Fulfilling the designers' second objective requires an understanding of internationalization, translation, and localization issues within the context of a globalization strategy.

Globalization refers to the entire process of preparing products or services for worldwide production and consumption. Globalization includes analysis of issues at international, intercultural, and local scales. In our information-oriented society, globalization affects almost all types of computer-mediated communication and interaction.

Internationalization refers to the process of preparing code that separates data and resources (i.e., items needed for input and output) from the primary functionality of the software. Software created in this way does not need to be rewritten or recompiled for each local market. This separation may also include the ability for the UI to work on different platforms in one or more geographic region.

Typically, internationalization is required due to geographic, political, linguistic, and typographic differences between nations or groups of nations. For instance, different countries will have different provinces, states, or political subdivisions and different denominations or metrics for currency, time, and physical measurements that need to be accommodated in pull-downs, menus, or fields (Table 15.1). People in global cities like Dubai, and countries with high levels of immigration, may also need to take advantage of internationalization features due to differences in religion, dialects, esthetics, or other humanistic issues of particular importance. Examples include calendars that acknowledge different religious time cycles; terminology for color, type, and signs that reflect different popular cultures; and web search criteria based on cultural preferences. Sometimes these issues reach national political importance, as in the 2005 debate in Iraq over whether Thursday and Friday (the Muslim Sabbath) should constitute the "weekend" rather than including Saturday (the Jewish Sabbath) or Sunday (the Christian Sabbath) (Kuhn 2005).

Technical, financial, political, and legal matters also affect designs. The European Union has developed a variety of requirements for open source and software interoperability that have led to prolonged litigation against Microsoft (Raby 2007); computer programs imported into Canada must meet a legal requirement for bilingual English and French displays; and national requirements for censorship (and privacy) continue to affect the use of Internet browsers and social media in parts of Asia (Helft and Barboza 2010). The ISO has developed a number of software, hardware, and human factors standards in an effort to establish international standards for some parts of a UI.

Translation, the conversion of text from one language to another, can be accomplished by certified in-house staff or by one or more outside contractors specialized in that service. Translators generally use software provided by third-party firms (e.g., Systran), for a preliminary pass, but it is vital that someone skilled in the language review the output.

It is tempting to rely on translation software, but it remains a "work in progress." According to Quebec translator Gisèle Foucault (2010), a better understanding of the current types of systems explains why.

In automatic translation systems, like Systran, the computer performs the translation based on dictionaries, grammar algorithms, and so on. In very specialized areas where the vocabulary is well established, metaphors are minimal, and the system has been "trained" on large volumes of documents revised by human translators, the systems can eventually provide acceptable translations. After considerable effort, the European Commission now uses Systran for administrative documents. In Canada, an automatic translation system has been developed for weather forecasts, which is also quite good. However, such success stories remain limited. Google and others browsers offer such automatic translation systems, but the sheer variety of vocabulary and contexts in which words are used means that translations are sometimes defective. In particular, industry-specific vocabulary may not be included in the application's internal dictionary. As an example, the verb to "spawn" (as in an Internet application that "spawns windows") is defined as "fish eggs" in some Chinese language dictionaries.

Translation memory systems, like the Trados Translator's Workbench or SDLX, are the second category of translation software. A human being does the translation, and the computer saves the original sentence and corresponding translation for future use should a similar sentence (100% match or 70%–100% "fuzzy" match) be found again. Thus, the initial

TABLE 15.1
Examples of Differing Displays for Currency, Time, and Physical Measurements

Item	U.S. Examples	European Examples	Asian Examples
Currency	$1,234.00 (U.S. Dollars)	DM1.234 (German marks)	¥1,234 (Japanese yen)
Time measures	8:00 PM, August 24, 1999	20:00, 24 August 1999 (England)	20:00, 1999.08.24, or Imperial Heisei 11, or H11 (Japan)
	8:00 PM, 8/24/99	20:00, 24.08.99 (Germany, traditional) 20:00, 1999-08-24 (ISO 8601 Euro standard)	
Physical measures	3 lb, 14 oz	3.54 kg, 8.32 m (England)	3.54 kg, 8.32 m in Roman or Katakana
Chars	39 100, 3 feet and 10 inches	3,54 kg, 8,32 m (Euro standard)	

translation can be reused as is, or with minimal revision. However, this kind of system is only as good as the human translator who provides the initial translation (although the translations memorized by the system can always be edited by the next translator). Such systems are very useful for online help files, software user guides, training modules, or any text with much repetition (e.g., contracts).

In Canada, work is progressing on a third type of system, statistical machine translation. It is a blend of the two other types, with statistical analysis of an extremely large corpus of human-translated documents (in the Canadian case, the Hansard, deliberations of the House of Commons). The system analyzes one word, then two words, then three words, and so on, and their equivalents in French. With the help of statistical formulas, the system matches "co-occurrences" with their equivalents and "learns" to translate in context. If the product becomes a commercially viable product, it could change the translation market in specific niches.

Ideally, translations are checked by having them back-translated into the original language. This technique is particularly important for a text that asks users to reply to a prompt or question, and the technique ensures consistency within data collected across linguistic boundaries.

Preparing texts in local languages often requires the use of additional or different characters. The American Standard Code for Information (ASCII) system, which uses seven or eight bits to represent characters, supports English, and the single-byte ISO 8859-1 character set supports Western European languages that use the Latin alphabet, such as Spanish, French, and German. Other character encoding systems include EBCDIC, Shift-JIS, UTF-8, and UTF-16. ISO has established specific character sets for languages such as Cyrillic, Modern Greek, Hebrew, Japanese, and so on. However, most companies planning to globalize their products should use Unicode, a double-byte (16 bit) system that can represent 65,536 characters, which is sufficient to display Asian languages like Japanese and Korean and permits easier translation and presentation of character sets.

Localization may or may not be required depending on the degree of cultural difference between the original and global target users. For instance, a Canadian company selling into the United States generally does relatively little localization to prepare its products for sale. On the other hand, preparing an application for a specific, small-scale community (less than a country) or cross-national, ethnic "region" (unified by language and culture) may require significant localization. That same Canadian company selling to Nunavut (the federal Inuit territory in northern Canada) may make extensive changes to its product. Web-based companies planning on doing business in the European Union know that many language versions will be required for basic commercial penetration into the desired markets. Some situations may benefit from a culture audit, in which the icons, graphics, terminology, and concepts are inspected to alert translators to potential difficulties or dangers when translating. Otherwise, a perfectly good translation into another language and writing system may overlook items that are culturally alienating or offensive, requiring expensive later modifications when the product/service has already become available to users commercially.

Used informally, localization also applies to "corporate cultures" or age-stratified groups, which may be geographically dispersed. For instance, multinational companies with strong socialization practices can develop surprisingly coherent cultures centered on mission statements and "core values." One researcher, Geert Hofstede (1997), took advantage of this uniformity in his study of intercultural differences in 53 countries and regions by studying employees of only one company, IBM.

Other claims are made for the cultural stability of age cohorts like the current "millennials" or "digital natives." Digital natives have grown up surrounded by computers, mobile devices, video games, and the Internet, whereas others who have always used some other form of technology first are termed "digital immigrants," held back by their initial impressions of the "right" (older or previous) way to do things. Many claims have been made about how digital natives differ from digital immigrants, such as the following quote by Prensky (2001a) discussing changes in education:

> Digital Natives are used to receiving information really fast. They like to parallel process and multi-task. They prefer their graphics before their text rather than the opposite. They prefer random access (like hypertext). They function best when networked. They thrive on instant gratification and frequent rewards. They prefer games to "serious" work.… But Digital Immigrants typically have very little appreciation for these new skills that the Natives have acquired and perfected through years of interaction and practice.

In enhancing products for teamwork and coordination, localization might be required to address the different needs of different age cohorts. One could look at digital natives (millenials) versus digital immigrants or look more closely at the differences between millenials and baby boomers (those born between 1946 and 1964), Gen X (those born after the baby boomers, generally from about 1961–1970 until about 1980–1981), Gen Y (those born after Gen X, generally from about 1981 until about 1994–2000. Each of these age cohorts is distinguished by different levels of interest and trust in a variety of technologies.

Finally, localization can include affinity groups (e.g., French "twenty-somethings" or German Mercedes automobile owners), business or social organizations (e.g., U.S. golf club members), or specific intranational groups (e.g., Swedish househusbands, India's untouchables, or young Japanese professional women who are rejecting marriage as a life pattern). With the spread of web access, the term culture is frequently applied to all kinds of groups with strongly shared interests, members of which may or may not be geographically dispersed.

Note: This broad definition of "culture" is not accepted by all theorists (e.g., see Clausen as reported by Yardley 2000). However, for the purposes of this chapter, this broad definition is used.

15.2.2 User-Interface Elements

Ultimately, a globalization strategy may require designers to consider any or all of the following elements of a desktop, website, mobile device, appliance, vehicle display, or other kind of software application:

- Access limitations (e.g., children or the blind)
- Address formats
- Alphabetic sequence and nomenclature
- Arithmetic operations symbolism
- Business standards (quotes, tariffs, contracts, agreement terms, etc.)
- Calendars
- Censorship
- Character handling
- Colors
- Content categories
- Date and time formats
- Distance references
- Documentation nomenclature and formats
- Electrical and electronic plug formats and nomenclature
- Energy formats
- Environmental standards (“green” compliancy, low energy, low pollution, etc.)
- File formats
- Font nomenclature, sizes, faces, and byte formats
- Frequency (e.g., gigahertz)
- Hyphenation and syllabification
- Icons and symbols (e.g., mailboxes, trashcans, files)
- Intellectual property (protection via patents, copyrights, trademarks)
- Keyboard formats
- Language and dialect differences
- Legal processes
- Licensing standards
- Measurement units (length, volume, weight, electricity, energy, temperature, etc.)
- Monetary or currency formats
- Multilingual usage
- Name formats
- Negative formats
- Numeric formats and number symbols
- Packaging
- Paper formats
- Privacy
- Punctuation symbols and usage
- Reading/writing direction
- Sorting sequences
- Style formats
- Telephone/fax standards
- Temperature formats
- Text length (especially, expansion requirements for translation)
- Video recording and playback formats
- Voltage/amperage units and formats
- Weight formats

Table 15.2 hints at the potential complexity of globalizing products for North America/Europe, the Middle East, and East Asia. Table 15.3 shows how references can change even among English-language users.

Many of these user-interface elements are specified as industry standards. Unicode was developed by the Unicode Consortium, whereas other language encoding formats are supported by ISO. A variety of formats, such as calendars, dates, time zone, numbers, currency values, and sorting systems, are listed in the Unicode Consortium’s CLDR (Common Locale Data Repository) charts, available from cldr.unicode.org/.

TABLE 15.2
Examples of Differing Displays for Other Data Formats

Item	U.S. Examples	European Examples	Asian Examples
Numerics	1,234.56 (also Canada, China, United Kingdom)	1 234,56 (Finland, France, Luxembourg, Portugal, Sweden) 1.234,56 (Albania, Argentina, Denmark, Greece, the Netherlands) 1’234.56 (Switzerland: German, Italian) 1’234,56 (Switzerland: French)	1,234.56
Telephone numbers	1-234-567-8901, ext. 23 1.234.567.8901 (123) 456-7890	1234 56 78 90 (Austria) (123) 4 5 6 78 90 (Germany) (12) 3456 789 (Italy) 146(0)12 345 67 149 (1234) 5678-9 (Switzerland)	181-53-478-1481 (Japan) 82 2 3142 1100 (Korea) 182-(0)2-535-3893 (Korea) 86 12 34567890 (China)
Address formats	Title, First Name, MI, Last Name Department Company Number, Street, City, State, Zip-Code, Country	Paternal Name, Maternal Name, First Name Company, Department Street, Number City, District/Region Zip-Code, Country (Order may vary from country to country)	Family Name, First Name Department Company Number, Street, Neighborhood, District, Zip-Code, City (Japan)

TABLE 15.3
Examples of Differing Cultural References

Item	North America/Europe Example	Middle Eastern Example	Asian Example
Sacred colors	White, blue, gold, scarlet (Judeo-Christian)	Green, light blue (Islam)	Saffron yellow (Buddhism)
Reading direction	Left to right	Right to left	Top to bottom
Item	United States	France, Germany	Japan
Web search	"Culture" doesn't imply political discussions	"Culture" implies political discussions	"Culture" implies tea ceremony discussions
Sports	Baseball, football, basketball; golf is a sport	Soccer	Sumo wrestling, baseball; golf is a religion

Additional information on specific internationalization/localization issues can be found through LISA (Localization Industry Standards Association, lisa.org), which has an active program of standards development through OSCAR (Open Standards for Container/content Allowing Reuse).

15.2.3 Globalization Development Processes

The "globalized" UI development process is a sequence of partially overlapping steps, some of which are partially or completely iterative:

- *Plan*: Define the strategy, including the challenges or opportunities for globalization; establish objectives and tactics; and determine budget, schedule, tasks, development team, and other resources. Globalization must be specifically accounted for in each item of project planning; otherwise, cost overruns, delays in schedule, and lack of resources are likely to occur. In most cases, business managers will expect to see a return-on-investment (ROI) analysis of the expected benefits, benchmarking standards, likely tools and process, and metrics to be used in "proving" the results are better.
- *Research*: Investigate dimensions of global variables and techniques for all subsequent steps, for example, techniques for analysis, criteria for evaluation, media for documentation, and so on. In particular, identify items among data and functions that should be targets for change and identify sources of national/cultural/local reference. Globalized user-centered design stresses the need to adequately research users' wants and needs according to a sufficiently varied spectrum of potential users, across specific dimensions of differentiation. In the mid-1980s, Xerox PARC (Palo Alto Research Center Incorporated) began employing cultural anthropologists to study service technicians; by the mid-2000s, Microsoft (and many other multinationals) was hiring anthropologists to undertake ethnographic analyses of work to support product development (Suchman 1987; Murphy 2005). During the past few years, many companies have had anthropologists and ethnographers attend user-interface conferences and anthropology conferences to report on their findings. Several applied anthropology groups regularly post and answer inquiries about information resources, tools, educational institutions, and case studies related to anthropology in design; one of the most active is *anthrodesign* in Yahoo groups.
- *Analyze*: Examine challenges or opportunities in the prospective markets; refine criteria for success in solving problems or exploiting opportunities (write marketing or technical requirements); determine key criteria for usability, usefulness, and appeal (i.e., the user experience); and define the design brief or primary statement of the design's goals. At this stage, globalization targets should be itemized.
- *Design*: Visualize ways to satisfy criteria using alternative prototypes. Based on prior or current evaluations, select the design that best satisfies criteria for both good general UI design and globalization requirements. Prepare documents that enable consistent, efficient, precise, and accurate implementation.
- *Implement*: Build the design to complete the final product, that is, write easily internationalized code using appropriate, effective, efficient tools identified in planning and research steps.
- *Evaluate*: At any stage, review or test results in the marketplace against defined criteria for success, that is, conduct focus groups, test usability on specific functions, and gather sales data and user feedback. Identify and evaluate matches and mismatches, and then revise the designs. Test prototypes or final products with international, intercultural, or specific localized user groups to achieve globalized UI designs. As noted in recent proceedings of UI conferences such as the Association for Computing Machinery's Special Interest Group on Human–Computer Interaction (ACM/SIGHCI), Usability Professionals Association (UPA), Human–Computer Interaction International (HCII), and the International Workshop on the Internationalization of Products and Services (IWIPS), the techniques of evaluation may need to be adjusted to be successful in different cultures and geographic circumstances (Chavan 2005; Gould 2009). Many studies have

focused on website visitors and mobile phone users (Lee et al. 2005; Kim and Lee 2010).

- *Document*: Record the development history, issues, and decisions in specifications, guidelines, and recommendation documents. Honold (1999), for example, notes that German and Chinese mobile phone users require different strategies for documentation, as well as training, which are related to cultural differences predicted by classical models. Even designing the "ideal" documentation for a particular culture of developers may require user-centered design processes, for example, recognizing that some may prefer paper and text, and others visual, interactive means with minimal text reading.
- *Maintain and Train*: Determine which documents, customer-response services, and other processes will require multiple languages, different graphics, and changes in media or delivery techniques. Prepare appropriate guidelines and templates.

15.2.4 Critical Aspects for Globalization: Specific Guidelines

Beyond the high-level UI development process steps identified in the Section 15.2.3, the following guidelines can assist developers in preparing a "checklist" for specific tasks. The following recommendations are grouped under the UI design terms referred to earlier.

15.2.4.1 User Demographics

- Identify national and cultural target user populations and segments within those populations, and then identify possible needs for differentiation of UI components and the probable cost of delivering them.
- Identify potential savings in development time through the reuse of UI components based on common attributes among user groups. For example, certain primary (or top-level) controls in a mobile phone application might be designed for culturally different cognitive styles to aid comprehension and to improve appeal for specific user groups (Kim and Lee 2007). Lower level controls, on the other hand, might be designed with standardized, unvarying form-like elements.
- Consider legal issues in target communities, which may involve issues of religion, privacy, intellectual property, spamming, defamation, pornography and obscenity, vandalism (e.g., viruses), hate speech, fraud, theft, exploitation and abuse (children, environment, elderly, etc.), legal jurisdiction, seller/buyer protection, and so on.

15.2.4.2 Technology

- Determine the appropriate media for the appropriate target user categories, for example, emphasis of sound, visual, or three-dimensional tactile media; verbal versus visual content; and so on.
- Account for international differences in support platform, population and software needs, including languages, scripts, fonts, colors, file formats, and so on.
- Research and obtain appropriate software for code development and content management systems.

15.2.4.3 Metaphors

- Determine optimum minimum number of concepts, terms, and primary images to meet target user needs.
- Check for potential miscommunication and misunderstanding due to differences in language and culture.
- Adjust metaphorical images or text to account for national or cultural differences. Publications and projects from/for China and India have suggested metaphors that differ considerably from Western stereotypes. For example, Chavan (1994) stated that Indians relate more easily to bookshelves, books, chapters, sections, and pages, rather than the desktop, file folders, and files. The Wukong prototype personal digital assistant, developed by Ericsson for Chinese users in 2002, used metaphors based on the Chinese business-social concept of Guang-xi, or relationship maintenance. This approach meant that people, knowledge, and relationships were more fundamental and pervasive than folders, files, and applications (Marcus 2003).

15.2.4.4 Mental Models

- Determine optimum minimum varieties of content organization.
- Consider how hierarchies may need to change in detail and overall in terms of breadth and depth. Chiu (1972) found that United States and Chinese children categorized objects on the basis of different principles: categories and rules by the first, associations in the use of objects by the second. Choong and Salvendy (1999) noted that Chinese and North American users tended to organize the contents of a house in different ways, and Carroll (1999) noted that if one group was given the hierarchies of the other, the group had more difficulty navigating the hierarchy.
- Cognitive styles are also affected by culture. Masuda and Nisbett (2001) found that East Asians and Westerners selected different elements of figure and ground; in their study Asians were more focused on the relationships between elements while Westerners were more focused on central objects. Subsequently, Nisbett and Norenzayan (2002) defined two cognitive perspectives:
  - Holistic thought (orientation to context and the field as a whole, preference for experience-based knowledge, and acceptance of change and multiple perspectives) was linked to personal interdependence and was more common in East Asia.

- Analytic thought (decontextualization of objects, categorical thinking, preference for rule-based logic, and rejection of contradiction) was linked to personal independence and was more common in Europe and North America.

A later study by Knight and Nisbett (2007) found similar cognitive practices within Italy. People in industrialized and relatively independent northern Italy used analytic thought more than people in the more rural and interdependent southern regions. Furthermore, this effect was linked to class; middle-class participants thought more analytically than working class participants. These findings support Hall's (1976) idea that people tend to favor either high- or low-context communication. In high-context communication, messages are nonverbal, indirect, and embedded in the social and physical context of the interaction; in low-context communication, messages are verbal, direct, and stand on their own.

- Investigate different self-concepts and self-representations when considering the development or addition of social media to a product/service. United States market leaders tend to fail when attempting to enter China. Some of their problems are political but other problems stem from national preferences. As of 2010, Renren and QQ had developed strong followings that may be discouraging Facebook from entering the China market. One reason for their success may be different emphases in their applications that reflect different types of social interaction. A recent blog posting on China Hush listed Renren's emphasis on journaling, support for drought victims in southern China, summaries of trends and popular topics, and the ability to see who sees you as more desirable attributes than Facebook's simple lists and privacy functions; the author (not Chinese) was both supported for recognizing Chinese differences and condemned for simplistic thinking (China Hush 2010).

15.2.4.5 Navigation

- Determine need for navigation variations to meet target user requirements, determine cost-benefit, and revise as feasible. Studies by Dong (2007) showed significant differences of navigation among Chinese, Korean, and U.S. viewers of web pages presented with the same layouts but different scripts and languages. Asian viewers tended to look around the page more in a circular pattern looking at the relationships of items, while U.S. viewers looked more quickly in a figure S path sequentially through major "monuments," then clicked for further information. These differences were studied using typical eye-tracking equipment used for website analysis.

15.2.4.6 Interaction

- Determine optimum minimum variations of input and feedback. For example, because of web-access speed differences for users in countries with very slow access, it is important to provide text-only versions, without extensive graphics, as well as alternative text labels to avoid graphics that take considerable time to appear.

15.2.4.7 Appearance

- Determine optimum minimum variations of visual and verbal attributes. Visual attributes include layout, icons, and symbols, choice of graphics, typography, color, and general esthetics. Verbal attributes include language, formats, and ordering sequences. For example, many Asian written languages, such as Chinese and Japanese, contain symbols with many small strokes. This factor seems to lead to an acceptance of higher visual density of marks in complex public-information displays than is typical for Western countries. In the mobile device realm, Letowt-Vorbeck (2010) citing user testing in South Africa, note that some users in developing companies may be partially or completely illiterate, causing significant challenges in designing visual, nonverbal assistance in the UI.

15.2.5 Example of Specific Guidelines: Appearance

Guidelines for visual and verbal appearance follow. Further details can be found in (Aykin 2005; Gould 2001; Marcus and Gould 2000; del Galdo and Neilson 1996; Fernandes 1995; Nielsen 1990).

15.2.5.1 Layout and Orientation

- Adjust layout of menus, tables, dialogue boxes, and windows to account for varying reading directions and size of text. Roman languages read only left to right, but Asian languages may read in several directions. For example, in Japan, people read from the right and down, or down and to the right, and Arabic/Hebrew may include right-reading Roman-letters text within left-reading lines of Arabic/Hebrew text.
- If dialogues use sentence-like structure with embedded data fields and/or controls, these areas may need special restructuring to account for language changes that significantly alter sentence format. For example, German sentences often have verbs at the ends of sentences, while English and French verbs are placed in the middle of sentences.
- As appropriate, change layout or imagery that implies or requires a specific reading direction. Left-to-right sequencing may be inappropriate or confusing for use with right-to-left reading scripts and languages. A website design for Arabia online

of the late 1990s featured left-to-right English text on a home page intended for Western business people and tourists, but the page layout was still right-to-left, as in Arabic, with primary links at the far right, secondary, and tertiary links in the center and left sections of the screen, and small directional arrows pointing right to left. The designers had retained Arabic-language influence to the detriment of English-language readers.

- Check for misleading arrangements of images that lead the viewer's eye in directions inconsistent with language reading directions.
- For references to paper and printing, use appropriate printing formats and sizes. For example, in the United States, standard office letterhead size is 8.5 by 11 inches, but in Europe it is 210 by 297 mm.

15.2.5.2 Icons, Symbols, and Graphics

- Avoid the use of text elements and punctuation within icons and symbols to minimize the need for versions to accommodate varying languages and scripts.
- Adjust appearance and orientation to account for national or cultural differences. For instance, office equipment such as telephones, mailboxes, folders, and storage devices differs significantly from nation to nation. Using a mailbox as an icon for e-mail may require different images for different countries. A U.S. mailbox looks quite different from a British postbox. It may also be necessary to adjust visual references to technology that many younger users could find confusing. For example, many software products continue to use the image of a small "floppy disk" to represent saving a file to media other than the computer's hard drive. As Patrick Hofmann, a visual designer from Google pointed out at the UPA 2010 conference (Hoffmann 2010), regarding icon recognition worldwide, many younger users have never used or seen a floppy disk of the 1980s or early 1990s; some think it looks like a garage with a door, but come to accept this seemingly strange visual symbol for "save to media."
- Consider using signs or derivatives from international signage systems developed for safety, mass transit, and communication (American Institute of Graphic Arts 1981; Olgyay 1995; Pierce 1996). These signs require little or no translation and may require minimal culture-specific support information due to their use in other contexts.
- Avoid puns and local, unique references that will not transfer well. In addition, note that many "universal" signs may be covered by international trademark and copyright use, for example, Mickey Mouse and the "Smiley" smiling face. Similarly, the humor of "a little old lady in tennis shoes" is lost on people who view age and femininity in other ways.
- Check for appropriateness and use the following with caution:

Animals	People
Body parts/positions	Clothing
Colors	National emblems
Hand gestures	Religious, mythological signs

- Consider whether selection symbols, such as the X or check marks, convey correct distinctions of selected versus not selected items. Some users may interpret an X as crossing out what is not desired, not as selection.
- Symbols of merit or trustworthiness can vary. In a Western auction site like eBay.com, a high-rated vendor is identified by a "seal of approval." By contrast, the Chinese auction site Taobao uses an icon of two hands cradling a golden shopping bag that is often described as a "flower."

