," researchers have sought to give children a voice in the design of new technologies with the belief that more appropriate solutions can be found.

Historically, as summarized by Gregory (2003; see also Kensing and Blomberg [1998a]), PD has included both a "conflict-perspective," such as the collective resource tradition (Ehn and Kyng 1987), as well as approaches that are more integrated into conventional work processes (e.g., Beyer and Holtzblatt 1998; Noro and Imada 1991; Sanders 2000; and perhaps Bødker, Kensing, and Simonsen 2004). The integrationist approaches (including those practiced by one of us) have been critiqued as an insufficient "harmony perspective" by, for example, Ehn (1993) and Kyng (1998). Indeed, several definitions of conflict have been fruitful for PD. The concept of breakdowns in anticipated working practices was explored in an influential treatment by Bødker (1990) within the theoretical frame of activity theory. In this approach, the conflict is between expectation and initial outcomes, giving motivation and direction to a need for changes. The concept of class conflict has also been useful, especially in the Scandinavian context (Beck 1996, 2001; Bjerknes and Bratteteig 1995; Bjerknes, Ehn, and Bratteteig 1987; Gregory 2003), where it has served as the organizing principle for work with trade unions as powerful stakeholders and allies in those countries. Elsewhere, a more muted approach of identifying problems and gaps between the present and the future has informed participatory work where the labor movement is weaker (Beyer and Holtzblatt 1998; Carroll 1995, 2000; Checkland 1981; Lafreniére 1996; Muller et al. 1995b; Mumford 1983; Mumford and Henshall 1979/1983; Noro and Imada 1991), where the conflict is between history and current needs (Best et al. 2009; Cameron 1998; Carmien et al. 2003; Davies et al. 2004; Enquist and Tollmar 2008; Fowles 2000; Hirsch 2009; Moffatt et al. 2004; Nisonen 1994; Pecknold 2009; Salvador and Howells 1998; Salvador and Sato 1998; Taylor and Cheyerst 2009; Wu, Richard, and Baecker 2004; Wu, Baecker, and Richards 2005), or in projects in which the focus is on design rather than on workplace (e.g., Béguin 2003; Binder 1999; Brandt and Messter 2004; Buur, Binder, and Brandt 2000; Carter and Mankoff 2005; Dandavate, Steiner, and William 2000; Druin 1999; Druin et al. 2000/2009; Hornecker 2010; Howard et al. 2002; Iacucci, Iacucci, and Kuutti 2002; Iacucci and Kuutti 2002; Kankainen et al. 2005; Kantola et al. 2007; Kuutti, Iacucci, and Iacucci 2002; Merkel et al. 2004; Nielsen and Bødker 2009; Pedersen and Buur 2000; Sanders 2000, 2006; Sanders and Branaghan 1998; Sanders and Nutter 1994; Tschudy, Dykstra-Erickson, and Holloway 1996; Vaajakallio and Mattelmäki 2007; Wakkary and Tanenbaum 2009).

A more recent trend has been the maturing of lifecycle approaches to participatory work. Early and somewhat experimental lifecycle models were offered by Mumford (1983) and Floyd (1993), anticipated in some ways by Checkland (1981). Two more mature approaches have been offered by Beyer and Holtzblatt (1998) and Bødker, Kensing, and Simonsen (2004). A further incorporation of participatory methods into large-scale conventional processes was explored in Pew and Mavor (2007). Finally, we note that, according to some researchers in the field of end user innovation and user appropriation studies, new technologies have become so complex that ordinary users will have to modify those technologies in order to "domesticate them" and make them fit for use (e.g., Aune 1996; Cook and Light 2006; von Hippel 2002; Light and Luckin 2008; Silverstone and Haddon 1998; Wakkary and Tanenbaum 2009). This rich area of research and practice is regrettably beyond the scope of this chapter.

This chapter primarily addresses methods, techniques, and practices in PD, with modest anchoring of those practices in theory. We will not repeat our earlier encyclopedic survey of participatory practices (Muller, Haslwanter, and Dayton 1997). Rather, we will pursue a trend within those practices that has shown the most growth during the past years, and we will motivate our interest in that trend through recent advances in the domain of cultural studies. We will focus on participatory practices that fall in the hybrid realm between the two distinct work domains of (1) technology developers/researchers and (2) end users.

We should also say that our concern is for methods that have been *shown to work in real situations*—that is, that address real

* In the interest of fairness to other consultancies, we will not provide the names of commercial ventures.

problems in work life, education, home life, leisure, and so on—and in which the outcomes were of consequence, and in which the participants could freely choose whether to be involved in the work. We have therefore omitted many promising methods that have so far been explored only as in-laboratory university exercises, apparently as part of assigned coursework. Instead we look toward more realistic explorations of these new methods.

In this third edition of the *Handbook*, we have also expanded the domains in which we report participatory methods and techniques. Previous editions have focused on work and workers, usually in face-to-face settings. In our new version of this chapter, we also include participatory work with children and with people with disabilities, and we bring in methods from the emerging subfield of distributed PD (DPD) (as practiced among *non*colocated collaborators) where appropriate, and participatory methods as used in the special circumstances of the developing world. Our expanded scope may be seen as a further dilution of the labor orientation to PD. In response, we hope that this broadened sense of *who matters in design* will ultimately lead to greater enfranchisement and new alliances for change.

49.1.1 Major Bibliographic Sources for Participatory Design

Theory, practice, and experience in PD have been published in a series of conference proceedings and several major books.

49.1.1.1 Conference Series

Seven important conference series have made major contributions to PD:

- *Critical Computing.* Four conferences have been held, at 10-year intervals, in the Critical Computing series, most recently in 2005. Major papers from the conferences have appeared as two influential books (Bjerknes, Ehn, and Bratteteig 1987; Kyng and Matthiessen 1997).
- *Information Systems Research in Scandinavia (IRIS) Conference.* The annual IRIS conference series often include sessions and individual contributions on participatory topics. *Proceedings* may be available through the IRIS Association or online.*
- *PD Conference.* The PD Conference has met on even-numbered years since 1990. Earlier *Proceedings* were published by computer professionals for social responsibility (CPSR);† more recent *Proceedings* were published by the Association for Computing Machinery.‡ Selected papers from several conferences have appeared in edited volumes or special journal issues (e.g., Kensing and Blomberg 1998a; Muller and Kuhn 1993; Schuler and Namioka 1993). Papers from recent conference years are available through the ACM Digital Library.§
- *Include Conferences.* The Helen Hamlyn Center¶ has sponsored a series of conferences on inclusive design since 2003, and provides additional materials in this area. The concept of inclusive design emphasizes enfranchising as broad a range of people as possible, usually with a focus on removing barriers related to physical, cognitive, and emotional disabilities. The Include Conferences have explicitly included emphases on home, civic life, and *workplace* within this broader agenda, and with themes of participatory work with people of diverse backgrounds and abilities.