15.2.5.3 Typography

- Recognize that character-coding schemes often differ dramatically for different languages. ASCII is primarily limited to English, single-byte schemes accommodate European languages, and double-byte Unicode best supports Asian languages. These differences, as well as bidirectional fonts for Hebrew and Arabic display, make it more challenging to support multilingual UIs. Unless developers can switch (or allow users to switch) character-coding schemes, it is difficult for users to access content easily.
- Use fonts supported for the range of languages required.
- Consider whether special font characters are required for currency, physical measurements, and so on.
- Use appropriate alphabetic sequence and nomenclature (e.g., U.S. "zee" vs. Canadian/English "zed").
- Ensure appropriate decimal, ordinal, and currency number usage. Formats and positioning of special symbols vary from language to language.
- Consider appropriate numeric formats for decimal numbers and their separators (Aykin 2000):

1,234.56	Canada, China, United Kingdom, United States
1.234,56	Albania, Argentina, Denmark, Greece, the Netherlands
1 234,56	Finland, France, Luxembourg, Portugal, Sweden
1’234.56	Switzerland (German, Italian)
1’234,56	Switzerland (French)

- Other numeric issues include the following:
  - Names of characters
  - Standards for display of negative and positive numbers
  - Percent indication

    - Use of leading zeros for decimal values (e.g., 0.1 or .1)
    - List separators
    - Lucky and unlucky numbers (e.g., "lucky" telephone numbers in Asian countries sometimes sell for higher prices. Note that Chinese prefer even numbers, but Japanese prefer odd numbers.)
- Use appropriate temperature formats, that is, Fahrenheit, Centigrade, and Kelvin.
- Use appropriate typography and language for calendar, time zone, and telephone/fax references.
- Consider these date and time issues, among others:
    - Calendars: Gregorian, Muslim, Jewish, Indian, Chinese, Japanese, and so on. Note that within India there are three major Hindu religious calendars (one used by northern Indians, one by southern Indians, and one shared by both) separate from a secular calendar
    - Character representation: Hindu-Arabic, Arabic, Chinese, Roman, and so on
    - Clock of 12 or 24 hours
    - Capitalization rules: for example, book titles in Britain capitalize the first word only versus all main words in U.S. titles and all nouns in German
    - Days considered for start of week and for weekend: Christian, Muslim, and Israeli calendars have different work and rest days. North American monthly calendars typically begin on Sunday; European monthly calendars typically begin on Monday
    - Format field separators
    - Maximum and minimum lengths of date and time
    - Names and abbreviations for days of week and months: two-, three-, and multicharacter standards
    - Short and long date formats for dates and times
    - Time zone(s) appropriate for a country and their names
    - Use of AM and PM character strings
    - Use of daylight savings time
    - Use of leading zeros
- Consider monetary format issues:
    - Credit-/debit-card formats, usage conventions
    - Currency names, denominations
    - Currency symbols (local vs. international versions)
    - Currency conversion rates
    - Monetary formats, symbols, and names
    - Rules for combining different monetary formats: for instance, Euros are often listed with local currencies
    - Requirements for validating monetary input
- Consider name and address formats:
    - Address elements and number of lines
    - Address line order
    - Address punctuation and listing of street numbers (first or last): for example, 4, route de Monastère; 1504 South 58th Street; Motza Illit 11
    - Address zip/postal codes: numeric versus alphanumeric, typography, order in relation to city, state/province, or country
    - Character sets
    - Data field labels (family name vs. last name vs. surname; first name vs. given name vs. Christian name)
    - Field labels: city/town/district/province, and so on
    - Location and location order: neighborhood, district, city/town, state/province
    - Name formats: name order (e.g., family name first for Asian names); capitalization (family names in all caps in Asia); number of names (one name is common in Indonesia); number and order of names (even within Spanish-speaking countries, some list double family names with maternal first, and others list family names with paternal first); surnames (maternal vs. paternal); suffixes (e.g., Jr.); use of middle name or initials
    - Name honorifics, prefixes, and titles: use of Mrs, Miss, or Ms. in English-speaking countries; German double titles like Dr. Eng.
- Consider telephone, fax, and mobile phone number formats:
    - Grouping of digits varies from country to country
    - Internal dialing (initial area code zeros) versus external (without)
    - Numeric versus alphanumeric (i.e., 11-510-767-2676 vs. 510-POP-CORN)
    - Number grouping, separators (e.g., comma, hyphen, period, space, etc.)
    - Use of plus sign for country codes in telephone numbers
    - Use of parentheses for area codes
        – Format for multiple sequential numbers of businesses (slash, commas, etc.)

15.2.5.4 Color

- Follow perceptual guidelines for good color usage. For example, use warm colors for advancing elements and cool colors for receding elements; avoid requiring users to recall in short-term memory more than five plus-or-minus two different coded colors.
- Follow appropriate professional/popular usage of colors, color names, denotation, and connotation.
- Respect national and cultural variations in colors, where feasible, for the target users. For example, Kim and Moon (1998, pp. 16–17) tested emotional

responses to early banking interfaces In Korea. They found color was extremely important in enhancing (or diminishing) trustworthiness:

> The color layout of the interface is also apparently important in enhancing the extent of trustworthiness which the customer of the cyber-banking system feels.… The preferable tone of color for the interface should be cool rather than/ warm and its main color should be a moderate pastel color. At the same time, the colors used in the interface should be of low brightness and the colors should be used symmetrically. On the other hand, the interface that has a bright color background and uses an asymmetrical color scheme will induce a feeling of untrustworthiness in the cyber-banking system.

- In other countries, strong colors and layouts may be used to evoke professionalism and trustworthiness.
- Aykin and Milewski (2005) list color meanings in various countries. For instance, yellow is the imperial color in China but seen as a color of mourning in Egypt.

15.2.5.5 Esthetics

- Respect, where feasible, different esthetic values among target users. For example, some cultures have significant attachment to wooded natural scenes, textures, patterns, and imagery (e.g., the Finnish—Figure 15.1—and the Japanese). Chinese, Korean, and Japanese people enjoy cartoon characters appearing in their products and services, more than would seem appropriate for other cultures.
- Consider specific culture-dependent attitudes. For example, Japanese viewers find disembodied body parts, such as eyes and mouths, unappealing in visual imagery.
- Some cultures prefer to adopt designs from market-leading software. A recent study by Marcus's firm looked at localization issues for Saudi Arabia; Microsoft icons were preferred due to the company's world renown. Similarly, Gould (2007) found that aesthetic standards of "professional design" were associated with websites developed by well-known global companies. Stille (2002) notes that copying is itself a cultural characteristic. Figures 15.2 and 15.3 show the similarity between Baidu.com, a leading Chinese search engine, and Western market leader, Google.com. (For more on these two companies, see Barboza 2006).

15.2.5.6 Language and Verbal Style

- Consider which languages are appropriate for the target users, including the possibility of multiple national languages within one country. For example, English and French within Canada; French, German, and Italian within Switzerland; French or Dutch in Belgium; and Hebrew, Arabic, French (official), and English (unofficial) in Israel. South Africa has eleven official languages (with English listed sixth); India has more than 20. Note also that some languages have different dialects, for example, Mexican, Argentinian, and Castillian (Spain) Spanish; Parisian, Swiss, and Canadian French.

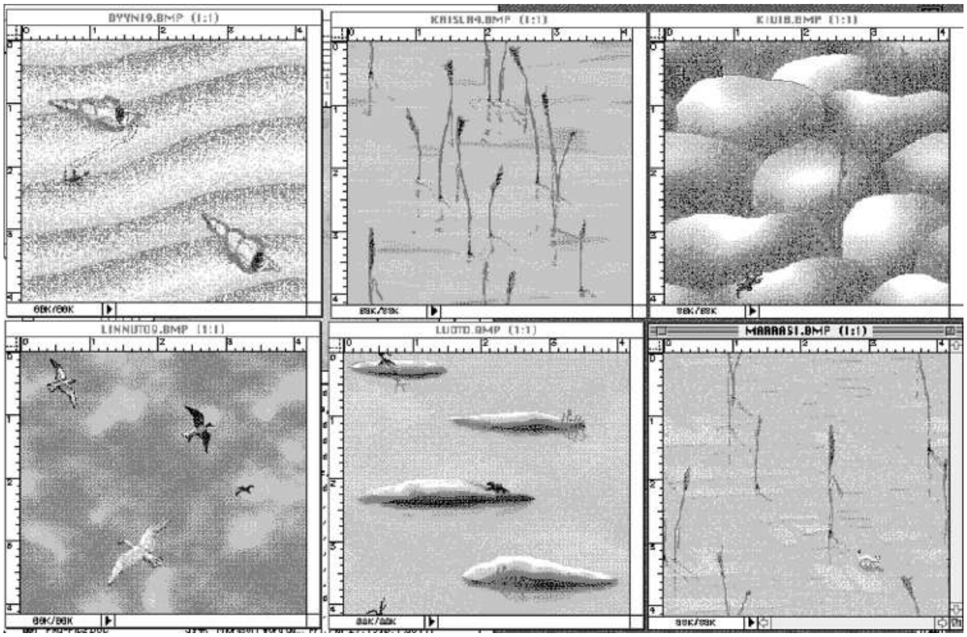

FIGURE 15.1 Example of window application background patterns that seemed appropriate to Finnish software developers. This imagery might be suitable for Finnish and perhaps Japanese, but might not be ideally suited for other cultures.

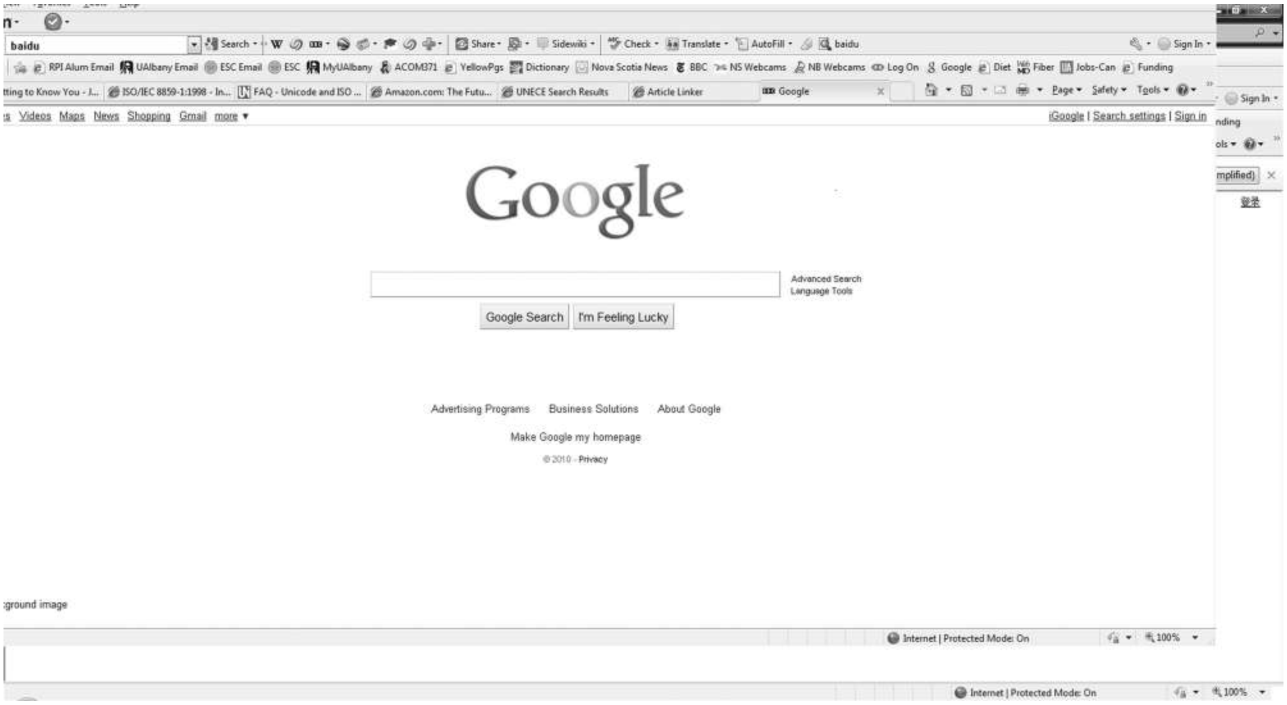

FIGURE 15.2 Example of a Baidu.com Chinese search engine screen home page, which bore a strong resemblance to Google's home page.

FIGURE 15.3 Example of Google.com search engine screen home page. This particular design was noted for its simplicity and large amount of white space, which establish a strong brand and visual identity.

- Understand which dialects and variant spellings are appropriate within language groupings and check vocabulary carefully: British versus American terms in English (see Table 15.4), Mexican versus Spanish terms in Spanish, or Mainland China versus Taiwanese terms in Mandarin Chinese. For example, the use of the word *cheque* tends to identify a website as coming from a British or Commonwealth country.
- Analyze the impact of varying languages on the length and layout of text. For example, German,

TABLE 15.4
Comparison of English-Language User Community Conventions

	United States	United Kingdom
Dates	Month/Day/Year: March 17, 2001, 3/17/01	Day/Month/Year: 17 March 2001, 17/03/01
Time	12-hour clock, AM/PM No leading zero (8:32 AM)	24-hour clock Leading zero (08:32)
Currency	US$189.56, 56¢	GB£189.56, £189.56, 56p
Spelling	Center Color	Centre Colour
Terminology	Truck Bathroom	Lorrie Toilet
Book spine title	Top-down	Bottom up

French, and English versions of text generally have increasingly shorter lengths. Some Asian texts are 50%–80% shorter than English; some non-English Roman-character prose texts can be 50%–200% longer. Some labels can be even longer.

Example (Aykin 2000):

English	Undo	Dutch	Ongedaan maken
English	Autoscroll	Swedish	Automatisk rullning
English	Preferences	German	Bildschirmeinstellungen

- Kwintessential.co.uk (2010) provides some examples of expansion/contraction requirements for various pairs of languages.
- Accommodate the different alphabetic sorting or ordering sequences for the varied languages and scripts by preparing variations that correspond to the alphabets. Different languages may place the same letters in different locations; for example, Å comes after A in French but after Z in Finnish.
- Consider differences of hyphenation, insertion point location, and emphasis, for example, use of bold, italic, quotes, double quotes, brackets, and so on.
- Use appropriate abbreviations for typical items such as dates, time, and physical measurements.

15.3 CULTURE AND LOCALIZATION OPPORTUNITIES

15.3.1 Definitions of Culture

Localization goes beyond software internationalization and language translation to consider target market cultures. Culture has many definitions, which can elicit intense discussion. However, for the purposes of global UI design, it is important to recognize that cultural differences are real. This section analyzes some of the needs, wants, preferences, and expectations of different cultures. Most of the analysis is based on a cross-cultural theory developed by Geert Hofstede; however, other competing theories exist, a discussion of which follows.

As an example of culture differences, consider the order in which one might wish to customize a mobile phone. Some people find it most intuitive to work logically: begin on the main screen by selecting Settings and add sound and display preferences. Others find it easier to work thematically: select Sound (and later Display) on the main screen, review possible options, and then set one's ringtone and wallpaper. Is one path better than another? As previously mentioned, it might depend on whether one is an analytical or holistic thinker. Different people, and different cultures, have different cognitive styles and follow different action pathways (Kim and Lee 2007).

Kim and Lee (2010) note that most academic views of culture rely on similar models of perception and cognition and then contrasts models by Bosa, White, Spradley, Hall, Trompenaars, Hoft, Vask and Grantham, Kluckhohn, and Stewart and Bennett. Most such models consist of layers (or levels) that move from unconscious sensation to conscious awareness. In terms of technology, the top layer is the artifact which reflects the values of designers and users, and basic assumptions from their (generally) shared culture. Lee cites Doblin who said that, the product is "frozen information." Adler (2002) similarly notes that cultural symbols and behaviors rest on attitudes and values and can be used to uncover cultural orientations.

However, one of the first issues when dealing with culture is to recognize that people vary widely; culture itself is not deterministic of what any given person will expect or need from a UI. Even within relatively homogeneous groups, there is individual variation; culture merely reflects the central tendency or consensus of the group. People within single countries may be very different, for example, French-Canadians within Canada, or Muslim groups within European countries. However, even if culture is not always predictive, it is frequently highly descriptive in identifying significant social factors affecting user expectations and use. As such, it can also be viewed as a powerful heuristic for all UI designs. By considering alternative approaches and solutions to interface tasks and problems, an understanding of culture can help designers create much more robust designs that can be more easily localized for new markets.

Many organizational and intercultural communication scholars have published classic studies and theories of culture; in the past decade, culture-oriented works have become better known within the UI design community. Theorists include Hall (1969), Victor (1992), Hofstede (1997), Trompenaars and Hampden-Turner (1998), and Schwartz (2004). Gould (2005) summarizes much of the cultural values literature and suggests implications for UI design. Other researchers have applied these theories to a wide range of social contexts, from business relations and commerce to health and education (e.g., Samovar, Porter, and McDaniel 2008; Adler 2002). Books on "cultural intelligence" promise "the new secret to success."

Recent publications have generated controversy regarding the permanence and identity of many characterizations of cultures. Popular entertainment and the wide availability of new media seem to be washing away cultural differences. The permanence of cultural attributes has been questioned in articles by Ona and Spindle (2000) and Herskovitz (2000), who note the rise of individualism (IDV) in classically collectivist Japan and the acceptance, as well as the influence, of Japanese pop-cultural artifacts (i.e., music, movies, and television) in Asian nations that were recently mortal enemies of Japan. Friedman (2005) notes that the world is "flat" (also "hot and crowded," 2008). However, during the same period, Nisbett (2003) was conducting his research program on analytic and holistic thought, demonstrating differences that he attributes to the origins of Eastern and Western cultures in Confucian China and classical Greece.

Other scholars have criticized technology and popular culture as real manifestations of culture. Clausen (2000), as reported by Yardley (2000), argued that the anthropological term "culture" refers to "the (essentially inescapable) total structure of life of a particular society" while many today use culture to refer to (optional) "shared values." By contrast, "…the 'culture' of the Internet has none of the characteristics of a real culture. It is not a total way of life; it did not evolve among a distinct people; nobody inherited it or was raised in it; it makes no moral demands, has no religion at its center, and produces no art." Although complex, its rules are procedural. From the perspective of Internet "dwellers," some of his statements are likely to stir debate, as will his assertions that in terms of the strict definition, culture no longer exists in the United States. At the very least, Clausen stands in direct contrast to Johnston and Johal (1999) who early defined the Internet as a "virtual cultural region" inhabited by low power distance (PD), individualistic, risk-taking men (and a few women).

Hofstede (1997) has discussed the relation of culture to economic success and made notably differing assertions. He feels people are influenced by a complex mixture of culture plus geography and idiosyncratic drifts in technology, that is, both culture and creativity. Because we are socialized as children, people tend to retain their cultural orientations, values, and attitudes throughout their lives. Self-image may be undermined by change but, even in denial, people remain molded by their culture.

The application of Hofstede's theories will demonstrate the value of intercultural communication research for UI design, using examples in web design. The following Sections 15.3.2 to 15.3.2.5 introduce Hofstede's concept of cultural dimensions.

15.3.2 Hofstede's Dimensions of Culture

During 1978–1983, the Dutch cultural anthropologist Geert Hofstede conducted detailed interviews and surveys with thousands of IBM employees in 53 countries. Through standard statistical analysis of large data sets, he was able to determine patterns of similarities and differences among their replies. From this analysis, he formulated his theory that world cultures vary along consistent, fundamental dimensions. Because his subjects were constrained to one multinational corporation's worldwide employees, and thus to one company culture, he ascribed their differences to the effects of their national cultures. (One debated characteristic of his approach is that he maintained that each country has just one dominant culture.) Hofstede's methodology has been frequently criticized (McSweeney 2002) but his work has tremendous face validity and is widely used in the fields of management and intercultural and organizational communication.

In 1997, Hofstede published a version of his research as *Cultures and organizations: Software of the mind*. His focus was not on defining culture as refinement of the mind but rather on essential patterns of thinking, feeling, and acting that are well established during childhood. These cultural differences manifest themselves in a culture's choices of symbols, heroes/heroines, rituals, and values.

Hofstede rated 53 countries on indices including five dimensions normalized to values (usually) of 0–100. His five dimensions (indices) of culture are as follows:

- Power distance (PDI)
- Collectivism/individualism (IDV)
- Femininity/masculinity (MAS)
- Uncertainty avoidance (UAI)
- Long-term/short-term time orientation (LTO)

Each of Hofstede's dimensions follows with an explanation of implications for UI (especially web UI) design, and illustrations of characteristic websites. The complete data for all countries appears in Table 15.5.

15.3.2.1 Power Distance

PD refers to the extent to which less powerful members expect and accept unequal power distribution within a culture.

High-PD countries tend to have centralized political power and exhibit tall hierarchies in organizations with large differences in salary and status. Subordinates may view the boss as a benevolent dictator who expects them to do as they are told. Parents teach children to be obedient and expect respect. Teachers are considered wise and are esteemed. Inequalities are expected, and even may be desired.

Low-PD countries tend to view subordinates and supervisors more as equals and more interchangeable, with flatter hierarchies in organizations and less difference in salaries and status. Parents and children, as well as teachers and students, may view themselves more as equals. Equality is expected and generally desired.

Hofstede noted that these differences are hundreds or even thousands of years old. He does not believe they will disappear quickly from traditional cultures, even with powerful global telecommunication systems. Based on this definition, (high vs. low) PD may influence the following aspects of UI design:

- Access to information: highly structured versus not as highly structured
- Hierarchies in mental models: tall versus shallow

TABLE 15.5
Indices from Hofstede

	PDI Rank	Score	IDV Rank	Score	MAS Rank	Score	UAI Rank	Score	LTO Rank	Score

Source: Hofstede, G. *Cultures and Organizations: Software of the Mind, Intercultural Cooperation and Its Importance for Survival*, McGraw-Hill, New York, 1997. With permission.

Abbreviations: PDI = power distance; IDV = collectivism/individualism; MAS = femininity/masculinity; UAI = uncertainty avoidance; LTO = long-/short-term time orientation.

- Emphasis on the social and moral order (e.g., nationalism or religion) and its symbols: significant/frequent versus minor/infrequent use
- Focus on expertise, authority, certifications, and official logos: strong versus weak
- Prominence given to leaders versus citizens, customers, or employees
- Importance of security, restrictions, or barriers to access: explicit, enforced, frequent restrictions on users versus transparent, integrated, implicit freedom to roam
- Social roles used to organize information (e.g., a managers' section that is obvious to all but sealed off from nonmanagers)
- Acceptance of website censorship; reduced concern with privacy within social media

15.3.2.2 Individualism versus Collectivism

Individualism in cultures implies loose ties; everyone is expected to look after one's self or immediate family but no one else. *Collectivism* (low IDV) implies that people are integrated from birth into strong, cohesive groups that protect them in exchange for unquestioning loyalty.

Hofstede found individualistic cultures value personal time, freedom, challenge, and such extrinsic motivators as material rewards at work. In family relations, they value being honest, talking things out, using guilt to achieve behavioral goals, and maintaining self-respect. Their societies and governments place individual social-economic interests over the group, maintain strong rights to privacy, nurture strong private opinions (expected from everyone), restrain the power of the state in the economy, emphasize the political power of voters, maintain strong freedom of the press, and profess the ideologies of self-actualization, self-realization, self-government, and freedom.

At work, collectivist cultures value training, physical conditions, skills, and the intrinsic rewards of mastery. In family relations, they value harmony more than honesty/truth (and silence more than speech), use shame to achieve behavioral goals, and strive to maintain face. Their societies and governments place collective social-economic interests over the individual, may invade private life and regulate opinions, favor laws and rights for groups over individuals, dominate the economy, control the press, and profess the ideologies of harmony, consensus, and equality.

Individualism and collectivism may influence, respectively, the following web UI aspects:

- Motivation based on personal achievement: maximized (expect the extraordinary) for individualist cultures versus underplayed (noncompetitive and internal) for collectivist cultures.
- Images of success: demonstrated through materialism and consumerism versus achievement of social, religious, or charitable agendas.
- Rhetorical style: direct, controversial/argumentative speech and tolerance or encouragement of extreme claims versus indirect (apparently vague) speech, official slogans, harmony, modesty, and subdued controversy.
- Prominence given to youth and action versus to aged, experienced, wise leaders and contemplative states of being.
- Importance of individuals; products shown in use by single person versus products shown by themselves or used by groups.
- Central area of focus versus contextual images that place objects against a background. (You [2009] has investigated the relationships of objects to context.)
- Underlying sense of social morality: emphasis on rules and absolute truth versus emphasis on relationships and an ethic of care.
- Emphasis on change: what is new and unique versus what constitutes tradition and maintains historical trends.
- Willingness to provide personal information to all versus sharply defined in-/out-groups (sharing of information with the in-group and protection of personal data from the out-group).

15.3.2.3 Masculinity versus Femininity

Masculinity and *Femininity* (low MAS) refer to gender roles, not physical characteristics. Hofstede focused on the traditional assignment to masculine roles of assertiveness, competition, and toughness, and the assignment of feminine roles to home and children, people, and tenderness. He acknowledged that, in different cultures, different professions are dominated by different genders. (e.g., women dominated the medical profession in the former Soviet Union, while men dominated in the United States). However, in masculine cultures, the traditional distinctions are strongly maintained; whereas feminine cultures tend to collapse the distinctions and overlap gender roles (both men and women can exhibit modesty, tenderness, and a concern with both quality of life and material success). Traditional masculine work goals include earnings, recognition, advancement, and challenge. Traditional feminine work goals include good relations with supervisors, peers, and subordinates; good living and working conditions; and employment security.

The following list shows some typical MAS index values, where a high value implies a strongly masculine culture:

95	Japan
79	Austria
63	South Africa
62	United States
53	Arab countries
47	Israel
43	France
39	South Korea
05	Sweden

Since Hofstede's definition focused on the balance between roles and relationships, masculinity and femininity may be expressed on the web through different emphases. High-MAS cultures might focus on the following UI design elements:

- Traditional gender/family/age distinctions; clothing and personal appearance of men and women expected to be strongly differentiated
- Focus given to masculine accomplishment
- Work tasks, roles, and mastery, with quick results for limited tasks
- Navigation oriented to exploration and control
- Attention gained through games and competitions; games have winners and losers
- Graphics, sound, and animation used for utilitarian purposes

Feminine cultures might emphasize the following UI design elements:

- Blurring of gender roles; clothing and personal appearance of men and women often androgynous
- Mutual cooperation, exchange, and support (vs. mastery and winning)
- Attention gained through visual esthetics, appeals to unifying values, poetry, images of nature

15.3.2.4 Uncertainty Avoidance

People vary in the extent to which they feel anxiety about uncertain or unknown matters, as opposed to the more specific feeling of fear caused by known or understood threats. Cultures vary in their avoidance of uncertainty, creating different rituals and having different values regarding formality, punctuality, legal-religious-social requirements, and tolerance for ambiguity.

Hofstede noted that cultures with high UA tend to have high rates of suicide, alcoholism, and accidental deaths, and high numbers of prisoners per capita. Businesses may have more formal rules, require longer career commitments, and focus on tactical operations rather than strategy. At least in Europe and South Asia, these cultures tend to be expressive; people talk with their hands, raise their voices, and show emotions. People seem active, emotional, and even aggressive. They shun ambiguous situations and expect structure in organizations, institutions, and relationships to help make events easy to interpret and predictable. Teachers are expected to be experts who know the answers and may speak in cryptic, academic language that excludes novices. In high-UA cultures, what is different may be viewed as a threat, and what is "dirty" (unconventional) is often equated with what is dangerous.

By contrast, low-UA cultures tend to be less expressive and less openly anxious; people behave quietly without showing aggression or strong emotions (though their excessive caffeine consumption may be to combat depression from their inability to express their feelings). People seem easygoing, even relaxed. Teachers may not know all the answers (or there may be more than one correct answer), conduct more open-ended classes, and are expected to speak in plain language. In these cultures, what is different may be viewed as simply curious, or perhaps ridiculous.

Based on this definition, UA may influence contrary aspects of UI and web design. High-UA cultures might emphasize the following:

- Simplicity, with clear metaphors, limited choices, and restricted data; high-UI websites would give users far fewer choices to help them avoid making errors
- Attempts to reveal or forecast results of actions before users act
- Navigation schemes intended to prevent users from becoming lost: use of "bread crumbs" and other methods help keep users situated
- Mental models and help systems that focus on reducing "user errors"
- Redundant cues (color, typography, sound, etc.) to reduce ambiguity; lower information density

Low-UA cultures might emphasize the reverse:

- Complexity with maximal content and choices; low-UA websites will give power users much more flexibility
- Acceptance (even encouragement) of wandering and risk, with a stigma on "over-protection"
- Less control of navigation; for example, links might open new windows leading away from the original location
- Mental models and help systems might focus on understanding underlying concepts rather than narrow tasks
- Coding of color, typography, and sound maximize information to provide greater information density

15.3.2.5 Long- versus Short-Term Time Orientation

In the early 1980s, shortly after Hofstede first formulated his cultural dimensions, criticism convinced him that another dimension was needed to explain East Asian countries. After additional research with the Chinese Culture Connection (1987), he developed a new survey and extracted a fifth cultural dimension. LTO seemed to play an important role in Asian countries (influenced by Confucian philosophy over thousands of years) that shared these beliefs:

- A stable society requires unequal relations.
- Social life is governed by the *five relationships* (parent/child; elder sibling/younger sibling; husband/wife; friend/friend; and ruler/subjects).
- The extended family is the prototype of all social organizations; consequently, older people (parents) have more authority than younger (and men more than women).

- Virtuous behavior to others means not treating them as one would not like to be treated.
- Virtuous behavior in work means trying to acquire skills and education, working hard, and being frugal, patient, and persevering.

Western countries, by contrast, were more likely to promote equal relationships, emphasize IDV, focus on treating others as you would like to be treated, and find fulfillment through creativity and self-actualization. When Hofstede and Bond developed a survey specifically for Asia and reevaluated earlier data, they found that long-term orientation cancelled out some of the effects of masculinity/femininity and UA. They concluded that Asian countries are oriented to practice and the search for virtuous behavior while Western countries are oriented to belief and the search for truth. Of the 23 countries compared, the following showed the most extreme values (ranked in parentheses):

118	China (ranked 1)
80	Japan (4)
29	United States (17)
0	Pakistan (23)

High-LTO countries might emphasize the following aspects of UI design:

- Content focused on experience-based knowledge, practice, and practical value
- Relationships as the main source of information and credibility
- Patience in achieving results and goals

Low-LTO (short-term time orientation) countries might emphasize the contrary:

- Content focused on analytic knowledge, logical truth, and strong claims and assertions
- Rules and logic as the basis of information and credibility
- Desire for immediate results and achievement of goals

15.3.2.6 Cultural Dimensions and Design

Hofstede noted that some cultural relativism is necessary: it is difficult to establish absolute criteria for what is noble and what is disgusting. There is no escaping bias; all people develop cultural values based on their environment and early training as children. Not everyone in a society fits the cultural pattern precisely, but there is enough statistical regularity to identify trends and tendencies. These trends and tendencies should not be treated as defective or used to create negative stereotypes but recognized as different patterns of values and thought. In a multicultural world, it is necessary to cooperate to achieve practical goals without requiring everyone to think, act, and believe identically. In fact, contradiction should be viewed as a source of creativity.

Hofstede's cultural differences were applied to website design by Gould, Zakaria, and Yusof (2000) and Marcus and Gould (2000). Although appearances have changed in many of the sites, certain features related to metaphors, mental models, and navigation have survived for long periods of time. A study by Marcus (2005) showed that over a three-year period, websites associated with Sabena and British Airways changed dramatically but appeared to reflect different orientations to UA. The main air-booking areas had approximately the same number of links, but the UK site had twice as many links surrounding the central area, indicating that more complexity was tolerated.

Although this analysis has focused on Hofstede's dimensions, other authors have used other sets of dimensions (up to 762 in number) sometimes mixing several theorists. Marcus and Baumgartner (2004a and b) published a summary of Baumgartner's thesis, which surveyed approximately 60 experts worldwide on their views of the best dimensions from 11 theories for evaluating UIs. Twenty-nine dimensions emerged, from which five dimensions seemed to be most esteemed: (1) high versus low context, (2) technology attitudes and status, (3) UA, (4) time perception, and (5) authority perception. While the optimum set of dimensions continues to be debated, more publications and conference presentation within the UI community advocate the use of culture dimensions (or aligned concepts like cultural cognitive style) to analyze and design UIs.

In recent years, even the concept of usability has been the subject of cultural analysis. Frandsen-Thorlacius et al. (2009) showed that Danish and Chinese users differ substantially in their understanding of the concept of "usability." Chinese users include more association with "fun" and "appeal."

A growth area for research and analysis has been an interest in studying the differences of Web 2.0 applications, social networking, and mobile devices in regard to culture differences. User testing of mobile device usage, especially in daily use contexts is challenging. However, mobile-device eye-tracking equipment, such as that available from Mangold (see Figure 15.4) and other suppliers, and mobile-user message collection and management software, such as the Info-Pal tool from HP Labs (Jain 2010), promise to make the study and development of products/services more sophisticated and sensitive to local needs and cultural differences.

This review of cultural dimensions raises many issues about UI design, especially for the web and for mobile devices:

- How formal or rewarding should interaction be?
- What will motivate different people? Money? Fame? Honor? Achievement?
- How much conflict can people tolerate in content or style of argumentation?

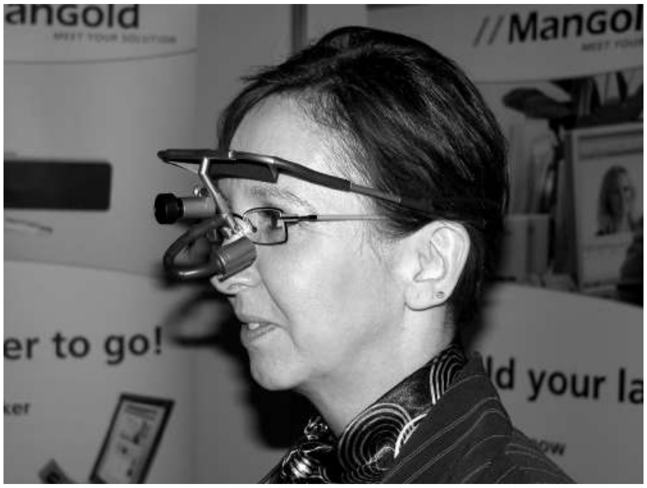

FIGURE 15.4 Example of a head-mounted display for conducting eye tracking of users during testing of mobile-phone applications. The unit is attached to a small portable device that the user carries. (Courtesy of Mangold International, Arnstorf, Germany).

- Should sincerity, harmony, or honesty be used to make appeals?
- What role exists for personal opinion versus group opinion?
- How well are ambiguity and UA received?
- Will shame or guilt constrain negative behavior on social media?
- What role do community values play in individualist versus collectivist cultures?
- Does the objective of distance learning change what can be learned in individualist versus collectivist cultures? Should these sites focus on tradition? Skills? Expertise? Earning power?
- Should online teachers or trainers act as friends, experts, or gurus?
- Would job sites differ for individualist versus collectivist cultures?
- Should there be different sites for men and women in different cultures?
- Would personal webcams be okay? Not okay?
- How much advertising hyperbole is likely to be tolerated?
- Would an emphasis on truth as opposed to practice and virtue require different types of social media for Western or Asian audiences?

To make cross-cultural theory an accepted element of UI design, we need to make it feasible to develop multiple culturally distinguished versions of interfaces and websites in a cost-effective manner, perhaps through templates or through specific versioning tools. As personal computer, web, and mobile products/services continue to develop globally, exploring and exploiting these dimensions of culture will become a necessity, not an option, for successful theory and practice.

15.4 CONCLUSIONS AND FUTURE RESEARCH ISSUES

To achieve culturally sensitive, successful global access to UIs provides many design challenges in the UI-development process. Progress in technology increases the number and kinds of functions, data, platforms, and users of computer-based communication media. The challenge of enabling more people and more kinds of people to use this content and these tools effectively will depend increasingly upon appropriately localized solutions. By recognizing the need for, and benefit to users of UI designs intended for international and intercultural markets, developers will achieve greater success and increased profitability through the global distribution and increased acceptance of their products and services.

The recommendations provided in this chapter include an initial set of heuristics that will assist developers in achieving global solutions to their product/service development. Design methodologies must support globalization throughout the development process. In addition, it is likely that some international and intercultural references will change rapidly, requiring frequent updating of designs. One urgent need is a collection of ROI case studies that show compelling business value of focusing on globalization/localization of UIs, especially in regard to cross-cultural issues. The subject-matter equivalent of an earlier study showing the ROI of usability in general (Marcus 2005) would benefit the field. Future work on global UI design may also address the following issues:

1. How many different kinds of user interfaces should be/can be prepared? Might global UIs be designed to account for different kinds of intelligence? Gardner (1985) identified the following dimensions of intelligence. These dimensions suggest users might have varying strengths of conceptual competence with regard to using UIs on an individual basis, but these might also vary internationally, or interculturally, due to influences of language, history, or other factors:

   - Verbal/image comprehension
   - Word/image fluency
   - Numerical/graphical fluency
   - Spatial visualization
   - Associative memory
   - Perceptual speed
   - Reasoning
   - Interpersonal awareness
   - Self-awareness

2. How might content management systems account for and adjust the metaphors, mental models, and navigation designed precisely for different cultures that might differ by such dimensions as age, gender, national or regional group, or profession? Further, what means can be developed to enable these variations to be produced in a cost-effective manner

using templates and a content-management system that can handle culture bases? Marcus has posed this issue earlier as a question to the UI analysis/design community (Marcus 1993a and b). The topic is discussed broadly in DelGaldo and Nielsen (1996).

The taxonomic analyses of global issues for UIs, the theoretical basis for their component selection, the criteria for their evaluation, and their design methodology have all emerged in the UI-development field. Articles about the impact of culture differences on UI design and techniques of ethnographic analysis appear ever more frequently in primary industry publications and in professional conferences such as those of ACM/SIGHCI, Human–Computer Interface International, UPA, American Anthropologists' Association, IWIPS, and others. The lively exchanges to be found on Anthropologists in Design's Internet discussions likewise attest to the growing numbers of professionals involved in this cross-disciplinary practice (see URL references for resources). Designers should be aware of the scope of the activity, know sources of insight, and incorporate professional techniques in their development process in order to improve the value and success of their international and intercultural computer-mediated products and services.

ACKNOWLEDGMENTS

The authors acknowledge Marcus et al. (1999) and Marcus and Gould (2000), on which this chapter was originally based. Mr. Marcus thanks his staff at Aaron Marcus and Associates, Inc., his coauthor Dr. Emile W. Gould, the editors of this book, and Dr. Constantine Stephanidis, the editor of *User Interfaces for All*, for their assistance in preparing this and earlier versions of this chapter. The authors also acknowledge DelGaldo and Nielsen (1996), Fernandes (1995), and Nielsen (1990), which provided a basis for some points raised in this chapter; and the advice of Peter Simlinger, Dipl.-Ing, Director, International Institute for Information Design, Vienna, Austria; Prof. Andreas Schneider, Information Design Department, Tama Art University, Tokyo, Japan; and Dr. Nuray Aykin, formerly New School, New York.

16 Speech and Language Interfaces, Applications, and Technologies

Clare-Marie Karat, Jennifer Lai, Osamuyimen Stewart, and Nicole Yankelovich

CONTENTS

16.1 INTRODUCTION

A spoken interface for a computer often emulates human–human interaction by calling on our inherent ability as humans to speak and listen. While human speech is a skill we acquire early and practice frequently, getting computers to map sounds to actions and to respond appropriately with either synthesized or recorded speech is a massive programming undertaking. Because we all speak a little differently from each other, and because the accuracy of the recognition is dependent on an audio signal that can be distorted by many factors, speech technology, like the other recognition technologies, lacks 100% accuracy. When designing a spoken interface, one must design to the strengths and weaknesses of the technology to optimize the overall user experience.

The goal for a spoken user interface is to emulate a human dialog convincingly enough that the person interacting with the computer can use what he has learned in a lifetime of conversations. Successful communication is when the sender and receiver of the message achieve a shared understanding. Human-to-human conversations are characterized by turn-taking, shifts in initiative, as well as verbal and nonverbal feedback to indicate understanding. Herb Clark (1993) says, "Speaking and listening are two parts of a collective activity." Because language use is deeply ingrained in human behavior, successful speech interfaces should be based on an understanding of the different ways that people use language to communicate. Speech applications should adopt language conventions that help people know what they should say next and avoid conversational patterns that violate standards of polite, cooperative behavior.

There are excellent examples of speech user interfaces that emulate effective conversational partners. In these systems, the computer "speaker" appears to remember contextual information and gives the impression of understanding what the user is saying. For example, several airlines use speech applications to handle telephone reservations or lost baggage tracking (Cohen, Giangola, and Balogh 2004). These systems are a substantial improvement over earlier interactive voice response (IVR) systems that relied solely on telephone keypad input. Instead of pressing 1 for this and 2 for that, users can speak natural language phrases such as "I'd like to travel from Boston to New York."

A crucial factor in determining the success of a spoken application is whether there is a clear benefit to using speech technology. Speech is best used when it enables something such as conducting transactions (e.g., checking bank balances) that cannot otherwise be done over the telephone when a computer keyboard is not available, or for providing real-time automated translation services in a business setting for a user in conversation with another person speaking a different language. In general, it is effective to use speech applications for situations when speech can enable a task to be done more efficiently, for example, when a user's hands and eyes are busy doing another task. Likewise, speech input is useful when there is no keyboard available for text entry, or if people have a physical disability that limits use of their hands, or if they are just not comfortable typing. Speech output is particularly liberating for people with visual impairments. In addition, it provides a way of communicating information if the user is in a divided attention state such as driving, and it can be used to grab users' attention or to embody a particular personality for a computer system or character.

Although speech seems like it might be the ideal way to communicate with a computer anytime, there are situations when it is best not to use a speech user interface. For example, speech output is ineffective for delivering large amounts of information. Not only is it difficult for users to maintain the information in short-term memory, but people can read much faster than they can listen. Speech input can also be problematic when the speaker is not in a private environment or when there are other voices in the background that might interfere with the speech recognition.

The success of a spoken interaction with a computer depends not only on the task and the motivation of the user, but it is also dependent on the physical devices being used. Speech input and output capabilities of devices vary a lot. For example, personal computers (PCs) provide good-quality audio subsystems and speakers, and there are a variety of microphones that can be used with them that perform very well under quiet conditions. The audio channels for other devices are not on par with PCs. While most smartphones offer speech input capabilities, the quality of their microphones and audio subsystems degrade the speech signal, resulting in poor recognition performance for many applications. Also handheld devices have insufficient computing resources to enable large vocabulary speech recognition processing. For telephony applications, when the input device is either a cell phone or a land line, the speech recognition engines are usually deployed on large servers. The accuracy of telephony systems for a given task is normally lower than that for a similar PC configuration with a headset microphone in a quiet environment. Background noise, signal degradation, poor cellular connection, and the application of compression techniques can substantially reduce the performance of speech recognition systems. Nevertheless, careful design can compensate for many of these problems and lead to successful interaction with a telephone-based speech application. In this chapter, we will also introduce and discuss the current status of language translation applications. When considering speech-to-speech or text-to-text translation applications, it is even more important to address the issues raised above in the design process as there is the additional complexity of working with two or more languages and the need for graceful error recovery within the application.

Speech recognition technology can be used for the following types of tasks:

- *Composition.* Composition tasks have the creation of a document such as word processing documents, e-mails, or instant messaging text as their primary goal. Composition includes dictating the text and fixing any recognition errors.
- *Transcription.* Transcription is similar to composition in that a document is created from speech, but it differs by virtue of the fact that the primary user task is parallel to the creation of a document. Broadcast news, business meetings, and calls are examples of situations in which having a permanent, textual record of the speech is valuable. A digital (textual) record of the conversation is searchable, readable by the deaf and supports advanced business intelligence applications such as data mining. These are all examples of transcription tasks.
- *Transaction.* The third type of interaction, and a major focus of this chapter, is one in which users have as their goal the completion of one or more transactions, rather than the creation of a document

or a permanent record of a conversation. Examples of transactional applications include financial account management such as trading stocks, e-commerce applications such as the purchase of computer equipment, searching for information on the Internet, or controlling the environment.

- *Translation*. The fourth type of interaction, an emerging and critical domain in the interconnected world in which we live, involves the use of computers to translate written or spoken communications from one language to another. The process whereby a computer (e.g., a smartphone or handheld device) systematically transfers or translates the meaning of a text string or a speech utterance from one language to another is called machine translation. The translation task can range from the translation of written documents (newspapers, articles, transcriptions, etc.) to the asynchronous or nearly real-time communication between two people facilitated through computer technology. In one of the most technically challenging scenarios of use, machine translation enables Speaker A's communication in language A to be translated to Speaker B's language B so that the two speakers can read or hear the communication of the other person in his or her desired language, understand the communication, and respond appropriately in an ongoing dialog.
- *Collaboration*. The final type of conversational task is collaboration. Collaborative conversational applications are characterized by tasks that result in human-to-human communication. An example of this is the use of speech recognition as an input modality to an instant messaging application. Human-to-human collaboration is also one of the major applications of machine translation.

As can be seen from the types of tasks that speech technology can be applied to, speech applications may involve the use of speech technology appropriate to one or more of the tasks described above. The set of examples and scenarios described above illustrate the building block nature of the design solutions for speech technology. For example, a speech application may require a design solution for users that handles both composition and collaboration. A second more challenging speech and language application may handle several tasks to complete the user's goal (e.g., working with service providers from other countries to create travel plans and pay for a trip): composition with translation, transaction with real-time translation, and collaboration with real-time translation. A usable design solution may require the combined use of different speech technologies to address the user and system requirements, and the output from one task in an application may be the input for the next step in the application solution.

Designing a speech user interface is similar to designing any other interface for human–computer interaction. A good design relies on applying principles of user-centered design, and many of these same principles and techniques can be used with speech interfaces. In this chapter, we discuss the lifecycle of a speech application from the starting point of understanding how the current and emerging speech and language translation technologies work and their capabilities and limitations, and we discuss the human–computer interaction (HCI) process of crafting a spoken interaction, including understanding the user requirements for speech, knowing which technology to use, selecting a dialog style, and designing the prompts. All these steps are completed in an iterative testing process with target users to refine the speech or language application.

We have expanded the scope of the chapter in this edition by introducing the emerging domain of language translation. Language translation applications build on the technological methods used in speech applications. These methods can be viewed as building blocks in the speech and language technologies domain. Language and translation applications break new ground with informational and collaboration applications. HCI methods and processes are used in the design of language and translation applications and examples of the design process for these new types of applications are provided. The additional challenges of translation interfaces as compared with speech interfaces are discussed and research to address some of these challenges is reviewed. We conclude the chapter with a look to the future of research and development in speech and language technologies and applications.

16.2 SPOKEN INTERFACE LIFECYCLE

Once a designer has clearly established that including speech technology for input, output, or both, is an appropriate design decision, he/she must begin to define how speech best fits into the accomplishment of the task. In order to do this, the designer must first have a clear understanding of the task. With the task well understood, the designer needs to overlay speech onto that model by listening to how people speak in the domain. Observing humans interacting and speaking to accomplish the task may result in additional refinements to the model. The next step is to select the appropriate speech technology, or combination of technologies, for the task, context of use, and user group. The heart of the work for a speech interface designer is to craft the prompts that the system will "speak" and to prepare the system to recognize what the users will most likely say in response. Lastly, there should be a series of tests for the system, initially in the lab and ultimately out in the real world with users accomplishing real tasks. In between the various forms of testing, a designer needs to allocate time to refine the design and make changes based on what he learns from the results of the testing. In this chapter, we will discuss certain steps in greater detail than others. These steps include selecting the technology, and the design of the system including the user prompts.

Thus, the first step in the lifecycle of a spoken interface is modeling the task the users will be accomplishing. This requires the designer to sketch out the logical steps that make up the task, along with the pieces of information that need to be exchanged in order to complete each step. With a speech application, each interaction between the system and a user is often referred to as a "turn." Thus the *task model* tries to capture the expected number of turns as well as the vocabulary that is required to support the information exchange during those turns. It is important for the designer to consider alternate flows because not all users will necessarily approach the task in the same way. For example, when making a flight reservation, some users will select a flight based exclusively on time schedules, whereas others will opt for airline loyalty and price points, accepting any flight time that meets their criteria for loyalty and cost.

The model needs to operate within the set of constraints for the application. Constraints usually include the business goals for creating the speech application, as well as the requirements resulting from the environment that users may find themselves in (e.g., noisy environment) and the users themselves (e.g., the majority of users will be more than 65 years of age and uncomfortable with technology). For example, if a business goal is to cross-sell related items when a customer makes a purchase by calling into a speech-enabled call center application, the designer will want to incorporate a turn that involves the system suggesting related items that are on sale today.

16.3 UNDERSTANDING SPEECH AND LANGUAGE TECHNOLOGIES

Although good interaction design in a speech application can compensate for some short-comings in speech technology, if a certain baseline level of accuracy is not achieved, the application will probably not succeed. Accuracy depends on the choice of the underlying speech technology, and making the best match between the technology, the task, the users, and the context of use. Automatic speech recognition (ASR) can have explicitly defined rule-based grammars or use statistical grammars such as a language model. Usually a transactional system uses explicitly defined grammars while dictation systems or natural language understanding (NLU) systems use statistical models. The designer will also have to decide whether to use synthetic speech in the system or not. Synthetic speech, also known as text-to-speech (TTS), is speech produced by a computer. Given that today's synthesizers still do not sound entirely natural, the choice whether to use synthesized output, recorded output, or no speech output can be a difficult one. The next section discusses the various technologies in more detail.

16.3.1 How Does Automatic Speech Recognition Work?

ASR systems work by analyzing the acoustic signal received through a microphone connected to the computer (see Figure 16.1). The user speaks some text and the microphone captures the acoustic signal as digital data, which is then analyzed by an acoustic model and a language model. The different speech recognition systems on the market differ in the building blocks (e.g., phonemes) that they use to analyze the acoustic signal data. The analysis uses algorithms based on Hidden Markov Models, a type of algorithm that uses stochastic modeling to decode a sequence of symbols, to complete the computations (Rabiner 1989; Roe and Wilpon 1993). After the acoustic analysis is complete, the system analyzes the resulting strings of building block data using a language model that contains a base vocabulary and any specific domain topics (e.g., computer, medical) that may have been added. When the analysis is completed, the text appears on the computer screen.

Output of text on computer display
Acoustic model
Language model

FIGURE 16.1 Overview of human–computer interaction model for speech recognition.

Speech recognition systems require computers with an approximate minimum of 200-MHz processor, 32 MB of RAM, 300 MB of available hard disk, and a 16-bit sound card with a microphone input jack and good recording. These requirements enable local decoding of the recognized speech. It is possible to have a system, such as a small pervasive device, capture a user's speech and then decode it on a remote server (e.g., Price and Sears 2005) and return the decoded text to the user, albeit with a short time delay. Multiple users can work with one installation of a speech recognition system. In some systems, a user creates a personal voice model and logs on with their individual user name, and the system uses their personalized speech files for the recognition processing. Each user can also create several different user voice models in order to achieve the best recognition rates in environments with different levels of background noise (e.g., home, office, and mobile work locations). For results on the effectiveness of creating and using different user voice models, see Price et al. (2006).

16.3.2 Current Capabilities and Limitations of Automatic Speech Recognition Systems

Karat et al. (1999) report ASR system accuracy rates in the mid-90s for "in vocabulary" words (i.e., words in the 20,000 word vocabulary included with the software) in people's initial use of continuous speech recognition software. With more frequent use, error rates of 2%–5% are common. Karat et al. (1999) tested three commercially available speech recognition systems in 1998 with users in initial and extended use and found initial use data of 13.6 corrected words per minute with an average of one incorrect, missing, or extra word for every 20 words and one formatting error every 75 words. Improved ASR system accuracy and higher user productivity were measured when users used more recent versions of the speech recognition software (Sears et al. 2000, Feng 2006) because users are able to correct errors more easily and quickly. The product also provided a better quality microphone to reduce the number of recognition errors that occurred in the first place.

In general, there are three types of errors in ASR systems (Halverson et al. 1999; Karat et al. 2000). Users can make direct errors where they mis-speak, stutter, or press the wrong key. Second, users can make errors of intent, where they decide to restate something. The third type of error is an indirect error, where the speech recognition system misrecognizes what the user says. The indirect errors are difficult to detect during proofreading. All three types of errors can lead to cascading errors where in the process of correcting one error, others occur. These types of errors challenge the usability of ASR speech systems for users and their adoption and continued use by users. An HCI case study of speech research and design considerations for usability in ASR speech systems is provided in Karat and Karat (2010). Motivated users (users with learning disabilities, disabled users) can certainly learn to use ASR systems productively over time. Some improvements have been made in the gracefulness of error recovery for users. However, these systems do not yet display the usability required for widespread adoption by the population.

Most telephony systems are speaker-independent (i.e., no personalized training of the voice models required) speech recognition systems. They are also usually server based and must handle the signal degradation that occurs across the telephone lines. Telephony systems can be created from a combination of speech recognition and natural language processing (NLP) technologies. In telephony systems, a dialog manager component works with the speech recognition software to handle the course of the conversation with the user. The system provides feedback to the user through the dialog manager using recordings of either human voice or TTS. Telephony systems have capabilities such as "barge in" and "talk ahead" that enable the user to redirect the action of the system and complete multiple requests before being prompted for additional information necessary to complete the task. Conversational telephony systems include IVR systems and new systems built using voice XML (please see Section 16.3.5 on NLP for description of the technology). These systems work well and allow users to efficiently complete desired tasks.

16.3.3 How Does Text-to-Speech Work?

TTS synthesis enables computers or other electronic systems such as telephones to output simulated human speech. Synthetic speech is based on the fields of text analysis, phonetics, phonology, syntax, acoustic phonetics, and signal processing. There is a hierarchy of the quality and effectiveness of speech synthesis. The base level of achievement is to produce speech synthesis that is intelligible by human beings. The second level is to produce speech synthesis that simulates the natural qualities of human speech. The third level of speech synthesis is to produce synthesized speech that is personalized to the person it is representing; that is, it has the intonation of the particular person's speech being represented. The fourth and highest level of achievement in synthesized speech is to produce speech based on a person's own voice recordings so that the speech sounds just like the actual person being represented. Currently, speech synthesis technology has achieved the base level of quality and effectiveness, and concatenated synthesis can simulate the natural quality of human speech, although at great expense. The third and fourth levels of speech synthesis technology are the focus of research in laboratories around the world.

There are two types of speech synthesis commercially available today, concatenated synthesis and formant synthesis, which is the most prevalent type. Concatenated synthesis uses computers to assemble recorded voice sounds into speech output. It sounds fairly natural but can be prohibitively expensive for many applications, as it requires large disk storage space for the units of recorded speech and significant computational power to assemble the speech units on demand. Concatenated synthesizers rely on databases of diphones and demisyllables to create the natural sounding synthesized speech. Diphones are the transitions between phonemes. Demisyllables are the half-syllables recorded from the beginning of a sound to the center point, or from the center point to the end of a sound (Weinschenk and Barker 2000). After the voice units are recorded, the database of units is coded for changes in frequency, pitch, and prosody (intonation and duration). The coding process enables the database of voice units to be as efficient as possible.

Formant synthesis is a rule-based process that creates machine-generated speech (see Figure 16.2). A set of phonological rules is applied to an audio waveform that simulates human speech. Formant synthesis involves two complex steps. The first includes the conversion of the input text into a phonetic representation. The second encompasses the production of sound based on that phonetic representation. In the first step, the text is input from a database or file and is normalized so that any symbols or abbreviations are resolved as full alphabetic words. To convert the words into phonemes, a pronunciation dictionary is used for most words and a set

FIGURE 16.2 Model of text-to-speech synthesis.

of letter-to-sound rules is used for word exceptions not available in the dictionary. In the second step, the phonemes are analyzed using a sound inventory and intonation rules about pitch and duration. The speech synthesis is the resulting output that is heard by users through a speaker or headphone.

The quality of the synthetic speech should be evaluated along the lines of its acceptability, naturalness, and intelligibility. It is important to ask users to evaluate different speech against each other because these qualities are always relative (Francis and Nusbaum 1999). Although these subjective differences in opinion will probably always exist, a study by Lai, Wood, and Considine (2000) showed that there were no significant differences in comprehension levels for longer messages (i.e., with a word length ranging from 100 to 500 words) among five major commercial TTS engines.

16.3.4 Current Capabilities and Limitations of Speech Synthesis Software

Formant synthesis produces speech that is highly intelligible but sounds unnatural. However, it has the power to produce nearly unlimited speech inexpensively from a resource point of view. The limitation of using formant synthesis is the complexity of the required linguistic rules to produce accurate speech output. Utilizing domain-specific information and assumptions produces a substantial improvement in the synthesizer's prosody. Prosody refers to speech elements such as intonation, duration, pitch, rate, loudness, or rhythm. Users will be able to comprehend the speech at a higher rate and will perceive the voice to be more natural.

Some applications of concatenated synthesis attempt to reduce costs by basing the voice recordings on whole words. However, these systems often sound unnatural and unevenly paced, which makes the synthetic speech hard to understand or remember. An application of concatenated synthesis should be done correctly or not at all. Also it is advisable when using synthetic speech to not mix it with human speech as this tends to degrade comprehensibility (Gong and Lai 2003).

In the last several years, numerous business organizations have successfully deployed speech systems that are a mixture of IVR and speech recognition technologies to handle customer service calls. For example, these speech systems are successfully used to handle prescription refills for healthcare organizations, track a package or lost luggage, as well as enable customers to check on the status of their financial accounts in banking/finance organizations. These systems are now complemented by websites so customers have a choice in the type of contact channel to use in interactions with the organizations.

16.3.5 How do Natural Language Processing and Natural Language Understanding Work?

NLP refers to a wide range of processing techniques aimed at extracting, representing, responding to and ultimately understanding the semantics of text. NLU is an area of NLP focused on the understanding of natural language text. It is the process of analyzing text and taking some action based on the meaning of the text. We include any technology that allows a user to communicate with a system using a language that is not rigidly structured (i.e., a "formal" language). The focus of this chapter is on systems where communication between the user and the system has constructs similar in grammar and dialog to the language of everyday human–human communication.

As a technology, NLU is independent from speech recognition, although the combination of the two yields a powerful HCI paradigm. When combined with NLU, speech recognition transcribes an acoustic signal into text, which then is interpreted by an understanding component to extract meaning. In a conversational system, a dialog manager will then determine the appropriate response to give the user. Communication with the user can take place through a variety of modalities including speech input and output, text input and output, handwriting, or some combination of these modalities. Figure 16.3 shows a block diagram of a prototypical multimodal conversational system that allows speech and keyboard natural language input, and speech and graphical user interface (GUI) text output.

NLU has been an active area of research for many decades. The promise of NLU lies in the "naturalness" of the interaction. Because humans have deep expertise in interacting with each other through the use of language, it has been an implicit and explicit hypothesis in a wide array of research studies and technology-development efforts that leveraging a user's ability to interact using language will result in systems with greater usability. Designing systems that use natural interaction techniques mean the user is freed from learning the formal language of a system. Thus, instead of using formalisms (e.g., UNIX commands), scripting languages or graphical menus and buttons, users can engage in a dialog with the system. Less user training, more rapid development of expertise, and better error recovery are all promising aspects of systems that use NLU.

Dialog can be described as a series of related conversational interactions. It adds the richness of context and the knowledge of multiple interactions over time to the user interface, transforming natural language interfaces into conversational interfaces. Such interactions require the system to maintain a history of the interaction as well as the state of the interaction at all times (Chai 2001). Two important components, which must be represented in any dialog system, are user goals and the current context of the interaction. The history of the interaction must be evaluated against the user goal, with prompts to the user designed to acquire the necessary information required to satisfy a goal. Dialog technology can be embedded in an application to enable either user-initiated, system-initiated, or mixed-initiative conversations (see descriptions of these different dialog styles in Section 16.4.1). The conversations are guided by dialog management technology.

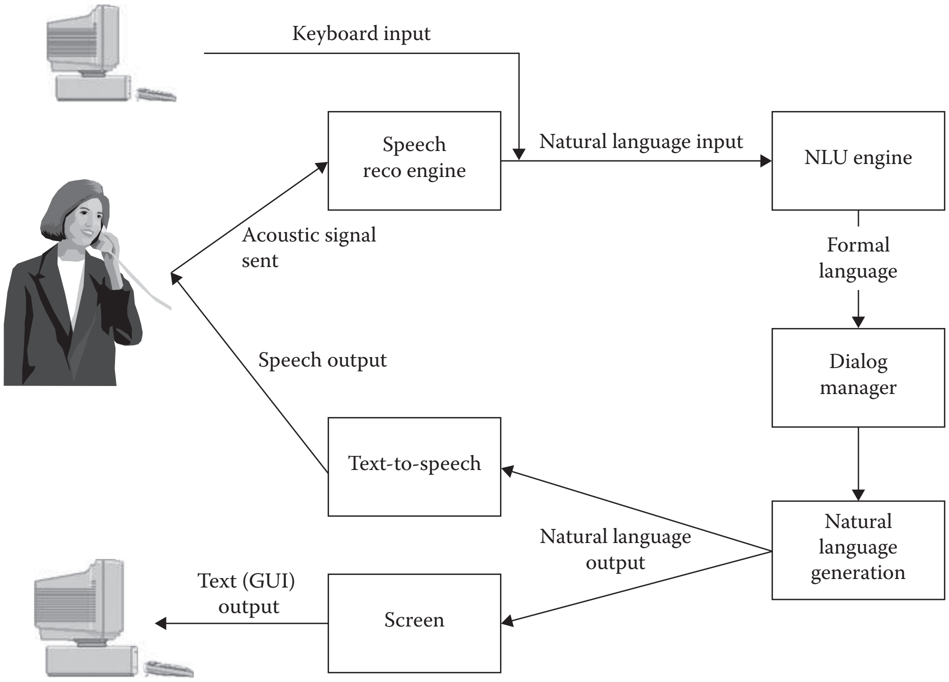

FIGURE 16.3 Diagram of a prototypical multimodal conversational system.

16.3.6 Current Capabilities and Limitations of Natural Language Processing and Natural Language Understanding Systems

Designing speech and language systems poses substantial challenges. Understanding these challenges and assessing the various trade-offs that must be made during the design process will help to produce the most effective interface.

By its nature, speech is *transient*. Once you hear it or say it, it is gone. By contrast, graphics are *persistent*. A graphical interface typically stays on the screen until the user performs some action. Listening to speech taxes users' short-term memory. Because speech is transient, users can remember only a limited number of items in a list and they may forget important information provided at the beginning of a long sentence. Users' limited ability to remember transient information has substantial implications for the speech interface design. In general, transience means that speech is not a good medium for delivering large amounts of information. The transient nature of speech can also provide benefits. Because people can look and listen at the same time, speech is ideal for grabbing attention or for providing an alternate mechanism for feedback. Imagine receiving a notification about the arrival of an e-mail message while working on a spreadsheet. Speech might give the user the opportunity to ask for the sender or the subject of the message. The information can be delivered without forcing the user to switch contexts.

Speech is also *invisible*. The lack of visibility makes it challenging to communicate the functional boundaries of an application to the user (Yankelovich 1996). In a graphical application, menus and other screen elements make most or all of the functionality of an application visible to a user. In contrast, in a speech application, it is much more difficult to indicate to the user what actions they may perform, and what words and phrases they must say to perform those actions.

Capturing and representing knowledge of a domain is a complex and labor-intensive process. As the scope of the application domain increases, it becomes increasingly difficult to build and maintain NLU applications. As a result, all successful examples of rich NLU interfaces have relatively narrow application domains. This has direct impact on the definition of user profiles for any given application. Simply stated, the narrower the conceptual, functional, syntactic, and lexical domains of the target user population, the greater the chance of building an NLU application that satisfies its users. There is currently no way to quantify and measure these characteristics, and determining whether a particular application represents a tractable problem in NLU is largely an issue of experience and instinct on the part of designers and engineers. An NLU engine along with speech input and output technologies are the building blocks for a conversational application. Now let's turn our attention to the emerging domain of language translation technologies.

16.3.7 How Does Machine Translation Work?

Language remains one of the major barriers in a linguistically diverse and globally connected world with an ever-increasing need for people to communicate and collaborate with each other. Thus, it is common to find, in formal settings like the United Nations, representatives of the various nations wearing head-phones through which they receive translations by a human translator or interpreter who works behind the scenes. Moreover, with recent advances in machine translation technology, computers (translation software programs on a PC, smartphones, or other handheld devices) are now also used to facilitate communication between people who speak different languages or to empower people to consume information that is typically only available in a language different from theirs. The process whereby a computer (e.g., smartphones or handheld devices) systematically transfers (translates) the meaning of a text string or a speech utterance from one natural language to another is called machine translation.

The success of machine translation is predicated on the computer system's ability to know all the relevant words or sentences along with their meaning in a source language which are then mapped to the corresponding words, sentences, and their meanings in a target language. This kind of mapping and its effectiveness (accuracy) remains an enormous challenge for machine translation systems and underscores the usability limitations of the technology. As a result, machine translation operates based on the notion of "domain." A domain refers to the thematic content that is required for the interaction in a specified topic or area of conversation. This includes Information Technology (IT Support for technical documents), product manuals, government documents, patents, travel or tourism, weather information, news items, and so on. Indeed, language translation is a complex natural linguistic activity due to the vast amount of variations in how we speak and interpret what is spoken. This makes domains very critical to the success of machine translation technology by defining a priori the domain of thematic content required in the translation corpus. As Goshawke, Kelly, and Wigg (1987) point out "we cannot ask for translations of poetry or subtle literary references or puns or jokes," because of the linguistic and cognitive features necessary for interpreting language including culture, context, and so on.

In general, machine translation domains are comparable with conversational tasks discussed in the speech technology section; however, there is one major difference: translation is a derivative in the conversational task or indirect (embedded) step in the communication process (see Table 16.1). Essentially, a user must first perform a task in the source language (native language), which is then automatically rendered in the target language through machine translation. Thus, the successful outcome of the translation into the target language is dependent on the accuracy or proper characterization from the source language. In light of this interaction flow, it will be beneficial to evaluate how conversational tasks apply (or are realized) through machine translation:

In light of these tasks or functions, it is important to note that millions of people use machine translation every day, mostly on the Internet, to view information in a foreign language. When it does not work, people often wonder how difficult machine translation can really be. In simple terms, the translation process consists of two parts:

1. Decoding the meaning of the text or speech in the source language
2. Re-encoding this meaning in the target language

To perform step 2, machine translation must know and be able to analyze all the features of the string being translated. This requires deep linguistic and cognitive knowledge of the morphology, semantics, syntax, idioms, and so on of the source language, as well as the culture and stylistics of its speakers. Similar in-depth knowledge is required for re-encoding the meaning in the target language. For machine translation technology to be successful, the requirement is for the computer to be able to mediate (translate) between two linguistic universes of the source and target languages. There are two major approaches to handling this requirement: rule based and statistical.

16.3.7.1 Rule-Based Machine Translation

A rule-based machine translation (RBMT) combines dictionary entries of the words in a language plus the "linguistic rules" governing the use of those words which are then encoded into a computer to operate over input data (TAUS Report 2007). Linguistic rules refer to information pertaining

TABLE 16.1
Types of Conversational Tasks

Conversational Task	Objective	Machine Translation
Composition	Create a document (e.g., Word, e-mail, instant messaging)	Document creation: an entire document or a text already created in a source language is translated into a target language
Transcription	The rendering of the content of a document, done in parallel to the composition or creation to create a permanent textual record (e.g., broadcast news, business meetings, calls)	Informational function: translation of content either in real time (e.g., broadcast news, viewing foreign websites), or through batch processing (e.g., viewing meetings, calls, etc.)
Transaction	Completion of one or more transactions	Transactional function: real-time translation to facilitate the completion of one or more transactions between two people who speak different languages (e.g., in tourism, for booking a room in Beijing during the 2008 Olympics)
Collaboration	Aid human–human communication	Collaboration function: real-time translation to facilitate collaboration between two people who speak different languages (e.g., the use of web-based multilingual translator for instant text or speech messaging)

to morphology (word structure such as tense inflection, singular versus plural inflection, etc.), semantics (word meanings as encoded through dictionary definitions), syntax (grammatical outline of how words are combined to form correct phrases and sentences), homonyms (lexical information about word ambiguity that may be triggered depending on various contexts), and so on. All these rules are itemized as formal features of a linguistic system, and then packaged in software programs for translation.

16.3.7.2 Statistical Machine Translation

A statistical machine translation (SMT) works with textual data, not predefined language rules. It processes text by means of pattern-matching algorithms that do not contain any formal "language rules" just a collection of patterns or words that make up the bilingual text corpora to which the statistical methods apply (TAUS Report 2007). Essentially, the system looks at and stores all the linear patterns of words (groups of two, three, or more words) in a text in one language. It then tries to "match" a correlating pattern in a translated version of this same text. This matching can be exact (where the patterns are exactly the same) or fuzzy (where the patterns do not match 100%). In principle, a SMT "learns" from a body of existing translations in order to identify plausible patterns of language in both texts, without reference to any linguistic rules. In this regard, one crucial component necessary for teaching the SMT to recognize or "learn" recurring patterns is the "translation memory." A translation memory is the repository of all the exact matches that exist in parallel text corpora. Quite often, the SMT system relies very heavily on the knowledge-bases provided by the translation memory, and these patterns therein can be used to translate segments of new texts, which will often contain similar groups of words (TAUS Report 2007).

There are some major differences between these two approaches. RBMT requires intensive human-effort (skilled linguists) to come up with the extensive dictionary of words along with the associated large sets of linguistic rules spanning several levels: phonological, morphological, semantic, and syntactic. Most machine translation systems (and especially commercial deployments) now use SMT, whose major drawback is the difficulty in getting enough parallel corpora (of the right kind) to support the learning approach. However, both approaches are similar based on the fact that in order to be successful, all machine translation systems need to be customized. According to the TAUS Report (2007), customization in RBMT involves the adaptation of the dictionary (or glossary) of terms to include new insights or new user requirements, and the linguistic rules. In SMTs, this usually involves retraining the system on a translation memory corpus plus relevant dictionary terms (or glossary). Most practitioners and researchers focus on SMT and so we will only focus on SMT in the subsequent discussion of machine translation technology.

There are two general kinds of SMT systems: speech-to-speech and text-to-text, with the obvious difference attributable to the nature of the input/output mode, whether speech or text.

16.3.7.2.1 Speech-to-Speech

In a speech-to-speech system, two people who speak different languages can engage in real-time communication over the telephone or any socket connection over the Internet (see Figure 16.4). For example, Speaker A speaks in English and the audio (speech) of the utterance is recognized by the ASR (comprising the acoustic and language model) for English, which converts the speech to text. If the speech-to-speech system is a conversational one, then the text string is passed on to the NLU component which assigns or extracts the meaning, otherwise an NLU component is not necessary. Subsequently, the NLU output (form and meaning) is sent to the machine translation component for translation into

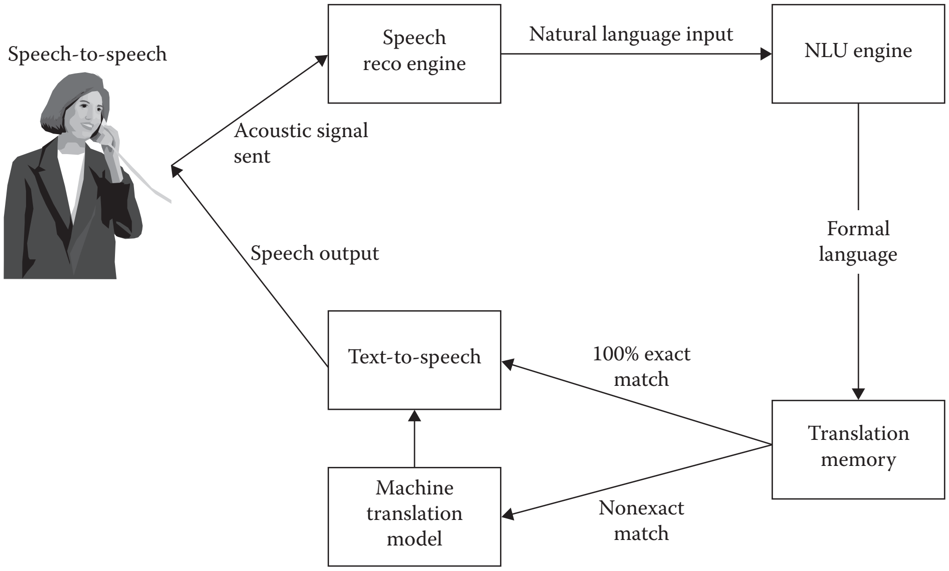

FIGURE 16.4 Diagram of a prototypical speech-to-speech machine translation system.

a target language, for example, Chinese. In its most rudimentary form, there are two subsystems inside the machine translation component: translation memory and machine translation model. The incoming text string initially goes to the translation memory to see if there is an exact match. If one exists, then that is offered as the translation which is presented to the Speaker B. However, if no exact match exists (and the business logic rules out accepting fuzzy matches), then the text string is passed on to the machine translation model where the statistical methods apply to generate the "best guess" translation. Subsequently, the translated utterance (in Chinese) is presented to Speaker B through the Chinese TTS. The entire process happens in real time with latency around 3 seconds or less on the average between the dialog turns. Stewart et al. (2009a) have shown that one problem arising from this multistage process of speech recognition, followed by translation, and then voice synthesis, is that it strips away many of the features of the variations in voice dynamics. More specifically, the eventual TTS output comes out mostly flat without any systematic variations in the tone of voice appropriate to the content of the translation, culture, or language. However, most users are currently preoccupied with the accuracy of the translation and will readily accept poor TTS quality.

16.3.7.2.2 Text-to-Text

A text-to-text system allows people who speak different languages to view information or communicate using various web-based clients or widgets on the Internet. Text-to-text systems work pretty much like the speech-to-speech with the difference being that the input mode is only text (see Figure 16.5). This somewhat simplifies the way text-to-text systems work because there is no need for an acoustic model in the ASR, only the language model is required and the recognized text string is passed on the machine translation component. Also, most text-to-text systems do not include an NLU component (nonconversational systems). With these exclusions in place, then, in general, the same translation process with speech-to-speech also applies: First it looks for exact match in the translation memory and then defaults to the machine translation engine. Thereafter, as there is no need for TTS, the translated text string is passed on the Speaker B in the user interface on the client or widget. With the simplification, the entire process happens in real time with little or no latency (in milliseconds) between the dialog turns.

16.3.8 Current Capabilities and Limitations of Machine Translation Systems

The Internet has truly made the world a global village because it has been able to remove or mitigate the traditional space and time constraints from collaboration. However, along with this growth and adoption is the increasing demand to consume content or collaborate in local languages as only 8%–10% of the world's population of 6.1 billion speaks English (Aykin 2005). Furthermore, there is also the trend that more people travel to different parts of the world (for business or vacation) where English is not the first language. Finally, as globally integrated (multinational) companies, like IBM, with linguistically diverse teams and customers, expand their business to various parts of the world, there is the need to make their services available in the local language and to also empower their employees to engage in cross-national, cross-lingual collaboration. Within the enterprise, there is usually a deluge of online content that grows faster than with which the finite set of professional human translators can ever cope. In addition, companies are faced with the ever-increasing cost of translating online content and continue to seek ways to mitigate the cost of human translation. The translation problem is further compounded because, oftentimes, work in process content becomes obsolete even before the translation cycle is complete, and this content is published by the human professional translators. These conditions (and more) have greatly influenced the development of machine translation solutions based on SMT algorithms.

There is currently no real-world deployment of telephone or Internet-based (non face-to-face) speech-to-speech translation systems. The problem may be attributed to many complex technical and usability issues including disambiguation, accuracy, and latency that get in the way of successful conversational interaction between two people who may be on different continents. Moreover, besides the research-turned commercial version of IBM's multilingual automatic speech-to-speech translator system (Gao et al. 2002, Zhou, Dechelotte, and Gao 2004), there are also very few successful implementations of face-to-face speech-to-speech translation

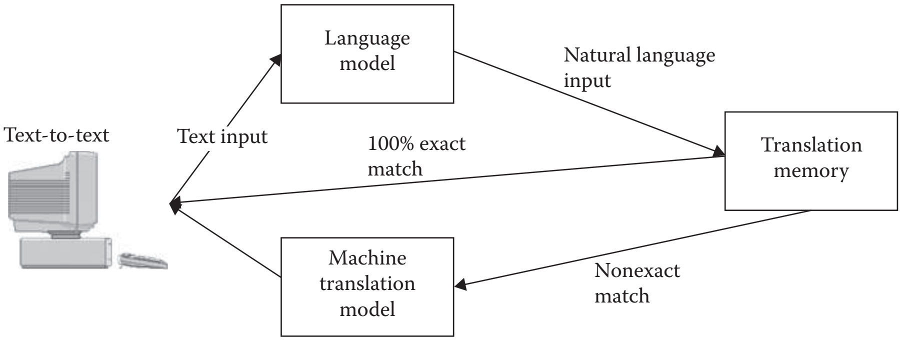

FIGURE 16.5 Diagram of a prototypical text-to-text machine translation system.

systems on devices like smartphones. Therefore, the promise of constructing robust speech-to-speech translations systems to empower people who speak different languages (and may physically be in different locations) to engage in cross-lingual communication is still a dream of speech and natural language research.

In contrast, there are very many successful implementations of text-to-text translation systems, especially those that are offered as widgets on web pages on the Internet and various online software programs (e.g., www.asiaonline.net, www.google.com/translate) for translating documents on the Internet. In addition, there are many commercial translation companies called Language Service Providers, for example, Language Weaver, Lionbridge, and so on, who also use text-to-text machine translation for translation localization, that is, for augmenting the human translation process where machine translation is used to do an initial pass of a document and then a human translator applies postediting rules for completing the document translation. There are also a few machine translation applications now available on smartphones for the business traveler that translate, for example, the most frequent questions or phrases that travelers use in designated locations. Against this background, there are several issues facing machine translation systems, in addition to the technical and usability limitations. The biggest one has to do with public perception and trust. For example, do they really work? This further drives the rapid adoption of this technology to domains where the cost of errors is low, that is, an appreciation for the ability of the technology to basically make information available that is not possible otherwise, like viewing IT or technical support information, news, weather, sports, but not legal or medical information (or any formal domain) where there is a higher demand for accuracy.

With an understanding of how speech and translation technologies work as well as their current capabilities and limitations, let's now consider the design of speech and language applications for users.

16.4 CRAFTING A SPOKEN INTERACTION

The first step in designing a speech interface is to educate yourself about the ways people speak in the domain of the task. The best approach is to find users who are doing an activity that is as close as possible to the target task. Keep in mind that the vocabulary and sentence structure used in graphical computer applications or in printed material may be quite different from the way people actually speak about a task. For example, imagine that you want to provide a speech interface to a calendar. Printed calendars and online calendars typically show day, week, and month views of calendar appointments. They always show days of the week and numbered dates. As soon as you listen to two people talk about appointments and scheduling, however, you learn that they only use numbered dates occasionally. The more common way to discuss dates with other people is to use relative descriptions: "What do you have a week from Monday? Are you busy this Thursday? What about the next day?" The concept of relative dates is completely absent from paper-based and online calendars. But when speaking, users will expect to be able to use them.

With a little creativity, you can find or create situations in which two people can talk about the target task. Although you might want to plan out the interactions a little bit, care must be taken not to put words in the mouths of the users. The idea is to allow people's natural social instincts to drive the dialog. If at all possible, record the natural dialogs. They will serve as the basis for the speech interface design. Listening in this way is called a *natural dialog study* (Yankelovich 2008). Using natural dialog studies, you can learn about concepts used when talking about the task that are absent in other media, common vocabulary used when talking about the task, tone of voice that is considered polite in the context of the task, sentence structure typical for the domain patterns of interaction, and methods people use to give one another feedback.

16.4.1 Dialog Styles

Once you have an understanding of your task and the way people speak in this domain, you will need to decide if your application would benefit most from a directed, user-initiated, or mixed-initiative dialog style.

16.4.1.1 Directed Dialog (System-Initiated)

This is the most commonly used style of interaction in speech-based telephony systems on the market today. With a directed dialog, the user is instructed or "directed" what to say at each prompt (Kamm 1994). Systems that use this style can often be recognized by the use of the word "say" in the prompts. "Welcome to ABC Bank. You can check an account balance, transfer funds, or pay a bill. Say Balance, Transfer, or Pay." The reason most systems use this dialog style is to increase the accuracy of the speech recognition. By telling the user what to say, the chances of the user speaking an out-of-vocabulary utterance are much lower. This style is sometimes referred to as system-initiated because the user plays a more passive role, waiting for the system to prompt him for what is needed.

16.4.1.2 User-Initiated

Unlike a directed dialog, which works well for novice users, user-initiated systems are intended for use by expert users. With this type of interaction style, the system is passive and the user is not prompted for specific information. For example,

Computer: How can I help you?
User: I would like to buy 100 shares of Amazon.com at the market price with funds from my current account number 345198.

These types of dialogs do not work well with new users who do not know what to say, and tend to have much lower recognition accuracy rates.

16.4.1.3 Mixed Initiative

The type of interaction that is easiest for users and feels the most natural is a mixed-initiative system. In this style of interaction, the system and the user take turns initiating the communication depending on the flow of the conversation and the status of the task. With a mixed-initiative system, the prompts can fluctuate between open-ended prompts and more directed prompts depending on the context. The following is a sample dialog:

Computer: What would you like to do? (*open ended*)
User: What is the price of Fidelity Magellan? (*user-initiated*)
Computer: Price of Fidelity Magellan is $36.05 per share. What else?
User: I want to buy 500 shares. (*which shares to buy is implied in the previous interaction*)
Computer: Confirming purchase of 500 shares of Fidelity Magellan fund, please say yes or no. (*directed*)
User: No, skip the purchase. I'd like to transfer $1,000 from my index fund (*user-initiated*).
Computer: Purchase canceled. To which fund would you like to transfer? *(prompt for missing information*)

In this example, we see the system functioning as a cooperative partner in the conversation.

16.4.2 Prompt Design

The challenges of working with speech can often be mitigated by well-designed prompts. Many factors must be considered when designing prompts, but the most important is assessing the trade-off between flexibility and performance. The more you constrain what the user can say to an application, the less likely they are to encounter recognition errors. However, allowing users to speak information flexibly can often speed the interaction (if recognition succeeds), feel more natural, and avoid forcing users to memorize commands. The following are some tips for creating useful prompts.

- Use *explicit directed prompts* when the user input must be tightly constrained. For example, after recording a message, the prompt might be "Say cancel, send, or review." This sort of prompt directs the user to say just one of those three keywords. Even mixed-initiative systems should fall back on this type of prompt when it is critical that the input be correctly recognized, as with transactions that involve transferring money. "Are you sure you want to transfer $1,000 from your savings to your checking account. Please say Yes or No."
- Use *implicit prompts* when the application is able to accept more flexible input. These prompts rely on conversational conventions to constrain the user input. For example, if the user says "Send mail to Bill," and "Bill" is ambiguous, the system prompt might be "Did you mean Bill Smith or Bill Jones?" Users are likely to respond with input such as "Smith" or "I meant Bill Jones." While possible, conversational convention makes it less likely that they would say "Bill Jones is the one I want."
- Using *variable prompts* is a good way to try to simulate a human–human conversation. Given a certain condition or state of the system (e.g., the ready state, or a system response to silence), it is preferable not to play the exact same system prompt every time. Subtle variations in the wording impart a much more natural feel to the interaction. Note the following possibilities for the ready state in an NLU system: "What now," "I'm ready to help," "What's next?"
- Another interaction that we can model on human speech is the use of *tapered prompts*. Tapering can be accomplished in one of two ways. If an application is presenting a set of data such as current quotes for a stock portfolio, drop out unnecessary words once a pattern is established. For example: "As of 15 minutes ago, Acme Industries was trading at 45 up ½, BioStartup was at 83 up ½, and TechGiant was at 106 down ¼." Tapering can also happen over time. That is, if you need to tell the user the same information more than once, make it shorter each time the function is used.
- One way to speed interaction for expert users and provide help for less-experienced users is to use *incremental prompts*. This technique involves starting with a short prompt. If the user does not respond within a time-out period, the application prompts again with more detailed instructions. For example, the initial prompt might be "Which service?" If the user says nothing, then the prompt could be expanded to "Say banking, address book, or yellow pages." Incremental prompts have been used successfully in a number of systems, but suffer from several problems. A first-time user is just as likely to say something to the first prompt, as they are to say nothing. This often results in a recognition error. Another common pitfall with incremental prompts is that they tend to cause collision errors where both the system and the user speak at the same time. It is not uncommon for timing problems to happen repeatedly once started, increasing the user's frustration along the way.

16.4.3 Providing Help

There are two basic types of help. In the first case, the user initiates by requesting help. Common queries for help in speech systems are "Help," "What can I say?" or "What are my choices?" It is always a good idea to support several variations of this request in the speech recognition grammar or language model. In the second type of help, the system detects that the user is in trouble and presents help automatically. Although not all forms of user problems are detectable by the system, one can presume if a series of errors or long silences occur that the user probably needs some assistance.

Help, when given, needs to be specific to the user's current task. There are few things as frustrating as being stuck and asking for help only to find that the information presented, while long and detailed, has no bearing on the current situation. A good approach for help is to provide the user with an example of a successful utterance just as he starts the downward spiral of repeated errors. If several errors have occurred in a row, the system should present the user with sample phrasing that would be expected to work, based on the context that he or she is in. For example, "You could say: I want to sell 300 shares of Ultrasoft." If you cannot determine the exact context, another option is to list the functions that are available at the current branch and have the user point the system in the right direction. Here is an example:

Computer: Let's start over. You can forward, reply, delete, or create a new message. What do you want to do?
User: I want to forward a message.
Computer: To forward a message, say the first and last name of another subscriber. For example, say "Forward this message to John Smith."
User: Forward this message to Alishia Grant.

If the system returns a recognition error now, it is easy to establish that the name is at fault because we already know the function. This dialog might continue as follows:

Computer: Oh dear. I didn't catch that name. Just say the first name.
User: Alishia.
Computer: I think you said Alice, is that correct?
User: No, that is not correct.
Computer: Thanks for your patience with this. Please spell the first name.
User: A L I S H I A

Now the system can repeat a similar process for the last name, or can look up all subscribers with a first name of Alishia and offer the user a set of possible last names to choose from.

16.4.4 Handling Errors

How a system handles recognition errors can dramatically affect the quality of a user's experience. If either the application or the user detects an error, an effective speech user interface should provide one or more mechanisms for correcting the error. Although this seems obvious, correcting a speech input error is not always easy! If the user speaks a word or phrase again, the same error could reoccur depending on the cause of the error (Yankelovich, Levow and Marx 1995).

Recognition errors can be divided into three categories: rejection, substitution, and insertion (Schmandt 1994, Ballentine and Morgan 1999). A rejection error occurs when the recognizer has no hypothesis about what the user said. A substitution error involves the recognizer mistaking the user's utterance for a different valid utterance, as when "send a message" is interpreted as "seventh message." With an insertion error, the recognizer either interprets noise as a valid utterance, or decodes multiple words when only one was spoken. This can be caused by other people talking nearby or by the user inadvertently tapping the telephone or microphone.

16.4.4.1 Rejection Errors

In handling rejection errors, you want to avoid the "brick wall" effect, when every rejection is met with the same "I didn't understand" response. Users get frustrated very quickly when faced with repetitive error messages. Instead, give *progressive assistance*: a short error message the first couple of times, and if errors persist, offer more detailed assistance. For example, here is one progression of error messages that a user might encounter: "Sorry?", "What did you say?", "Sorry. Please rephrase.", "I didn't understand. Speak clearly, but do not overemphasize.", "Still no luck. Wait for the prompt tone before speaking." Progressive assistance does more than bring the error to the user's attention; the user is guided toward speaking a valid utterance with successively more informative error messages that consider possible causes of the error.

16.4.4.2 Substitution Errors

Although rejection errors are frustrating, substitution errors can be damaging. If the user asks a weather application for "Kuai," but the recognizer hears "Good-bye" and hangs up, the interaction could be completely terminated. In situations like this, the system should explicitly verify that the user's utterance was correctly understood. Verification should be commensurate with the cost of the action that would be effected by the recognized utterance. Reading the wrong stock quote or calendar entry will make the user wait a few seconds, but hanging up or sending a confidential message to the wrong person by mistake could have serious consequences.

16.4.4.3 Insertion Errors

These recognition errors typically occur because of background noise. The illusory utterance will either be rejected or mistaken for an actual command; in either case, the previous methods can be applied. The real challenge is to prevent insertion errors. One option is to provide users with a keypad command to turn off the speech recognizer to talk to someone, sneeze, or simply gather their thoughts. Pressing the keypad command again can restart the recognizer with a simple prompt, such as "What now?" to indicate that the recognizer is listening again.

Whatever the type of error, a general technique for avoiding errors in the first place is to filter recognition results for unlikely user input. For example, a scheduling application might assume that an error has occurred if the user appears to want to schedule a meeting for 3 A.M.

16.4.5 Correction Strategies

If errors do occur, it is important to provide a means for the user to correct the error (assuming they notice it). Flexible correction mechanisms that allow a user to correct a portion of the input are helpful. For example, if the user asks for a weather forecast for Boston for Tuesday, the system might respond, "Thursday's weather for Boston is…." A flexible correction mechanism would allow the user to just correct the day: "No, I said Tuesday." This however is challenging for the system as it would require it to keep the context of the previous query and recognize that Tuesday is a replacement for Thursday.

When possible, using an alternate form of input can alleviate the user's frustration. For dictation systems, eye tracking to rapidly select from a list of alternate words has been shown to be successful (Vertanen and MacKay 2010). For transactional telephony systems, the designer can fall back to telephone keypad with a limited set of choices. If the user is at a prompt where only a few choices are available and the user has encountered several rejection errors, the user could be instructed: "Press any key when you hear the option you want." The telephone keypad also works well when the requested input is numeric (e.g., telephone numbers, account, or social security numbers). Getting users to type alphabetic text using a telephone keypad is not a good idea, and it is to avoid this type of input that speech systems are usually recommended in the first place.

Another strategy is to have the system take its best guess at the requested function. This is a good tactic to take when the number of functions enabled at a particular branch in the dialog is too large to list for the user. A reasonable prompt is "I think you are trying to create a message, is that correct?" If the user answers in the affirmative, the conversation moves forward and the system can present the user with a sample valid utterance for that function. However, if the best guess is wrong, it is not a good idea to keep iterating through the N-best choices because this only leads to user frustration. If the response to the best guess is negative, a better solution is to reprompt with a restricted set of choices. Be sure to eliminate the choice that is definitely wrong (e.g., creating a message in the previous example). The goal is to move away from a very general prompt such as, "I'm sorry I do not understand, please try again" toward a directed prompt that will increase the likelihood of success. A series of errors in a row is a clear indication that simply having the user repeat the utterance, or rephrase it, is not working.

The best guess tactic can be combined with another correction strategy, switching to more constrained grammar, to increase its likelihood of success. For example, in the prior prompt, a directive of what utterances are available to the user can be added: "I think you are trying to create a message, is that correct? Please say yes or no."

16.4.6 Testing and Iterating

Once the preliminary application design is complete, a wizard-of-oz study can help test and refine the interface. The speech data collected from this study can be used to help refine the grammar (Rudnicky 1995) or, in the case of an NLU system, to statistically train the engine on potential utterances. In these studies, a human wizard—often using software tools—simulates the speech interface. Major usability problems are often uncovered with these types of simulations.

A wizard-of-oz study usually involves bringing participants into a lab and telling them they will be interacting with a computer. If it is a telephony application, they can be asked to call a telephone number, at which point a human "wizard" picks up the phone and manipulates software so that recordings of synthesized speech are played to the participant. As the participant makes requests to the computer, the wizard carries out the operations and has the computer speak the responses. Often, none of the participants suspect that they are not interacting with a real speech system (Dahlback, Jonsson, and Ahrenberg 1993). Because computer tools are usually necessary to carry out a convincing simulation, wizard-of-oz studies are more time-consuming and complicated to run than natural dialog studies. If a prototype of the final application can be built quickly, it may be more cost-effective to move directly to a usability study.

With speech applications, usability studies are particularly important for uncovering problems because of recognition errors, which are difficult to simulate effectively in a wizard-of-oz study, but are a leading cause of usability problems. The effectiveness of an application's error recovery functionality must be tested in the environments in which real users will use the application. Conducting usability tests of speech applications can be a bit tricky. Two standard techniques used in tests of graphical applications—facilitated discussions and speak-aloud protocols—cannot be used effectively with speech applications. It is best to have study participants work in isolation, speaking only into a telephone or microphone. A tester should not intervene unless the participant becomes completely stuck. A follow-up interview can be used to collect the participant's comments and reactions. Ultimately, the system needs to be tested with real users, accomplishing real tasks in a realistic environment. This type of testing will provide data that will allow the designer to modify the grammar and prompts as necessary.

16.5 DESIGNING LANGUAGE AND TRANSLATION APPLICATIONS

In light of the many odd jokes about errors made by machine translation, the current justification for using machine translation applications is as a "gisting" tool (so-called Fully Automated Useful Translation) that provides reasonable or useful real-time translation (instead of the more accurate Fully Automated High Quality Translation) to increase productivity and collaboration. The majority of translation applications can be classified into two categories:

1. Applications for viewing or consuming information that exist in a foreign language (informational applications): This includes web page translation, text translation, and speech transcription (or translation) that enable a user to view or read the content of a web page, or e-mail, or call details (excluding the images) in his or her language.

2. Applications for cross-lingual real-time communication or collaboration (collaboration applications): A good example of this involves instant messaging translation which enables a user to engage in a real-time chat with another person, using their respective native languages.

16.5.1 Inherent Challenges of Machine Translation

Similar to what has been discussed in Section 16.4 for speech applications, designing machine translation systems also poses substantial challenges. Understanding these challenges and assessing the various trade-offs that must be made during the design process will also help to produce the most effective interface for machine translation applications.

In our discussion of how machine translation works, we stated that one of the defining characteristics that underscores the usability limitations of the technology is the challenge for the system to know all the relevant words or sentences, along with their meaning in a source language, and then map these to the corresponding words, sentences, and their respective meanings in a target language. This is especially important in collaboration applications where machine translation is used for real-time conversational or translational interactions that requires a user to first perform a task in the source language (native language), which is then automatically rendered in the target language. Therefore, the successful outcome of the translation into the target language is dependent on the accuracy or proper characterization from the source language. What we find is that a lot of errors which require HCI intervention are introduced in this process of transitioning the linguistic forms between the two languages through their associated technological components. We will go into more details on this issue in our discussion of the design process (e.g., handling errors).

Another important consideration is that translation does not only need to deal with the formalism of mapping words between two languages but also finding appropriate ways of expressing cultural meanings in the process. Cultural meanings are intricately woven into the fabric of language. Although current algorithms and models have found ways to systematically deal with the purely observable linguistic aspect of language (mapping of words, phrase, sentences), there is a huge vacuum in mapping cultural meanings as part of the translation process in an effective and systematic way.

Unlike speech applications in which a human interacts with a computer that has been trained to respond with predefined prompts (using various conversational and prompting strategies), machine translation collaborative applications are the *invisible* mediator of the conversational interaction between two humans who speak different languages. Given this characterization, there is an additional complexity in that a different set of emotions (e.g., tolerance for errors, levels of expectation, etc.) apply to speech applications when compared with machine translation applications. The former involves HCI, whereas the latter involve both human–human computer mediation features as well as HCI. This difference is not trivial and needs to be accommodated in the design of machine translation applications.

Based on the issues outlined so far, the inherent challenges in designing machine translation systems (e.g., collaboration applications) can be summed up as follows in Table 16.2.

These design issues in a machine translation application pose greater challenges than those for a speech application and must be addressed in order to have an optimal interface.

16.5.2 Habitability

Habitability refers to the ability of users to stay within the limits of a system's domain while expressing themselves conversationally and productively in the ensuing dialog turns

TABLE 16.2
Summary of the Substantial Challenges Involved in the Design of a Machine Translation Application

Challenges	Speech Interfaces	Translation Interfaces
Recognition errors	Speech recognition errors	Speech recognition errors (for S2S systems); Text recognition errors (T2T systems)
Mapping errors	Map a form to a predefined semantic class (for NLU systems) in a single (shared) language	Map forms between two languages
Human factors errors	HCI	HCI; human–human and computer mediation
Cultural errors	Little or no cultural errors since communication occurs in a single (shared) language	Cultural errors abound; lacks any formalism for mapping cultural meanings between the languages

HCI = human–computer interaction; NLU = natural language understanding

(Watt 1968, Ogden 1988). In a speech application, this can be achieved and augmented by providing help to a user who takes too long to speak or says something that is out-of-grammar. Collaborative machine translation applications, as summarized in Table 16.2, involve human–human interaction that is mediated by a computer. Typically, when people engage in a conversation they seek clarification directly from each other, and because the computer is a mediator rather than a participant, there is really no basis for asking the system to provide help like "What are my choices?" or "What can I say?" Consequently, the design challenge is that of habitability, that is, to ensure that a user stays within the limits of the domain. Unfortunately, most of the current applications do not provide any formal functions in the interface where a user can ask for help on what to say in order to stay within the application's domain. Instead, this is left to the participants in the collaborative exchange to figure it out.

16.5.3 Providing Help

Rules for turn-taking have been formalized for human–human interaction (Sacks, Schegloff, and Jefferson 1974). Thus, one basic user interface design consideration is how a system yields control to the user in the conversational interaction. The issue is not whether turn-taking rules will be violated but rather what sort of help is available to enable the user recover. Only one of the two basic types of help discussed in speech application is relevant in collaborative machine translation applications, and this has to do with system-initiated help. An example is when a user is providing credit card information in a speech-to-speech application. This is one good example of an instance where the tolerance for machine translation errors is usually very low. Therefore, it is important to provide help. The way it works is that upon detecting digits in the user's utterance (especially after repeated attempts), the system can provide context-sensitive help to the user saying "Oh, I see you are trying to provide some numbers, you can do this error-free by simply typing them into the text box, rather than speaking." Another example is in text-to-text systems where the system determines that a particular translation has been mapped with very low confidence score. In this situation, rather than sending the translated text on to the other person, the system informs the user to preview the message by using "back translation," which translates the text back into the original message to allow this user make an informed decision either to simplify the text, or use an entirely different strategy altogether (like using only nouns or action words) to force a better translation.

16.5.4 Handling Errors

Like speech applications, machine translation systems are imperfect (and probably will always be) as the interaction is complicated by two potential sources of errors: recognition and translation. The same three categories of recognition errors (rejection, substitution, and insertion) that were earlier described for speech applications can also be found in the speech component of speech-to-speech machine translation applications. However, unlike speech applications, speech-to-speech machine translation applications do not currently have any systematic way of handling these errors in the interface. As we stated in Section 16.3.7, this is a consequence of how machine translation works. Translation depends on the accuracy of the input (in this case speech), but there is no provision in the interface to handle any of the recognition errors whatsoever, rather, the output from the recognition component is passed on directly to the translation component. For future speech-to-speech applications, this is one area in which the strategies already in place for speech applications can be applied or customized. The errors contained in the output from the translation component can also be modeled after the three types of errors in speech application: rejection, substitution, and insertion. Accordingly, a rejection error occurs when the machine translation algorithm has no valid hypothesis about what the user said. For example, a user says "May I run inside and give the keys to my visitor" and the translation outputs only function words like "in the to my" which is complete gibberish. A substitution error involves the machine translation algorithm changing the entire meaning of the original utterance by mistaking the user's utterance for a different valid utterance. For example, a user's initial message "How are you?" is translated as "How old are you?" which, though valid, sets the conversation on an entirely different path (and because two separate cultures are involved, this may even come across as too direct or offensive). In the case of an insertion error, the machine translation algorithm may decode multiple words when only one was spoken. For example, a user says "hello" but the system says "help me get all." The same vacuum in the handling of recognition errors also exist in translation errors; there are currently no formal or systematic ways in the interface for dealing with these categories of translation errors. As a result, the users are left to interpret errors and then try to repair them by picking from any number of available strategies that they think might work. This creates inconsistency in the interface and impedes the ability to learn how to use the system (learnability) as well as the usability of collaborative machine translation systems in general.

In light of the foregoing discussion of the various gaps in handling errors, we propose that a discourse manager should be included in future user interfaces of collaborative machine translation applications. This component will function much like the dialog manager in speech applications and regulate the various strategies for handling recognition and translation errors. The discourse manager will stand between the ASR and the translation component. In this new approach, the output from the ASR is first sent to the discourse manager which will respond with an appropriate error message to the user, where necessary, instead of passing on the erroneous utterance directly to the translation component. Conversely, the output of the translation manager will pass through the discourse manager to regulate any rejection, substitution, or insertion errors, with an appropriate message to the user, instead of passing on gibberish or utterances with low confidence. In addition, the discourse manager will contain formalism for mapping the various cultural (idiosyncratic) aspects of translation including taboo words, slangs, gender, euphemisms, metaphors, clichés, idioms, innuendos, honorifics, and so on. We believe the introduction of a discourse manager into the process of how machine translation works will empower users and ensure a more optimal interface that is able to guard against (or mitigate) instances of being "lost in translation" while using machine translation applications.

16.5.5 Correction Strategies

Although there are currently no systematic strategies for handling the specific types of errors discussed in Section 16.5.4, there are, however, some other general error correction strategies that provide a means for the user to correct a translation error (not recognition errors because those are passed on automatically from the ASR to the translation component).

In speech-to-speech application, the interface allows users to see the translated message that is passed on to the other participant. The standard practice is to show pictures or images on the interface to be used in disambiguating (or augmenting) a poor translation. For example, based on an English–Chinese speech-to-speech application, if a user says "I want to visit the Forbidden City" but all the words except the location (Forbidden City) is correctly recognized and translated, then the system automatically shows a picture of tourists visiting the Forbidden City to augment the poor translation. Similarly, when an ambiguous word like "duck" is the only recognized and correctly translated word in a sentence "I would like to order a duck," and then showing the user the images of a person in the act of ducking (from an object) and that of a duck (bird), usually helps with disambiguation because the user can simply click on the correct image which then sends a predefined relevant utterance in the target language.

In a text-to-text application, the interface allows the user to be able to suggest a better translation in place of a poor translation from the system. In this regard, the function to "suggest a better translation" is a correction feature that allows users to be able to make corrections from the interface. The drawback or weakness of this feature is that its effectiveness (or use) is based on a user being sufficiently bilingual in both the source and target languages. The way it works is that when a user sees a poorly translated text (in the target language), they can make changes to the text, which is then automatically refreshed in the translation memory. This is not a real-time change, that is, you cannot benefit immediately from your own correction; however, it takes effect in near real time in the sense that the correction is available to the very next user.

Another correction strategy used in machine translation applications is to automatically set the maximum number of re-tries in order to prevent dialog loops. This feature keeps track of successive and repeated errors so that when a predetermined threshold is reached, it informs the user either to try a default strategy (like providing credit card numbers while using speech as input and then being asked to default to text input), or to inform the user to pick from a selection of canned phrases or expressions. The canned list usually contains the most frequently used phrases, expressions, or sentences in the relevant domain. The user goes through the list and simply clicks (selects) the one that closely describes the original message he or she was trying to communicate.

16.5.6 Crowdsourcing and Machine Translation

Crowdsourcing is generally described as a web-based activity that harnesses the creative contributions of a diverse large network of individuals (the crowd) through an open call requesting for their participation and contributions (Howe 2006, 2008; Surowiecki 2004, 2005). The typical crowdsourcing ecosystem is one in which a problem (or task) is posted online (by a company or an individual), and a large number of people (the crowd) are motivated (incented) to solve the problem and receive appropriate rewards (Brabham 2008b). As an emerging web-based mass collaboration strategy, there is a lack of formal generalizations about the crowdsourcing community at large because there are currently so many different examples and uses that include www.youtube.com (videos and pictures), www.innocentive.com (basic level research and development), www.sringwise.com (recognizing upcoming trends and weak signals), www.threadless.com (end-product design), www.iStockphoto.com (pictures), www.amazon.com (product recommendations and ratings), and so on. Based on these examples, the scope of crowdsourcing appears to be very diverse even as the application of the strategy continues to expand into new areas (or uses). As far as we are aware, there is very little research on formalizing the differences in crowd behavior with respect to the nature of the task (Whittaker et al. 1998, Viitamaki 2008, Stewart et al. 2010). Given its popularity and exponential growth, it is important to have a model or characterization of crowdsourcing that goes beyond listing various types or characteristics (see Table 16.3). Viitamaki (2008) proposes an initial formalization of the types of crowdsourcing communities based on

TABLE 16.3
Typology of Crowdsourcing Based on Community and Orientation Features

Characteristics	Example
No strong community or community interaction between participants	Innocentive Amazon's mTurk
Individuals create in explicit competition; community interacts and, for example, helps select the best material	Threadless Ideastorm
Community cocreates and cooperates in a joint venture without financial commitment	Cambrian-House Wikipedia
Community makes financial investments and has a large role in directing action. Community "owns" the initiative	Sellaband MyFootballClub

the characteristics derived from community features and time orientation.

Although this proposal is foundational, however, as can be observed, the characteristics applied are a mix of marketing, social networking behavior, and financial. These are simply general and descriptive attributes that say nothing about the nature of the task. In our view, it is the nature of the task that defines a crowdsourcing community and pulls a crowd together (i.e., the essence of crowdsourcing). Therefore, based on the nature of the task, Stewart et al. (2010) propose that there are three general kinds of crowdsourcing communities (Table 16.4).

This classification of crowdsourcing allows us to systematically analyze various crowdsourcing communities. For example, focusing on the individualistic category we observe underlying behavioral similarities between the iStockphoto crowdsourcing community (Brabham 2008a) and the n.Fluent language translation crowdsourcing community (Stewart et al. 2009b) in that they are both individualistic. In both communities, the task requires that participants are one-person units and there is no need for social networking or collaboration among them. They are not interested in building a network of friends or creative professionals.

Crowdsourcing has become very central in the implementation of machine translation applications. In this context, it is often referred to as “community translation.” As the Internet grows in popularity and adoption, so has the use of online machine translation to make information from search portals consumable by the global community. In fact, millions of people turn to www.google.translate.com and other translation portals everyday seeking a cheap (no cost), fast, and reasonable translation of e-mails, text messages, and web pages. In general, this service is free to the end-users who, by using it, provide the much needed data (parallel corpora) for enhancing the SMT engines. This is the background for the two areas where crowdsourcing is currently used in machine translation. First, it is used as an error recovery (correction) strategy for improving imperfect translations. As previously discussed in Section 16.5.4 on handling errors, the translation interface allows (encourages) the user (who is bilingual) to make corrections to the translated content. Based on this strategy, improvements can be made to the translation memory as the crowd provides corrections to poorly translated texts, which are then used to update the translation memory for providing better translations. Another important use of crowdsourcing in machine translation is for data collection (parallel corpora) which is required for improving the SMT algorithms. As a case in point, Stewart et al. (2009b) describes the use of crowdsourcing inside IBM for collecting data to improve its SMT engines by creating a crowdsourcing community with an open call to about 400,000 employees spread over 160 countries. The crowdsourcing platform successfully harnesses the linguistic skills of bilingual employees in translating sentences from English to their native language (or vice-versa), for 11 language pairs including Arabic, Portuguese (Brazilian), Chinese (traditional), Chinese (simplified), French, Italian, Japanese, Korean, Portuguese, Spanish, and Russian.

TABLE 16.4
Typology of Crowdsourcing Based on Nature of the Task

Type	Characteristics and Example
Collectivistic	This involves a task where several people are handling small parts of a larger problem (e.g., uTest), and the community exhibits the need to collaborate and network with each other using available social tools.
Individualistic	This involves a task where many people are contributing (individually) toward a single goal or task (e.g., iStockphoto), and do not need to “socialize” with each other.
Collectivistic-individualistic	This is a mixture of collectivistic and individualistic properties, wherein the crowd is made up of subgroups who cooperate or collaborate to compete against other subgroups in the quest of completing a task (e.g., 2009 Defense Advanced Research Projects Agency experiment where 10 balloons were placed across the United States and teams were challenged to compete to be the first to report the location of all the balloons.

16.6 CONCLUSION

The design and development lifecycle for an effective speech and language translation application differs from a traditional GUI application. An effective speech and language translation application is one that uses speech and/or translation to enhance a user’s performance of a task or enable an activity that cannot be done without it. However, the design process does share common elements with the design of a successful GUI application, such as the need to first understand the task that the users are trying to accomplish. In the case of speech, modeling the task can usually be accomplished by listening to how humans accomplish the task today. Sometimes this involves listening to the interactions that take place between a call center employee and a caller; sometimes it involves constructing a situation between two humans and asking them to converse to accomplish the task. Observing users during the task modeling phase helps a designer to understand who the users are and what their goals are. Listening carefully to users while conducting natural dialog studies shows how they speak in the context of the task. A natural dialog study also ensures that prompts and feedback follow the conversational conventions that users expect in a cooperative interaction.

Once the task is modeled and well understood, and the business goals have been defined, the designer/developer must select the appropriate technology for the task, users, and context of use. Conversational interfaces that use speech technologies capitalize on human expertise in interacting with each other through the use of language. Not all tasks will be able to use NLU given the resource requirements and the need for a constrained domain. However, even speech applications that are built with grammar can carry many of the usability advantages of NLU and have a conversational feel to them if the prompts are carefully crafted. Successful dialogs will move between user-initiated, system-initiated, and mixed-initiative styles depending on the state of the task and the history of the interaction.

The HCI design issues in a machine translation application pose greater challenges than those for speech applications summarized in the previous paragraph. Language remains one of the major barriers in a linguistically diverse and globally connected world, with an ever-increasing need for people to communicate and collaborate with each other. There are research challenges to solve in this area before successful language applications are realized in real-world deployment of telephone or Internet-based (non face-to-face) speech-to-speech translation systems. With the exception of the multilingual automatic speech-to-speech translator system, face-to-face, speech-to-speech translation systems use devices like smartphones. Currently, there are many successful implementations of text-to-text translation systems, especially those that are offered as widgets on web pages on the Internet and various online software programs. To move beyond these speech applications to speech-to-speech translation systems, HCI research is needed to design interventions and mitigate issues introduced by the process of transitioning the linguistic constructs between the two languages, and expressing cultural meanings. These challenges stem from the complexity of managing and designing for both human–human computer mediation features as well as HCI in language translation applications.

Beyond the strategies described throughout this chapter, another key to successful design of usable and effective speech and language translation user interfaces is to follow an iterative HCI process. Not even the most experienced designer can craft a perfect dialog in the first iteration. Once an application is designed, wizard-of-oz and usability studies provide opportunities to test interaction techniques and refine application behavior based on feedback from prototypical users. To ensure that the system will be used over time, the designer must modify the design as new data is collected. One of the critical design aspects is enabling users to gracefully recover from errors in speech and language translation applications. Error recovery must be carefully designed for successful user acceptance and use of an application.

Finally, testing the design with target users ensures that the prompts are clear, that feedback is appropriate, and that errors are caught and corrected. Also, as part of the testing, verifying that the design accomplishes the business goals that were set out to be achieved helps the application gain approval from the sponsors. If problems are uncovered during testing, the design should be revised and tested again. By focusing on users and iterating on the design, one can produce an effective, polished speech interface design.

Looking to the future in speech and language translation research and development, we think that there will be increased focus on these applications. In terms of speech applications, continued research is needed to create more adventurous and successful dialogs that balance user-initiated, system-initiated, and mixed-initiative styles depending on the user's goal and context of use. In terms of language translation applications, the Internet has truly made the world a global village as it has removed or mitigated the traditional space and time constraints from collaboration. The next challenge is to make communication in local languages possible in order to empower people to engage in cross-national, cross-lingual collaboration. The design and development of advanced speech applications and robust speech-to-speech translations systems has the potential to create new capabilities of high value to users in both business and personal settings. The incorporation of HCI methods in these research and development efforts is critical in increasing the probability of success and decreasing the time and effort to create successful applications for users around the world.

17 Multimedia User Interface Design

Alistair Sutcliffe

CONTENTS

17.1 INTRODUCTION

The distinguishing characteristics of multimedia are information-intensive applications that have a complex design space for presenting information to people. Design of multimedia interfaces currently leaves a lot to be desired. As with many technologies, it is the fascination with new devices, functions, and forms of interaction that has motivated design rather than ease of use, or even utility of practical applications. Poor usability limits the effectiveness of multimedia products, which might look good but do not deliver effective use (Scaife et al. 1997). With the growth of the web, use of media has become a vital component of attractive and engaging design.

This chapter describes a design process that starts with an information analysis then progresses to deal with issues of media selection and integration. The background to the method and its evolution with experience can be found in several publications (Sutcliffe and De Angeli 2005; Faraday and Sutcliffe 1996, 1997, 1998; Sutcliffe and Faraday 1994). A more detailed description is given in Sutcliffe (2003). The time-to-market pressure gives little incentive for systematic, principled design, so at first reading, a systematic approach may seem to be counter to the commercial drivers of development. However, I would argue that if multimedia design does not adopt a usability engineering approach, it will fail to deliver effective and usable products.

Traditional multimedia markets have been in education and training, although dialogue in many systems has been restricted to drill and quiz interaction, interactive simulations and microworlds are more effective (Rogers and Scaife 1998). Multimedia has been used extensively in task-based applications in process control and safety-critical systems (Alty 1991; Hollan, Hutchins, and Weitzman 1984). With the advent of the Web 2.0 and beyond, interactive multimedia is a continuing design challenge.

Design for multimedia user interfaces (UIs) expands conventional definitions of usability (e.g., ISO 9241 Part 11: ISO 1997) into five concerns as follows:

1. *Operational usability:* It is the conventional sense of usability that concerns design of graphical user interface (GUI) features such as menus, icons, metaphors, and navigation in hypermedia.
2. *Information delivery:* It is a prime concern for multimedia or any information-intensive application and raises issues of media selection, integration, and design for attention.
3. *Learning*: Training and education are both important markets for multimedia and hence learnability of the product and its content are key quality attributes. However, design of educational technology is a complex subject in its own right, and multimedia is only one part of the design problem.
4. *Utility*: In some applications, this will be the functionality that supports the user's task; in others, information delivery and learning will represent the value perceived by the user.
5. *Engagement and attractiveness*: The attractiveness of multimedia is now a key factor especially for websites. Multimedia interfaces have to attract users and deliver a stimulating user experience, as well as being easy to use and learn.

Multimedia design involves several specialisms, which are technical subjects in their own right. For instance, design of text is the science (or art) of calligraphy that has developed new fonts over many years; visualization design encompasses the creation of images, either drawn or captured as photographs. Design of moving images, cartoons, video, and film are further specializations, as are musical composition and design of sound effects. Multimedia design lies on an interesting cultural boundary between the creative artistic community and science-based engineering. One implication of this cultural collision is that space precludes "within media" design, that is, guidelines for design of one particular medium, being dealt with in depth in this chapter. Successful multimedia design often requires teams of specialists who contribute from their own skill sets (Kristof and Satran 1995; Mullet and Sano 1995).

17.2 DEFINITIONS AND TERMINOLOGY

Multimedia essentially extends the GUI paradigm by providing a richer means of representing information for the user by use of image, video, sound, and speech. The following definitions broadly follow those in the ISO standard 14915 on Multimedia User Interface Design (ISO 1998). The starting point is to ask about the difference between what is perceived by someone and what is stored on a machine.

Communication concepts in multimedia can be separated into the following:

- *Message*: The content of communication between a sender and receiver.
- *Medium (*plural *media)*: The means by which that content is delivered. Note that this is how the message is represented rather than the technology for storing or delivering a message. There is a distinction between perceived media and physical media such as CD-ROM and hard disk.
- *Modality*: The sense by which a message is sent or received by people or machines. This refers to the senses of vision, hearing, touch, smell, and taste.

A message is conveyed by a medium and received through a modality. A modality is the sensory channel that we use to send and receive messages to and from the world, essentially our senses. Two principal modalities are used in human–computer communication as follows:

1. Vision: All information received through our eyes, including text and image-based media
2. Hearing: All information received through our ears, as sound, music, and speech

In the future, as multimedia converges with virtual reality (VR), we will use other modalities more frequently: haptic (sense of touch), kinaesthetic (sense of body posture and balance), gustation (taste), and olfaction (smell). These issues are dealt with in Chapters 19 and 29.

Defining a medium is not simple because it depends on how it was captured in the first place, how it was designed, and how it has been stored. For example, photograph can be taken on film, developed, and then scanned into a computer as a digitized image. The same image may have been captured directly by a digital camera and sent to a computer as an e-mail file. At the physical level, media may be stored by different techniques.

Physical media storage has usability implications for the quality of image and response time in networked multimedia. A screen image with 640 × 480 VGA resolution using 24 bits per pixel for good color coding gives 921,600 bytes, so at 30 frames per second, 1 second needs around 25 megabytes of memory or disk space. Compression algorithms, for example, MPEG (Moving Pictures Expert Group), reduce this by a factor of 10. Improvements in disc storage have reduced file size concerns; however, physical image media constraints are still important on networks, when bandwidth limits the desired display quality. For example, the low-resolution video on mobile phones is typically transmitted at 15 frames per second at a resolution of 240 × 320, although high-resolution cameras 1270 × 780 will be available in the near future. In contrast, Internet video and film on-demand services deliver much higher picture quality, by using intelligent fetch-ahead algorithms, but they need good quality and broadband connections. Sound, in comparison, is less of a problem. Full stereo audio with a complete range of harmonic frequencies consumes only 100 kilobytes for 5 minutes, so there are few technology constraints on high-quality audio.

17.3 COGNITIVE BACKGROUND

The purpose of this section is to give a brief overview of cognitive psychology as it affects multimedia design. More details can be found in Part I, Humans in HCI.

17.3.1 Perception and Comprehension

Generally, our eyes are drawn to moving shapes, then complex, different, and colorful objects. Visual comprehension can be summarized as "what you see depends on what you look at and what you know." Multimedia designers can influence what users look at by controlling attention with display techniques such as use of movement, highlighting, and salient icons. However, designers should be aware that the information people assimilate from an image also depends on their internal motivation, what they want to find, and how well they know the domain (Treisman 1988). A novice will not see interesting plant species in a tropical jungle, whereas a trained botanist will. Selection of visual content, therefore, has to take the user's knowledge and task into account.

Because the visual sense receives information continuously, it gets overwritten in working memory (Baddeley 1986). This means that memorization of visually transmitted information is not always effective unless users are given time to view and comprehend images. Furthermore, users only extract very high-level or "gist" (general sense) information from moving images. Visual information has to be understood by using memory. In realistic images, this process is automatic; however, with nonrealistic images, we have to think carefully about the meaning, for example, to interpret a diagram. Although extraction of information from images is rapid, it does vary according to the complexity of the image and how much we know about the domain. Sound is a transient medium, so unless it is processed quickly, the message can be lost. Even though people are remarkably effective at comprehending spoken language and can interpret other sounds quickly, the audio medium is prone to interference because other sounds can compete with the principal message. Because sound is transient, information in speech will not be assimilated in detail, and so only the gist will be memorized (Gardiner and Christie 1987).

17.3.2 Selective Attention

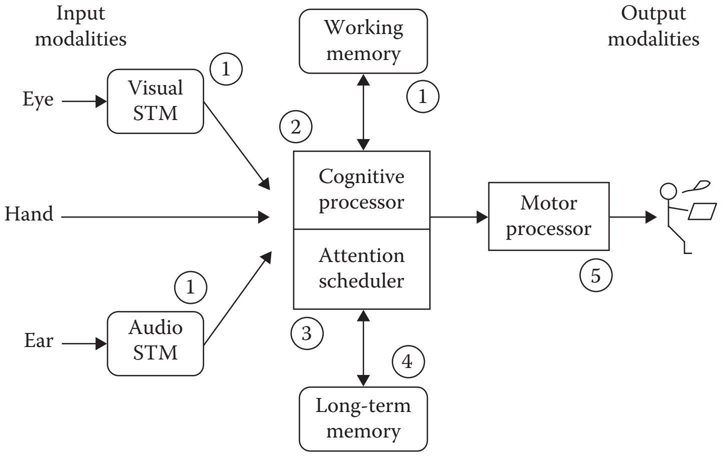
We can only attend to a limited number of inputs at once. Although people are remarkably good at integrating information received by different senses (e.g., watching a film and listening to the soundtrack), there are limits determined by the psychology of human information processing (Wickens, Sandry, and Vidulich 1983). Our attention is selective and closely related to perception; for instance, we can overhear a conversation in a room with many people speaking (the cocktail party effect). Furthermore, selective attention differs between individuals and can be improved by learning: for example, a conductor can distinguish the different instruments in an orchestra, whereas a typical listener cannot. However, all users have cognitive resource limitations, which means that information delivered on different modalities (e.g., by vision and sound) has to compete for the same resource. For instance, both speech and printed text require a language-understanding resource, whereas video and a still image use image interpretation resources. Cognitive models of information-processing architectures (e.g., interacting cognitive subsystems: Barnard 1985) can show that certain media combinations will not result in effective comprehension because they compete for the same cognitive resources, thus creating a processing bottleneck. We have two main perceptual channels for receiving information: vision and hearing; information going into these channels has to be comprehended before it can be used. Figure 17.1 shows the cognitive architecture of human information processing and resource limitations that lead to multimedia usability problems.

Capacity overflow (1) may happen when too much information is presented in a short period, swamping the user's limited working memory, and cognitive processor's capability to comprehend, chunk, and then memorize or use the information. The connotation is to give users control over the pace of information delivery. Integration problems (2) arise when the message on two media is different, making integration in working memory difficult; this leads to the thematic congruence principle. Contention problems (3) are caused by conflicting attention between dynamic media, and when two inputs compete for the same cognitive resources. For example, speech and text require language understanding. Comprehension (4) is related to congruence; we understand the world by making sense of it with our existing long-term memory. Consequently, if multimedia content is unfamiliar, we cannot make sense of it. Finally, multitasking (5) makes further demands on our cognitive processing, so we will experience difficulty in attending to multimedia input while performing output tasks.

Making clear a theme in a multimedia presentation involves directing the user's reading and viewing sequence across different media segments. Video and speech are processed in sequence, whereas text enforces a serial reading order by the syntactic convention of language. In contrast, viewing image media is less predictable since it depends on the size and complexity of the image, the user's knowledge of the contents, task and motivation (Norman and Shallice 1986), and designed effects for salience. Attention-directing effects can increase the probability that the user will attend to an image component, although no guarantee can be given that a component will be perceived or understood.

17.3.3 Emotion and Arousal

The content of image media in particular can evoke an emotional response, which can be used to promote a more exciting and engaging user experience. These issues are dealt with more extensively in other chapters; for example, the use of human image and speech to persuade users. People treat human photographs, video, and even animated characters with similar social responses as they give to real people, so human image content can be used to increase interest and



Bottlenecks
1. Capacity overflow: information overload
2. Integration: common message?
3. Contention: conflicting channels
4. Comprehension
5. Multitasking input/output

STM = short-term memory
Similar to working memory,
limited capacity,
continuously overwritten
with new input

FIGURE 17.1 Approximate model of human information processing using a "human as computer system" analogy, based on the Model Human Processor. For more on cognitive models, see Chapter 2 (Proctor and Vu) and Chapter 5 from the Second Edition of the HCI Handbook (Byrne). (From Card, S. K., T. P. Moran, and A. Newell. *The Psychology of Human Computer Interaction*, Lawrence Erlbaum Associates, Hillsdale, NJ, 1983. With permission.)

draw attention. Emotional responses (see Chapter 4 from the Second Edition of the HCI Handbook) can be invoked not only by content but also by surprise interactive effects, for example, when a character suddenly appears to challenge the users. Surprise effects, moving image, and stimulating images we are not expecting, all affect the arousal system that broadly equates with our feeling of excitement. Designs that stimulate our arousal are more likely to be memorable and engaging.

17.3.4 Learning and Memorization

Learning is the prime objective in tutorial multimedia. In these applications, the objective is to create a rich memory schema, which can be accessed easily in the future. We learn more effectively by active problem solving or learning by doing. This approach is at the heart of constructivist learning theory (Papert 1980), which has connotations for tutorial multimedia. Interactive microworlds where users learn by interacting with simulations, or constructing and testing the simulation, give a more vivid experience that forms better memories (Rogers et al. 1998). Multiple viewpoints help to develop rich schemata by presenting different aspects of the same problem, so the whole concept can be integrated from its parts. An example might be to explain the structure of an engine, then how it operates, and finally display a causal model of why it works. Schema integration during memorization fits the separate viewpoints together.

The implications from psychology are summarized in the form of multimedia design principles (ISO, 14915, Part 3 Media Integration, ISO 1997). The principles are high-level concepts, which are useful for general guidance, but they have to be interpreted in a context to give more specific advice.

- *Thematic congruence*: Messages presented in different media should be linked together to form a coherent whole. This helps comprehension as the different parts of the message make sense by fitting together. Congruence is partly a matter of designing the content so it follows a logical theme, for example, the script or story line makes sense and does not assume too much about the user's domain knowledge; and partly a matter of attentional design to help the user follow the message thread across different media.
- *Manageable information loading*: Messages presented in multimedia should be delivered at a pace which is either under the user's control or at a rate that allows for effective assimilation of information without causing fatigue. The rate of information delivery depends on the quantity and complexity of information in the message, the effectiveness of the design in helping the user extract the message from the media, and the user's domain knowledge and motivation. Some ways of reducing information overload are to avoid excessive use of concurrent dynamic media and give the user time to assimilate complex messages.
- *Ensure compatibility with the user's understanding*: Media should be selected that convey the content in a manner compatible with the user's existing knowledge, for example, the radiation symbol and road sign icons are used to convey hazards and dangers

to users who have the appropriate knowledge and cultural background. The user's ability to understand the message is important for designed image media (diagrams, graphs) when interpretation is dependent on the user's knowledge and background.

- *Complementary viewpoints*: Similar aspects of the same subject matter should be presented on different media to create an integrated whole. Showing different aspects of the same object, for example, picture and design diagram of a ship can help memorization by developing richer schema and better memory cues.
- *Consistency*: It helps users learn an interface by making the controls, command names, and layout follow a familiar pattern. People recognize patterns automatically, so operating the interface becomes an automatic skill. Consistent use of media to deliver messages of a specific type can help by cueing users with what to expect.
- *Interaction and engagement*: They help understanding and learning by encouraging the user to problem solve. Memory is an active process. Interaction increases arousal and this make the user's experience more vivid, exciting, and memorable.
- *Reinforce messages*: Redundant communication of the same message on different media can help learning. Presentation of the same or similar aspects of a message helps memorization by the frequency effect. Exposing users to the same thing in a different modality also promotes rich memory cues.

17.4 DESIGN PROCESS

Multimedia design has to address the problems inherent in the design of any UI, namely, defining user requirements, tasks, and dialogue design; however, there are three issues that concern multimedia specifically:

1. *Matching the media to the message* by selecting and integrating media so the user comprehends the information content effectively.
2. *Managing users' attention* so key items in the content are noticed and understood, and the user follows the message thread across several media.
3. *Interaction and navigation* so the user can access, play, and interact with media in an engaging and predictable manner.

Figure 17.2 gives an overview of the design process that addresses these issues.

The method shown in the figure starts by requirements and information analysis to establish the necessary content and communication goals of the application. It then progresses to domain and user characteristic analysis to establish a profile of the user and the system environment. The output from these stages feeds into media selection and integration, which match the information requirements to available media resources. This is interleaved with interaction design unless the application is restricted to information presentation. Design then progresses to thematic integration of the user's reading/viewing sequence and design to direct the users' attention. Even though the process is described as a sequence, in practice, the stages are interleaved and iterated; however, requirements, information modeling, and media selection should be carried out, even if they are not complete, before subsequent design stages commence.

Design approaches in multimedia tend to be iterative and user-centered. *Storyboards* are a well-known means of informal modeling in multimedia design (Nielsen 1995; Sutcliffe 1999). Originating from animation and cartoon design, storyboards are a set of images that represent key steps in a design. Translated into software, storyboards depict key stages in interaction and are used for conducting walk-throughs to explain what happens at each stage. Allowing the users to edit storyboards and giving them a construction kit to build their own encourages active participation. Storyboards are followed by building concept demonstrators using multimedia authoring tools (e.g., Macromedia Director, Adobe Dreamweaver) to rapidly develop early prototypes. *Concept demonstrators* are active simulations that follow a scenario script of interaction; departure from the preset sequence is not allowed. Several variations can be run to support comparison; however, the user experience is passive. In contrast, users can test *interactive prototypes* by running different commands or functions. The degree of interactivity depends on the implementation cost, which increases as prototypes converge with a fully functional product.

17.4.1 Users, Requirements, and Domains

The starting point for multimedia, as in all applications, is requirements analysis. The difference in multimedia lies in the greater emphasis on information requirements. A variety of analytic approaches can be adopted, such as task analysis (see Chapter 43), contextual inquiry (Chapter 44), or scenario analysis (Chapter 48). Requirements are listed and categorized into information, task-related, and nonfunctional classes. These will be expanded in subsequent analyses.

It is important to get a profile of the target user population to guide media selection. There are three motivations for user analysis:

1. *Choice of modalities*: This is important for people with disabilities, but also for user preferences. Some people prefer verbal-linguistic material over image.
2. *Tuning the content*: This is presented to the level of users' existing knowledge. This is particularly important for training and educational applications.
3. *Capturing the users' expectations*: So the experience can be geared to their background, for example, different styles for younger people, older people, culture, and socioeconomic audiences.

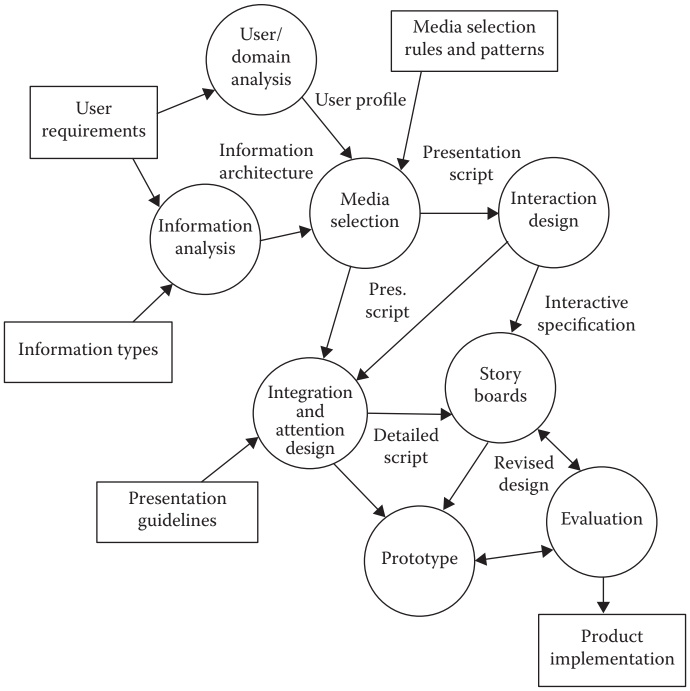


FIGURE 17.2 Overview of the multimedia design process expressed as a data flow diagram.

Acquiring information about the level of experience possessed by the potential user population is important for customization. User profiles are used to design training applications to ensure that the right level of tutorial support is provided, and to assess the users' domain knowledge so that appropriate media can be selected. This is particularly important when symbols, designed images, and diagrams may be involved. The role and background of users will have an important bearing on design. For example, marketing applications will need simple focused content and more aesthetic design, whereas tutorial systems need to deliver detailed content. Information kiosk applications need to provide information, as do task-based applications, but decision-support and persuasive systems (Fogg 1998; see also Chapter 14) also need to ensure that users comprehend and are convinced by messages. Domain knowledge, including use of conventions, symbols, and terminology in the domain, is important because less-experienced users will require more complete information to be presented.

The context and environment of a system will also have an important bearing on design. For example, tourist information systems in outdoor public areas will experience a wide range of lighting conditions, which can make image and text hard to read. High levels of ambient noise in public places or factory floors can make audio and speech useless. Hence, it is important to gather information on the location of use (office, factory floor, public/private space, and hazardous locations), pertinent environmental variables (ambient light, noise levels, and temperature), usage conditions (single user, shared use, broadcast), and expected range of locations (countries, languages, and cultures). Choice of language, icon conventions, interpretation of diagrams, and choice of content all have a bearing on design of international UIs.

As well as gathering general information about the system's context of use, domain modeling can prove useful for creating the system metaphor. Domain models are recorded as sketches of the work environment showing the layout and location of significant objects and artifacts, accompanied by lists of environmental factors. Structural metaphors for organizing information and operational metaphors for controls and devices have their origins in domain analysis.

17.4.2 Information Architecture

This activity consists of several activities that will differ according to the type of application. Some applications might have a strong task model, for instance, a multimedia process control application where the tasks are monitoring a chemical plant, diagnosing problems, and supporting the operator in controlling plant operation. In task-driven applications, information requirements are derived from the task model. In information-provision applications, such as websites with an informative role, information analysis involves categorization and the architecture generally follows a hierarchical model. In the third class of explanatory or thematic applications, analysis is concerned with the story or argument, that is, how the information should be explained or delivered. Educational multimedia and websites with persuasive missions fall into the last category.

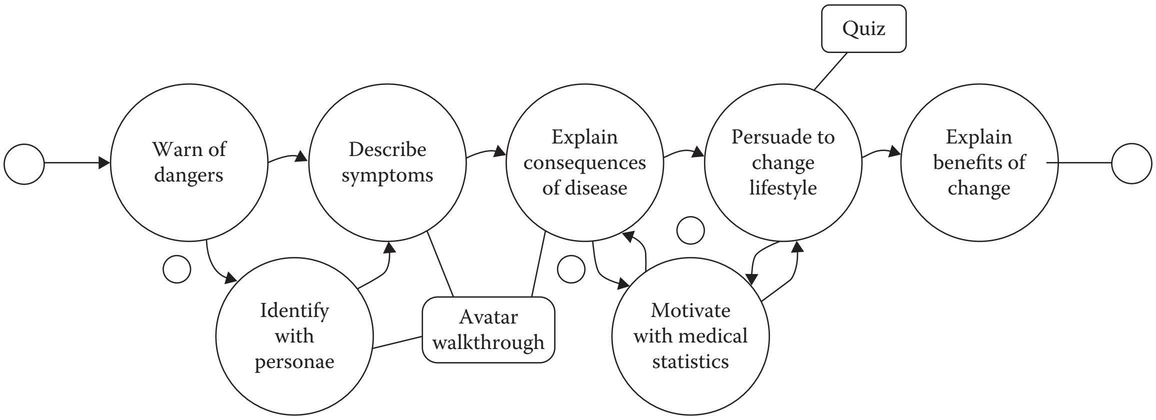
In task-driven applications, information needs are annotated on to the task model following a walk-through asking what information the users need to complete the task subgoal, or to take a decision at this step, or to provide as input (see Sutcliffe [1997] for more detail). In information-provision applications, classification of the content according to one of more user views defines the information architecture; for example, most university departments have an information structure with upper-level categories for research, undergraduate courses, postgraduate courses, staff interests, departmental organization, mission and objectives, and so on. For explanatory applications, a theme or story line needs to be developed. This will depend on the application's objectives and the message the owner wishes to deliver. An example thematic map from a health awareness application is illustrated in Figure 17.3.

The requirement is to convince people of the dangers of heart disease. The theme is a persuasive argument that first tries to convince people of the dangers from smoking, poor diet, stressed lifestyles, and so on, then explains how to improve their lifestyle to prevent heart disease, followed by reinforcing the message with the benefits of a healthy lifestyle such as lower health insurance, saving money, longer life. Subthemes are embedded at different points so users can explore the facts behind heart disease, the statistics and their exposure, and how to get help. Information is then gathered for each node in the thematic map. How this architecture will be delivered depends on interaction design decisions: it could become an interactive story to explore different lifestyle choices, combined with a quiz. The outcome of information architecture analysis will be an information-enhanced task model, a thematic map, or a hierarchy/network to show the structure and relationships of information categories. The next step is to analyze the information content by classifying it by types.

Information types are amodal, conceptual descriptions of information components that elaborate the content definition. Information components are classified into one or more of the following:

- Physical items relating to tangible observable aspects of the world
- Spatial items relating to geography and location in the world
- Conceptual-abstract information, facts, and concepts related to language
- Static information which does not change: objects, entities, relationships, states, and attributes
- Dynamic, or time-varying information: events, actions, activities, procedures, and movements
- Descriptive information, attributes of objects and entities
- Values and numbers
- Causal explanations

More complex taxonomies elaborate concepts and linguistic information as ontologies and arguments (Mann and Thompson 1988), but additional complexity is only warranted for tools that automatically generate multimedia output (Zhou and Feiner 1998). It is important to note that one component may be classified with more than one type; for instance, instructions on how to get to the railway station may contain procedural information (the instructions <turn left, straight ahead, etc.>) and spatial or descriptive information (the station is in the corner of the square, painted blue). The information types are "tools for thought" that can be used either to classify specifications of content or to consider what content may be necessary. To illustrate, for the task "navigate to the railway station," the content may be minimally specified as "instructions how to get there," in which case the information types prompt questions in the form "what sort of information does the user need to fulfill the task/user goal?" Alternatively, the content may be specified as a scenario narrative of directions, waymarks to recognize, and description of the target. In this case, the types classify components in the narrative to elucidate the deeper structure of the content. The granularity of components is a matter of the designer's choice and will depend on



Quiz
Warn of dangers
Describe symptoms
Explain consequences of disease

FIGURE 17.3 Thematic map for a healthcare promotion application.

the level of detail demanded by the application. To illustrate the analysis:

Communication goal: Explain how to assemble a bookshelf from ready-made parts.

Information component 1:
  Parts of the bookshelf, sides, back, shelves, connecting screws
  Mapping to information types:
    Physical-static-descriptive; parts of the bookshelf are tangible, do not change and need to be described
    Physical-static-spatial; dimensions of the parts, how they are organized
    Physical-static-relationship type could also be added to describe which parts fit together
Information component 2:
  How to assemble parts instructions
  Mapping to information types:
    Physical-dynamic-discrete action
    Physical-dynamic-procedure
    Physical-static-state; to show final assembled bookshelf

17.4.3 Media Selection and Combination

The information types are used to select appropriate categories of media resource(s). Media classifications focus on the psychological properties of the representations rather than the physical nature of the medium (e.g., digital or analogue encoding in video). Note that these definitions are combined to describe any specific medium, so speech is classified as an audio, linguistic medium, whereas a cartoon is classified as a nonrealistic (designed) moving image.

The definitions may be usefully considered in two dimensions of abstraction: the designer's involvement in creating the medium and rate of change. Media resources are classified using the decision tree illustrated in Figure 17.4. More fine-grained taxonomic distinctions can be made, for instance, between different signs and symbolic languages (see Bernsen [1994]), but as with information types, richer taxonomies increase specification effort.

The approach to classifying media uses a walk-through of the decision tree with the following questions that reflect the facets of the classification:

- Is the medium perceived to be realistic or not? Media resources captured directly from the real world will usually be realistic, for example, photographs of landscapes, sound recordings of bird song. In contrast, nonrealistic media are created by human action. However, the boundary case category that illustrates the dimension is a realistic painting of a landscape.
- Does the medium change over time or not? The boundary case here is the rate of change, particularly in animations where some people might judge 10 frames/s to be a video, but 5 slides in 1 minute shown by a PowerPoint presentation to be a sequence of static images.
- Which modality does the resource belong to? In this case, the categories are orthogonal, although one resource may exhibit two modalities; for example, a film with a soundtrack communicates in both visual and audio modalities.

Classification of media resources facilitates mapping of information types to media resources; however, the process may also guide the acquisition or creation of new resources,

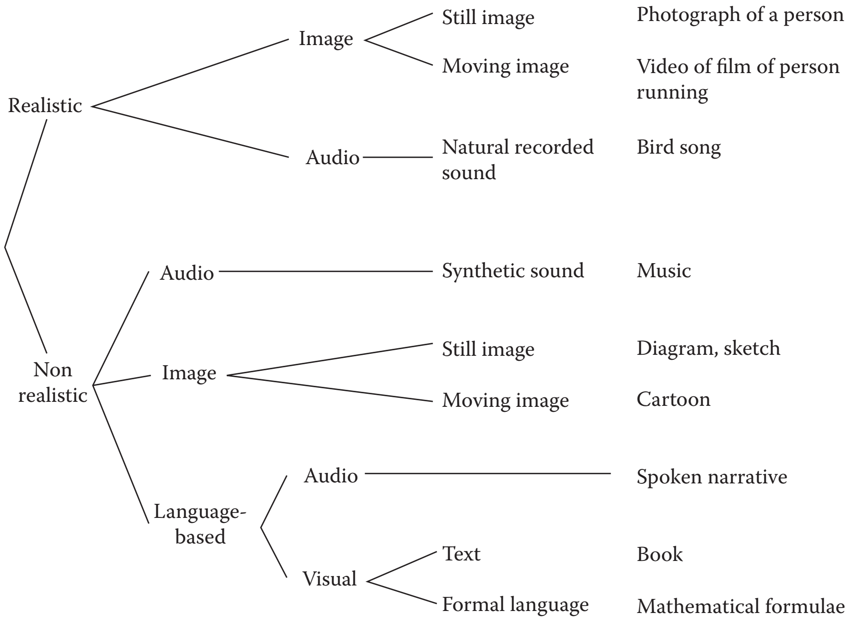

FIGURE 17.4 Decision tree for classifying media resources.

if appropriate resources are not present in the designer's media resource library. Finally, the classification provides a mechanism for indexing media resource libraries.

17.4.3.1 Media Selection

Recommendations for selecting media have to be interpreted according to the users' task and design goal. If information provision is the main design goal—for example, a tourist kiosk information system—then persistence of information and drawing attention to specific items is not necessarily as critical as in tutorial applications. Task and user characteristics influence media choice; for instance, verbal media are more appropriate to language-based and logical reasoning tasks; visual media are suitable for spatial tasks involving moving, positioning, and orienting objects. Some users may prefer visual media, whereas image is of little use for blind users. Media resources may be available for selection, or have to be purchased from elsewhere. If existing media can be edited and reused, this is usually preferable to creating new media from scratch. Graphical images can be particularly expensive to draw, whereas capture of images by scanning is usually quick and cheap. The following heuristics are supplemented by more detailed examples in Table 17.1.

- To convey detail, use static media, for example, text for language-based content, diagrams for models, or still image for physical detail of objects (Booher 1975; Faraday and Sutcliffe 1998).
- To engage the user and draw attention, use dynamic media—video for physical information, animation, or speech, for example.
- For spatial information, use diagrams, maps, with photographic images to illustrate detail, animations to indicate pathways (Bieger and Glock 1984; May and Barnard 1995).
- For values and quantitative information, use charts and graphs for overviews and trends, supplemented by tables for detail (Bertin 1983; Tufte 1997).
- Abstract concepts, relationships, and models should be illustrated with diagrams explained by text captions and speech to give supplementary information.
- Complex actions and procedures should be illustrated as a slideshow of images for each step, followed by a video of the whole sequence to integrate the steps. Text captions on the still images and speech commentary provide supplementary information (Hegarty and Just 1993). Text and bullet points summarize steps at the end, so choice trade-offs may be constrained by cost and quality considerations.
- To explain causality, still and moving image media need to be combined with text (Narayanan and Hegarty 1998). For example, the cause of a flood is explained by text describing excessive rainfall with an animation of the river level rising and overflowing its banks. Causal explanations of physical phenomena may be given by introducing the topic using linguistic media, showing the cause and effect by a combination of still image and text with speech captions for commentary; integrate the message by moving image with voice commentary and provide a bullet point text summary.

Because most components in the information architecture will have multiple information types and each information type may match several media, the selection process encourages multimedia integration. For example, when a procedure for explaining a physical task is required, first a series of realistic images will be selected, followed by video, and speech to integrate the steps, then text to summarize the key points.

The end point of media selection is media integration: one or more media will be selected for each information group to present complementary aspects of the topic. Some examples of media combination that amplify the basic selection guidelines are given in Table 17.1.

17.5 MEDIA DESIGN FOR USER ENGAGEMENT

The design process in Section 17.4 was oriented to a task-driven view of media. However, multimedia design is frequently motivated by the need to attract users' attention and to make the user experience interesting and engaging. These considerations may contradict some of the earlier guidelines because the design objective is to please the user and capture their attention rather than deliver information effectively. First, a health warning should be noted: The old saying "beauty is in the eye of the beholder" has good foundation. Judgments of aesthetic quality suffer from considerable individual differences. A person's reaction to a design is a function of their motivation (see Chapter 4 from the Second Edition of the HCI Handbook). Individual preferences, knowledge of the domain, and exposure to similar examples, to say nothing of peer opinion and "fashion." Furthermore, attractiveness is often influenced more by content than the choice of media or presentation format. The following guidelines should, therefore, be interpreted with care and their design manifestations tested with users.

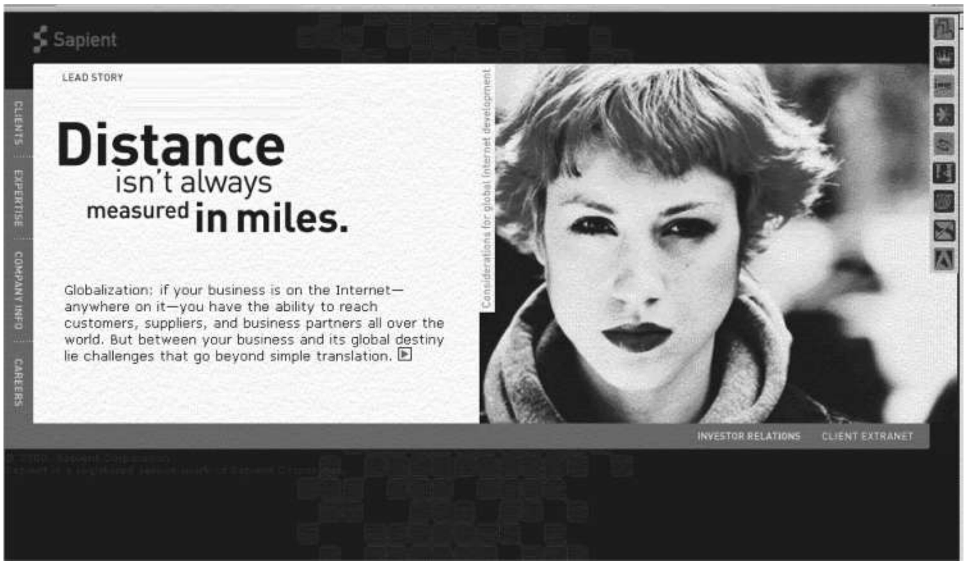
17.5.1 Multimedia to Motivate and Persuade

Design of media for motivation is a complex area in its own right, and this topic is dealt with in more depth in Chapter 7 of the Second Edition (Fogg), so the treatment here will focus on media selection issues. Simple photographs or more complex interactive animations (talking heads or full body mannequins) have an attractive effect. We appear to ascribe human properties to computers when interfaces give human-like visual cues (Reeves and Nass 1996); however, the effectiveness of media representing people depends on the characters' appearance and voice; see Figure 17.5. In human–human conversation, we modify our reactions according to our knowledge, or assumptions about, the other person's role, group identification, culture, and intention (Clark 1996). For example, reactions to a military mannequin will be very different from those to the representation of a parson. Male voices tend to be treated as more authoritative than female voices.

TABLE 17.1
Media Selection Example

Information Type Media Type	Causation	Conceptual	Continuous Action	Descriptive	Discrete Action	Event	Physical	Procedure	Relationship	Spatial Information	State	Value
Realistic audio	Sound of rain and storms		Sound of skiing		Click of ON switch	Sound of the starting gun	*Noise of a tornado*			Echoes in a cave	Sound of snoring	Musical note encodes a value
Nonrealistic audio		Rising tone illustrates increasing magnetic force	Continuous tone signals progress of action	Morse code describes a ship	Tones signal open/close door	*Alarm siren*			Tones associate two objects	Sonar and Doppler effect	Continuous sound in a heartbeat monitor	
Speech	*Tell someone why El Nino happens*	Tell someone about your religious beliefs	Tell someone what a ski turn looks like	Verbal description of a person	Tell someone how to turn computer on	*Tell someone race has started*	Tell someone how it feels to be in a storm	Speak instructions on engine assembly	Tell someone Jack and Jill are related	Tell someone pathway to and location of railway station	Tell someone "Jane's asleep"	Verbal report of numbers, figures
Realistic still image	*Photograph of El Nino storms and ocean currents*	Statue of Liberty photograph represents "freedom"	Set of photographs showing snap shots of action	*Overview and detail photographs of a car*	*Photograph of computer ON switch*	Photograph of the start of a race	*Photograph of a person's face*	*Photographs showing engine assembly*		*Photograph of a landscape*	Photograph of a person sleeping	
Nonrealistic still image	*Diagrams of ocean currents and sea temp. to explain El Nino*	*Hierarchy diagram of plant taxonomy*	Diagram with arrow depicting ski turn motion	Histogram of aging population	Diagram showing where and how to press ON switch	Event symbol in a race sequence diagram		Explode parts diagram of engine with assembly numbers	*Graphs, histograms,* ER *diagrams*	*Map of the landscape*	Waiting state symbol in race sequence diagram	*Charts, graphs, scatter plots*
Text	*Describe reasons for El Nino storms*	*Explain taxonomy of animals*	Describe ski turn action	*Describe a person's appearance*	Describe how to turn computer on	Report that the race has started	Report of the storm's properties	*Bullet point steps in assembling engine*	*Describe brother and sister relationship*	Describe dimensions of a room	*Report that the person is asleep*	*Written number one, two*
Realistic moving image	*Video of El Nino storms and ocean currents*		*Movie of person turning while skiing*	Aircraft flying		*Movie of the start of a race*	*Movie of a storm*	*Video of engine assembly sequence*		Fly through landscape	Video of a person sleeping	
Nonrealistic moving image	*Animation of ocean temperature change and current reversal*	Animated diagram of force of gravity	Animated mannequin doing ski turn		Animation showing operation of ON switch	Animation of start event symbol in diagram		*Animation of parts diagram in assembly sequence*	Animation of links on ER diagram			
Language-based: formal, numeric	Equations, functions formalizing cause and effect	*Symbols denoting concepts, for example, pi*			Finite state automata	Event-based notations		Procedural logics, process algebras	Functions, equations, grammars		State-based languages, for example, Z	numeric symbols

The table summarizes the media selection and combinations for each information type. The italics denote the preferred mappings for media and information types, whereas ordinary text shows other potential media uses for the information type.



Distance isn't always measured in miles.

Globalization: if your business is on the Internet—anywhere on it—you have the ability to reach customers, suppliers, and business partners all over the world. But between your business and its global destiny lie challenges that go beyond simple translation. ▶

FIGURE 17.5 Effective use of human image for attraction. The picture attracted by the direction of gaze to the user as well as by the appearance of the individual.

Use of human-like forms is feasible with prerecorded video and photographs; however, the need depends on the application. Video representation of the lecturer can augment presentations, and video communication helps interactive dialogue. A good speaker holds our attention by a variety of tricks, such as maintaining eye contact, varying the voice tone, using simple and concise language, and delivering an interesting message. These general effects can be reinforced by projected personality. Friendly people are preferred over colder, more hostile individuals. TV announcers who tend to be middle-aged, confident, but avuncular characters have the attention-drawing power of a dominant yet friendly personality. Both sexes pay attention to extrovert, young personalities, whereas the male preference for beautiful young women is a particularly strong effect. These traits have been exploited by advertisers for a long time. There are lessons here for multimedia designers as the web and interactive TV converge, and when we want media to convey a persuasive message (Reeves and Nass 1996; Fogg, this book). Media selection guidelines for motivation and persuasion, adapted from Reeves and Nass (1996), can be summarized as follows:

- Human image and speech invokes the computer-as-social actor effect to facilitate motivation and persuasion.
- Photographs of people attract attention especially when the person is looking directly at the user.
- Faces that represent the norm in a population (Mr./Ms. average) and young children are more attractive. We are very susceptible to the large-eyes effect in young animals, as exploited by Disney cartoons.
- Polite praise: Use of "Please," "Thank you," and simple compliments like "That was an excellent choice" increase people's tendency to judge the computer as pleasant and enjoyable.
- Short compelling argument: Such as the well-known British World War I recruiting poster featuring General Kitchener gazing directly at the viewer with the caption "Your country needs you."

For more detailed treatment of design for persuasive technology, see Fogg, Chapter 7, Second Edition of the HCI Handbook.

17.5.2 Media for Emotional Effects

Media design for affect (emotional response and arousal) involves both choice of content and interaction. Arousal is increased by interactive applications, surprising events during interaction, use of dynamic media, and challenging images. In contrast, if the objective is to calm the users, arousal can be decreased by choice of natural images and sounds, and soothing music. The most common emotional responses that designers may want to invoke are pleasure, anxiety and fear, and surprise. Pleasure, anxiety, and fear usually depend on our memory of agents, objects, and events (Ortony, Clore, and Collins 1988), so content selection is the important determinant. Anxiety can be evoked by uncertainty in interaction and cues to hidden effects, whereas emotional response of fear or pleasure will depend on matching content to the user's previous experience. Some guidelines to consider are as follows:

- *Dynamic media*, especially video, have an arousing effect and attract attention; hence, video and animation are useful in improving the attractiveness of presentations. However, animation must be used with care, as gratuitous video which cannot be turned off quickly offends (Spool et al. 1999).

- *Speech* engages attention because we naturally listen to conversation. Choice of voice depends on the application: female voices for more restful and information effects, male voices to suggest authority and respect (Reeves and Nass 1996).
- *Image*s may be selected for mood setting, for example, to provide a restful setting for more important foreground information (Mullet and Sano 1995). Backgrounds in half shades and low-saturation color provide more depth and interest in an image.
- *Music* has an important emotive appeal, but it needs to be used with care. Classical music may be counterproductive for a younger audience, whereas older listeners will not find heavy metal pop attractive. Music can set the appropriate mood, for example, loud strident pieces will arouse and excite, romantic music calms and invokes pleasure, and so on.
- *Natural sounds* such as running water, wind in trees, bird song, and waves on a sea shore have restful properties and hence decrease arousal.
- *Dangerous and threatening episodes*, for example, being chased by a tiger, gory images (mutilated body), and erotic content all increase arousal and invoke emotions ranging from fear to anger, whereas pleasant images (e.g., flowers, sunset) tend to decrease it, that is, have calming effects and produce pleasurable emotional responses.
- *Characters* can appear threatening or benevolent depending on their appearance or dress. For example, disfigured people appear threatening and evoke emotions ranging from fear to disgust. Characters familiar from popular culture can be used for emotional effect.
- *Dialogue* is probably the most powerful tool for creating emotional responses, from threats to empathy. Emotional effects are additive so choice of character with a threatening appearance, complemented by a menacing voice tone and an aggressive dialogue, all reinforce the emotions of anxiety and fear.

Media integration rules may be broken for emotive effects. For example, use of two concurrent video streams might be arousing for a younger audience, as music TV (MTV) and pop videos indicate. Multiple audio and speech tracks can give the impression of complex, busy, and interesting environments.

17.5.3 Multimedia and Aesthetic Design

If the requirements analysis indicates that having a pleasing and attractive design is important for the user's perception, then aesthetics need to be considered in depth. However, aesthetics should be considered as a design criterion for all applications since poor appearance and interaction design may provoke adverse reaction (Norman 2004). Some studies suggest that aesthetic design is an important component of usability and overall preference (Tractinsky 1997; Tractinsky, Shoval-Katz, and Ikar 2000; Hassenzahl 2004); however, others have shown that aesthetic preferences are open to contextual effects on users' judgment (Sutcliffe and De Angeli 2005; Hartmann, Sutcliffe, and De Angeli 2008). Judging when aesthetics may be important is not easy. For example, in e-commerce applications with high-value, designer-label products, aesthetic presentation is advisable; similarly, when selling to a design-oriented audience. However, in many applications, the decision is not clear-cut.

Aesthetic design primarily concerns graphics and visual media. Evaluation questionnaires assess design on classic aesthetics, which broadly equate with conventional usability guidelines on structured and consistent layout, and expressive aesthetics that capture the more creative aspects of visual design (Lavie and Tractinsky 2004); however, these measure user reaction to general design aspects such as "original," "fascinating," "clear," and "pleasant." The following heuristics provide more design-directed guidance, but they may also be used for evaluation (Sutcliffe 2002; Sutcliffe and De Angeli 2005).

- *Judicious use of color*: Color use should be balanced and low-saturation pastel colors should be used for backgrounds. Designs should not use more than two to three fully saturated intense colors. Yellow is salient for alerting, red/green have danger/safety positive/negative associations, and blue is more effective for background. Low-saturated colors (pale shades with white) have a calming effect and are also useful for backgrounds. Color is a complex subject in its own right; for more guidance, see Travis (1991).
- *Depth of field*: Use of layers in an image stimulates interest and can attract by promoting curiosity. Use of background image with low-saturated color provides depth for foreground components. Use of layers in an image and washed-out background images stimulate curiosity and can be attractive by promoting a peaceful effect.
- *Use of shape*: Use of curved shapes conveys an attractive visual style, in contrast to blocks and rectangles which portray structure, categories, and order in a layout.
- *Symmetry*: Symmetrical layouts, for example, bilateral, radial organization that can be folded over to show the symmetrical match.
- *Simplicity and space*: Uncluttered, simple layout that uses space to separate and emphasize key components.
- *Design of unusual or challenging images* that stimulate the users' imagination and increase attraction: Unusual images often disobey normal laws of form and perspective.
- *Visual structure and organization*: Dividing an image into thirds (right, center, left; or top, middle, bottom) provides an attractive visual organization,

whereas rectangular shapes following the golden ratio (height/width = 1.618) are aesthetically pleasing. Use of grids to structure image components promotes consistency between pages.

Although guidelines provide ideas that can improve aesthetic design and the attractiveness of interfaces, they are no guarantee that these effects will be achieved. Design is often a trade-off between ease of use and aesthetic design; for instance, use of progressive disclosure to promote flow may well be perceived by others as being difficult to learn. Visual effects often show considerable individual differences and learning effects, so a well-intentioned design might not be successful. The advice, as with most design, is test ideas and preliminary designs with users to check interpretations, critique ideas, and evaluate their acceptability. There are several sources of more detailed advice on aesthetics and visual design (Kristoff and Satran 1995, Mullet and Sano 1995; Lidwell, Holden, and Butler 2003); however, advice is usually given as examples of good design rather than specific guidelines.

17.6 INTERACTION AND NAVIGATION

Although discussion of interactive multimedia has been delayed until now, in practice, dialogue and presentation design proceed hand in hand. Task analysis provides the basis for dialogue design and specification of navigation controls. Navigational and control dialogues allow flexible access to the multimedia content and enable users to control how media are played. Dialogue design may also involve specifying how users interact with tools, agents, and objects in interactive microworlds.

17.6.1 Metaphors and Interaction Design

Although task and domain analysis can provide ideas for interaction design, this is also a creative process. Interaction design is essentially a set of choices along a dimension from simple controls such as menus and buttons where the user is aware of the interface, to embodiment in which the user becomes involved as part of the action by controlling an avatar or other representation of their presence. At this end of the dimension, multimedia interaction converges with VR (see Chapter 29). Interactive metaphors occupy the middle ground.

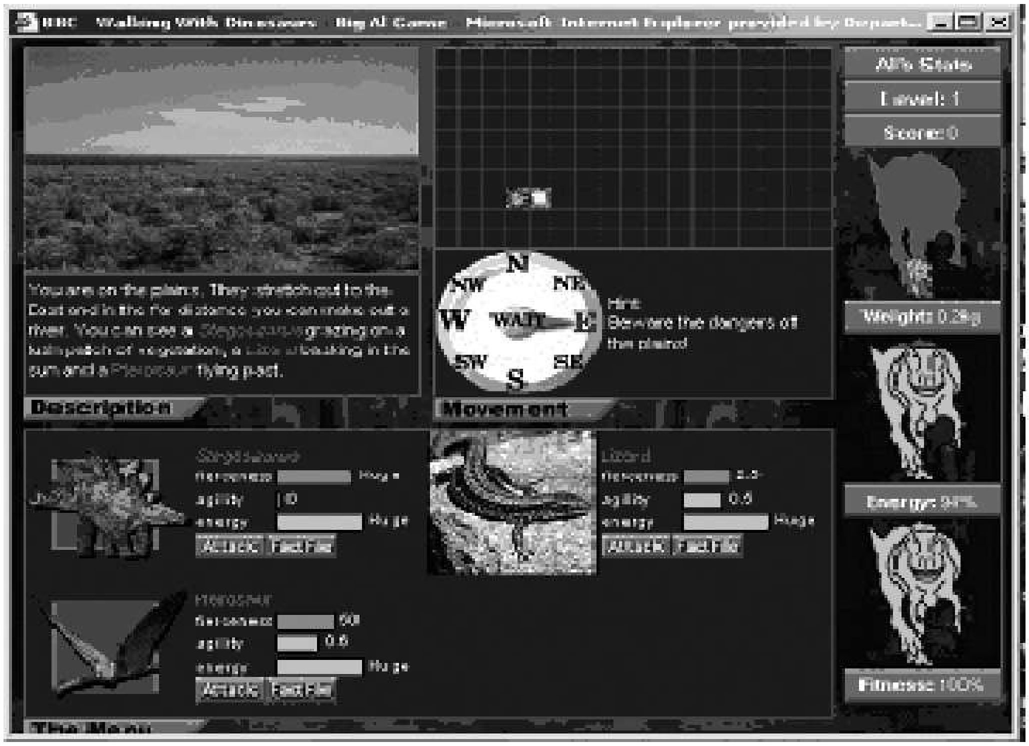
Some interactive metaphors are generally applicable, such as timelines to move through historical information, the use of a compass to control direction of movement in an interactive space, controls based on automobiles (steering wheels) or ships (rudders). Others will be more specific, for example, selecting and interacting with different characters (young, old, male, female, overweight, fit, etc.) in a health-promotion application. Design of interaction also involves creating the microworld within which the user moves and interactive objects that can be selected and manipulated.

Interaction via characters and avatars can increase the user's sense of engagement first by selecting or even constructing the character, although some users may not have the patience to build their own avatar using a graphical paint program. In character-based interaction, the user can either see the world from an egocentric viewpoint, that is, from their character's position, or exocentric when they see their character in the graphical world. The sophistication in control of movement and interaction will depend on the hardware available (e.g., joystick, wand, or standard mouse and keyboard). Although mimicking physical interaction via data gloves and tracking requires VR technology, relatively complex interaction (e.g., actions in a football game, pass, head ball in direction north/south/east/west) can be programmed using buttons and function keys. Engagement is also promoted by surprise and unexpected effects, so as the user moves into a particular area, a new subworld opens up, or system-controlled avatars appear. These techniques are well known to games programmers; however, they are also applicable to other genres of multimedia applications. The design concepts for engagement can be summarized as follows (see Chapter 32):

- *Character-driven interaction*: This interaction provides the user with a choice of avatars or personae they can adopt as representations of themselves within the interactive virtual world; see Figure 17.6. Avatar development tools enable virtual characters to be designed and scripted with actions, and simple speech dialogues. Most sophisticated semi-intelligent "chatterbots" (e.g., Alice, Jabberwocky*) use response-planning rules to analyze user input and generate naturally sounding output; however, it is easy to fool these systems with complex natural language input.
- *Tool-based interaction*: This places tools in the world which users can pick up; the tool becomes the interface, for example, a virtual mirror magnifies, a virtual helicopter flies (Tan, Robertson, and Czerwinski 2001).
- *Collaborative characters*: In computer-mediated communication, these characters may represent other users; in other applications, system-controlled avatars appear to explain, guide, or warn the user.
- *Surprise effects*: Although conventional human–computer interaction (HCI) guidelines should encourage making the affordances and presence of interactive objects explicit, when designing for engagement, hiding, and surprise are important.

Interaction design for an explanatory/tutorial application is illustrated in Figure 17.6. This is an interactive microworld in which the user plays the role of a dinosaur character, illustrating use of the engagement concepts. A compass navigation metaphor allows the user to act as the dinosaur moving

*http://alice.pandorabots.com/ and http://www.jabberwacky.com



You are on the plains. They stretch out to the East and in the far distance you can make out a river. You can see a Stegosaurus grazing on a lush patch of vegetation, a Lizard basking in the sun and a Pterosaur flying past.

Hint:
Beware the dangers of the plains!

FIGURE 17.6 Interactive microworld: Big Al game (www.bbc.co.uk/sn/). The user plays the dinosaur role by navigating with the compass metaphor. The photograph updates with each move and the user is given a choice of attacking or avoiding other dinosaurs in the virtual world.

around the landscape illustrated in photographs. The user is given feedback on the characteristics of other predators and prey in the vicinity and has to decide whether to attack or avoid them. Other controls that might be added to such interactive microworlds could be settings to change the environment, for example, add more predators, change the weather, and so on. Engagement can be taken even further by giving the user facilities to actually design the MacWorld so the application becomes a domain-oriented design environment (Fischer et al. 2004).

17.6.2 Navigation

In information-intensive multimedia where access to content is the main design goal, hypermedia dialogues that link content segments will be appropriate. Good hypertext design is based on a sound information analysis that specifies the pathways between related items, and use of cues to show the structure of the information space to the user. In document-based hypermedia (e.g., HTML and the web), links can only access the whole media resource rather than point to components within it. The access structure of most hypermedia will be hierarchical, organized according to the information model and categorization of content, for example, information grouped by function, organization, task usage, or user preference. Navigation design transforms the user's conceptual model of an information space into a hypermedia structure. Unfortunately, individual users have different models so this may not be an easy task. Implementing too many links to satisfy each user's view will make the system too complex and increase the chance of the user getting lost. Too few links will frustrate users who cannot find the associations they want. Unfortunately, hypermedia systems assume a fixed link structure so the user is limited to the pathways provided by the designer. More open-ended hypermedia environments (e.g., Microcosm: Lowe and Hall 1998) provide more flexibility via links with query facilities which allow access to databases. Dynamic links attached to hotspots in images or nodes in text documents provide access paths to a wider variety of data.

One problem with large hypermedia systems is that users get lost in them. Navigation cues, waymarks, and mini-map overviews can help to counter the effects of disorientation. *Mini-maps* give an overview of the hypertext area and a reference context for where users are in large networks. *Filters* help to reduce complexity by showing only a subset of nodes and links that the user is interested in. Having typed links helps filtering views because the user can guess the information content from the link type, for example, reference, example, source, related work, and so on. Other navigation facilities are *visit lists* containing a history of nodes traversed in a session and *bookmarks* so users can tailor a hypermedia application with their own navigation aide-memoires (Nielsen 1995). Once the structure has been designed, access structures and link cues need to be located within media resources, so the appropriate cues need to be considered for each medium, such as the following, for example.

- *Text media*: The web convention is to underline and highlight text in a consistent color, for example, blue or purple. Text image thumbnails can be used to illustrate document and page structure, to facilitate direct pointing access, as used in the Adobe PDF Reader.
- *Images*: Link cues can be set as standalone icons or as active components in images. Icons need to be tested with users because the designer's assumed meaning can be ambiguous. Active components should signal the link's presence by captions or pop-up hover text so the user can inspect a link before deciding whether to follow it. Mosaics of image thumbnails are an alternative access path and can be organized in dimensions or layers to communicate categories and properties, such as time × location dimensions, general views to close-ups arranged in concentric circles of magnification. Slideshow presentation of images organized in navigation sequences with a stop button is another option for rapid access (De Bruijn, Spence, and Chong 2002).
- *Moving images*: Links from animation and film are difficult to design because the medium is dynamic; however, link buttons can be placed below the video window. Active components, for example, overlaid buttons within a moving image, are technically more challenging to program. Buttons may also be timed to pop-up at appropriate times during the video. Sample frames set in a mosaic and timeline structure summarize videos and enables access by pointing to segments. This can be taken further with multirunning movie thumbnails to provide overviews; however, this can produce more distraction than useful navigation, and many instances of dynamically running media overload our attention (see Section 17.3).
- *Sound and speech* links are difficult for the same reason as with moving images. One solution is to use visual cues, possibly synchronized with the sound or speech track. If speech recognition is available, then voice commands can act as links, but these commands need to be explained to the user. Visual access structures can be based on sonograms of the audio track or more usefully annotated timelines.

In many cases, controls will be provided by the media-rendering device, for example, video player for .avi files, or Quicktime movies. If controls have to be implemented from scratch, the following should be considered for each media type:

- *Static media*. Size and scale controls to zoom and pan; page access if the medium has page segmentation, as in text and diagrams; the ability to change attributes such as color, display resolution, font type, and size in text.
- *Dynamic media*. The familiar video controls of stop, start, play, pause, fast-forward, and rewind, also the ability to address a particular point or event in the media stream by a time marker or an index, for example, "go to" component/marker, and so on.

Navigation controls use standard UI components (buttons, dialogue boxes, menus, icons, sliders) and techniques (form filling, dialogue boxes, and selection menus); for more guidance, see ISO 9241, Parts 12, 14, and 17 (ISO 1997) and ISO 14915 Part 2 (ISO 1998).

17.6.3 Design for Attention

Having selected the media resources, the designer must now ensure that the user will extract the appropriate information. An important consideration of multimedia design is to link the thread of a message across several different media. This section gives recommendations on planning the user's reading/viewing sequence, and guidelines for realizing these recommendations in presentation sequences, hypermedia dialogues, and navigation controls. The essential differences are timing and user control. In a presentation design, the reading/viewing sequence and timing are set by the designer; whereas the reading/viewing sequence in hypertext implementation and interactive dialogues is under user control.

Presentation techniques help to direct the user's attention to important information and specify the desired order of reading or viewing. Thematic links between information components are specified and attention-directing techniques are selected to implement the desired effect.

The design issues are as follows:

- To plan the overall thematic thread of the message
- To draw the user's attention to important information
- To establish a clear reading/viewing sequence
- To provide clear links when the theme crosses from one medium to another

Design for attention is particularly important for images. User attention to time-varying media is determined by the medium itself, that is, we have little choice but to listen to speech or to view animations in the order in which they are presented. The reading sequence is directed by the layout of text, although this is culturally dependent, for example, western languages read left to right, Arabic in the opposite direction. However, viewing order in images is unpredictable unless the design specifically selects the user's attention.

The design problem is how to direct the user's attention to the appropriate information at the correct level of detail. Initially, users will tend to extract information from images at the scene level, that is, major objects will be identified but with very little descriptive detail (Treisman 1988). Regular layout grids help design composite images (Mullet and Sano 1995) and encourage viewing sequences in image sets. Alternatively, the window frame can be set to control which parts of an image are viewed. Larger window frames will be attended to before smaller areas. A list of the key components that the user needs to focus on and the facts that should be extracted are checked against the initial presentation design to see if the key components will attract sufficient attention or whether the user is likely to be confused by extraneous detail.

Position on screen is a key influence on attention. Eye-tracking studies have demonstrated that components on the top-left and center areas of screens receive more attention than the lower and right-hand side (Beymer, Orton, and Russell 2007; Hornof and Halverson 2003). Furthermore, large centralized images tend to dominate attention while layout structure, such as columns and blocks focus users' gaze within these structures. So layout, as well as media choice, can be used to influence attention; then within each media type, attention can be directed by applying the following highlighting techniques.

17.6.3.1 Still Image Media

Highlighting techniques for designed and natural images, organized in approximate power of their effect, are summarized in Table 17.2. A common highlighting technique will pick out spatially distributed objects, for example, change all the related objects to the same color; co-located objects can be grouped by using a common color or texture for their background or drawing a box around them. The highlighted area will set the granularity of the user's attention. Captions linked to objects in an image are another useful means of drawing attention and providing supplementary information (e.g., identity). Dynamic revealing of captions is particularly effective for directing the user's viewing sequence. Sequential highlighting is also useful for showing the pathways or navigational instructions.

17.6.3.2 Moving Image Media

Directing attention to components within moving images is difficult because of the dynamic nature of the medium. Design of film and video is an extensive subject in its own right, so treatment here will necessarily be brief. The following design advice is based on Hochberg (1986). The design objectives, as for other media, are how to draw the user's attention to key components within the video or animation.

First, the content needs to be structured into scenes that correspond to the information script. To structure animation sequences and make scene boundaries obvious, use a cut, wipe, or dissolve to emphasize that a change in the content structure has taken place. However, cuts should be used with care and continuity maintained between the two sequences if they are to be integrated. Continuity is manifest as the same viewpoint and subject matter in two contiguous shots. Change in background or action, such as an individual walking left in one clip and walking right in the next, is quickly noticed as a change. An establishing shot that shows the whole scene helps to introduce a new sequence and provide context. To provide detail of a newly introduced object or context, the object is shown filling the frame with a small amount of surrounding scene; while to imply a relationship or compare two objects a tight two shot with both objects together in the same frame is advisable.

17.6.3.3 Linguistic Media (Text and Speech)

As with moving image, the literature is extensive, so the following heuristics are a brief summary; see Levie and Lentz (1982) for more detail. Text may be structured to indicate subsections by indentation, formatting into paragraphs, columns, or segmented by background color. Bullet points or

TABLE 17.2
Attention-Directing Techniques for Different Media

	Attention-Orienting Techniques in Approximate Order of Power	Notes
Still image: designed and natural	Movement of or change in the shape/size/color of an object. Use of bold outline. Object marked with a symbol (e.g., arrow) or icon. Draw boundary, use color, shape, size, or texture to distinguish important objects.	Some effects may compromise natural images because they overlay the background image with new components (e.g., arrows, arcs, icons). Group objects by a common technique.
Moving image	Freeze frame followed by applying a still image highlight. Zoom, close-up shot of the object. Cuts, wipes, and dissolve effects.	Change in topographic motion, in which an object moves across the ground of an image, is more effective than internal movement of an object's components. Size and shape may be less effective for highlighting a moving object.
Text	Bold, font size, type, color, or underlining. To direct attention to larger segments of text, use formatting, bullet points, sub-sections, indentation.	Formatting techniques are paragraphs; headings/titles as entry points; indents to show hierarchical nesting, with bullet points and lists.
Speech/sound	Familiar voice. Silence followed by onset of sound. Different voices, or a change in voice prosody (tonality), amplitude (loudness), change, and variations in pitch (frequency), voice rate, change source direction, alarm sounds (police sirens).	Voices familiar to the user (e.g., close relatives) attract attention over nonfamiliar speech. Discourse markers "next," "because," "so," and so on draw attention to subsequent phrases.

numbered sections indicate order more formally, such as for procedures. Different voices help to structure speech while also attracting attention. If language is being used to set the context for accompanying media, it is important that the correct level of identification is set. For instance, a higher level concept, or the whole scene in an accompanying image, is described at the beginning of a script, and then lower level topics reset the user's focus. Discourse markers can make phrases and sentences more salient.

Adding attention-directing effects completes the design process; however, as with all UIs, there is no substitute for usability testing. Designs are constructed incrementally by iterations of design and evaluation that checks for usability using standard methods, with additional memory and comprehension tests for multimedia. So when testing a design, ask the user to tell you what they understood the message to be. This can be done during the presentation with a think-aloud protocol to check that users did attend to key items, and afterwards by a memory test. If key components in the message are not being remembered, then the design may need to be improved.

17.7 CONCLUSIONS

Multimedia still poses many issues for further research. The design method described in this chapter coupled with user-centered design can improve quality; however, there is still a need for experts to create specific media resources, for example, film/video, audio experts. Furthermore, considerable research is still necessary before we fully understand the psychology of multimedia interaction. Design for motivation and attractiveness is still poorly understood, and personality effects in media may not be robust when usability errors impede communication. The process by which people extract information from complex images still requires extensive research, although the increasing number of eye-tracking studies is beginning to throw some light on this topic. In the future, language and multimodal communication will change our conception of multimedia from its current CD-ROM or web-based form into interfaces that are conversational and multisensory. Multimedia will become part of wearable and ubiquitous UIs where the media is part of our everyday environment. Design for multisensory communication will treat media and artifacts (e.g., our desks, clothes, walls in our homes) as a continuum, whereas managing the diverse inputs to multimedia from creative design, technology, and usability engineering will be one of the many interesting future challenges.

18 Multimodal Interfaces

Sharon Oviatt

CONTENTS

18.1 WHAT ARE MULTIMODAL SYSTEMS, AND WHY ARE WE BUILDING THEM?

Multimodal systems process two or more combined user input modes—such as speech, pen, touch, manual gestures, gaze, and head and body movements—in a coordinated manner with multimedia system output. This class of systems represents a new direction for computing, and a paradigm shift away from conventional Windows, Icons, Menus, and Pointer interfaces. Since the appearance of Bolt's (1980) "Put That There" demonstration system, which processed speech in parallel with touch pad pointing, a variety of new multimodal systems has emerged. This new class of interfaces aims to recognize naturally occurring forms of human language and behavior, which incorporate at least one recognition-based technology (e.g., speech, pen, vision). The development of novel multimodal systems has been enabled by the myriad input and output technologies currently becoming available, including new devices and improvements in recognition-based technologies. This chapter will review the main types of multimodal interfaces, their advantages and cognitive science underpinnings, primary features and architectural characteristics, and general research in the field of multimodal interaction and interface design.

The growing interest in multimodal interface design is inspired largely by the goal of supporting more transparent, flexible, efficient, and powerfully expressive means of human–computer interaction (HCI). Multimodal interfaces are expected to be easier to learn and use, and are preferred by users for many applications. They have the potential to expand computing to more challenging applications, to be used by a broader spectrum of everyday people, and to accommodate more adverse usage conditions than in the past. Such systems also have the potential to function in a more robust and stable manner than unimodal recognition systems involving a single recognition-based technology, such as speech, pen, or vision.

The advent of multimodal interfaces based on recognition of human speech, gaze, gesture, and other natural behavior represents only the beginning of a progression toward computational interfaces capable of relatively human-like sensory perception. Such interfaces eventually will interpret continuous input from a large number of different visual, auditory, and tactile input modes, which will be recognized as users engage in everyday activities. The same system will track and incorporate information from multiple sensors on the user's interface and surrounding physical environment in order to support intelligent adaptation to the user, task and usage environment. Future adaptive multimodal-multisensor interfaces have the potential to support new functionality, to achieve unparalleled robustness, and to perform flexibly as a multifunctional and personalized mobile system.

18.2 WHAT TYPES OF MULTIMODAL INTERFACES EXIST, AND WHAT IS THEIR HISTORY AND CURRENT STATUS?

Multimodal systems have developed rapidly during the past decade, with steady progress toward building more general and robust systems, as well as more transparent human interfaces than ever before (Benoit et al. 2000; Oviatt et al. 2000). Major developments have occurred in the hardware and software needed to support key component technologies incorporated within multimodal systems, as well as in techniques for integrating parallel input streams. Multimodal systems also have diversified to include new modality combinations, including speech and pen input, speech and lip movements, speech and manual gesturing, and gaze tracking and manual input (Benoit and Le Goff 1998; Cohen et al. 1997; Stork and Hennecke 1995; Turk and Robertson 2000; Zhai, Morimoto, and Ihde 1999). In addition, the array of multimodal applications has expanded extremely rapidly in recent years. Among other areas, it presently includes multimodal map-based systems for mobile and in-vehicle use, multimodal browsers, multimodal interfaces to virtual reality systems for simulation and training, multimodal person identification/verification systems for security purposes, multimodal medical, educational, robotics, military, and web-based transaction systems, and multimodal access and management of personal information on handhelds and cell phones (Cohen and McGee 2004; Iyengar, Nock, and Neti 2003; McGee 2003; Neti et al. 2000; Oviatt 2003; Oviatt, Flickner, and Darrell 2004; Oviatt and Lunsford 2005; Oviatt et al. 2000; Pankanti, Bolle, and Jain 2000; Reithinger et al. 2003).

In one of the earliest multimodal concept demonstrations, Bolt had users sit in front of a projection of "Dataland" in "the Media Room" (Negroponte 1978). Using the "Put That There" interface (Bolt 1980), they could use speech and pointing on an armrest-mounted touch pad to create and move objects on a two-dimensional (2D) large-screen display. For example, the user could issue a command to "Create a blue square there," with the intended location of "there" indicated by a 2D cursor mark on the screen. Semantic processing was based on the user's spoken input, and the meaning of the deictic "there" was resolved by processing the *x*,*y* coordinate indicated by the cursor at the time "there" was uttered. Since Bolt's early prototype, considerable strides have been made in developing a wide variety of different types of multimodal systems.

Among the earliest and most rudimentary multimodal systems were ones that supported speech input along with a standard keyboard-and-mouse interface. Conceptually, these multimodal interfaces represented the least departure from traditional graphical user interfaces (GUIs). Their initial focus was on providing richer natural language processing to support greater expressive power for the user when manipulating complex visuals and engaging in information extraction. As speech recognition technology matured during the late 1980s and 1990s, these systems added spoken input as an alternative to text entry with the keyboard. As such, they represent early involvement of the natural language and speech communities in developing the technologies needed to support new multimodal interfaces. Among the many examples of this type of multimodal interface are CUBRICON, Georal, Galaxy, XTRA, Shoptalk, and Miltalk (Cohen et al. 1989; Kobsa et al. 1986; Neal and Shapiro 1991; Seneff et al. 1996; Siroux et al. 1995; Wahlster 1991).

Several of these early systems were multimodal-multimedia map systems to which a user could speak or type and point with a mouse to extract tourist information or engage in military situation assessment (Cohen et al. 1989; Neal and Shapiro 1991; Seneff et al. 1996; Siroux et al. 1995). For example, using the CUBRICON system, a user could point to an object on a map and ask: *"Is this <point> an air base?"* CUBRICON was an expert system with extensive domain knowledge, as well as natural language-processing capabilities that included referent identification and dialog tracking (Neal and Shapiro 1991). With the Georal system, a user could query a tourist information system to plan travel routes using spoken input and pointing at a touch-sensitive screen (Siroux et al. 1995). In contrast, the Shoptalk system permitted users to interact with complex graphics representing factory production flow for chip manufacturing (Cohen et al. 1989). Using Shoptalk, a user could point to a specific machine in the production layout and issue the command: "Show me all the times when this machine was down." After the system delivered its answer as a list of time ranges, the user could click on one to ask the follow-up question, "What chips were waiting in its queue then, and were any of them hot lots?" Multimedia system feedback was available in the form of a text answer, or the user could click on the machine in question to view an exploded diagram of the machine queue's contents during that time interval.

More recent multimodal systems have moved away from processing simple mouse or touch pad pointing, and have begun designing systems based on two parallel input streams that each are capable of conveying rich semantic information. These multimodal systems recognize two natural forms of human language and behavior, for which two recognition-based technologies are incorporated within a more powerful bimodal user interface. To date, systems that combine either speech and pen input (Oviatt and Cohen 2000) or speech and lip movements (Benoit et al. 2000; Stork and Hennecke 1995; Rubin et al. 1998; Potamianos et al. 2003) constitute the two most mature areas within the field of multimodal research. In these cases, the keyboard and mouse have been abandoned. For speech and pen systems, spoken language sometimes is processed along with complex pen-based gestural input involving hundreds of different symbolic interpretations beyond pointing* (Oviatt et al. 2000). For speech and lip movement systems, spoken language is processed along with corresponding human lip movements during the natural audiovisual experience of spoken interaction. In both of these

* However, other recent pen/voice multimodal systems that emphasize mobile processing, such as multimodal interactive notepad and the Field Medic Information System (Holzman 1999; Huang et al. 2000), typically still limit pen input to pointing.

subliteratures, considerable work has been directed toward quantitative modeling of the integration and synchronization characteristics of the two rich input modes being processed, and innovative time-sensitive architectures have been developed to process these patterns in a robust manner.

Multimodal systems that recognize speech and pen-based gestures first were designed and studied in the early 1990s (Oviatt et al. 1992), with the original QuickSet system prototype built in 1994. The QuickSet system is an agent-based collaborative multimodal system that runs on a handheld PC (Cohen et al. 1997). With QuickSet, for example, a user can issue a multimodal command such as "Airstrips … facing this way <draws arrow>, and facing this way <draws arrow>," using combined speech and pen input to place the correct number, length, and orientation (e.g., SW, NE) of aircraft landing strips on a map. Other research-level systems of this type were built in the late 1990s. Examples include the Human-Centric Word Processor, Portable Voice Assistant, QuickDoc and MVIEWS (Bers, Miller, and Makhoul 1998; Cheyer 1998; Oviatt et al. 2000; Waibel et al. 1997). These systems represent a variety of different system features, applications, and information fusion and linguistic processing techniques. For illustration purposes, a comparison of five different speech and gesture systems is summarized in Figure 18.1. In most cases, these multimodal systems jointly interpreted speech and pen input based on a frame-based method of information fusion and a late semantic fusion approach, although QuickSet used a statistically-ranked unification process and a hybrid symbolic/statistical architecture (Wu, Oviatt, and Cohen 1999). Other recent systems also have adopted unification-based multimodal fusion and a hybrid architectural approach for processing multimodal input (Bangalore and Johnston 2000, 2009; Denecke and Yang 2000; Pfleger 2004; Wahlster 2001) and even multimodal output (Kopp, Tepper, and Cassell 2004).

Multimodal systems that process speech and continuous 3D manual gesturing are emerging, although these systems remain less mature than ones that process 2D pen input

Multimodal system characteristics	**QuickSet**	**Human-centric word processor**	**VR aircraft maintenance training**	**MATCH**	**Portable voice assistant**
Recognition of simultaneous or alternative individual modes	Simultaneous and individual modes	Simultaneous and individual modes	Simultaneous and individual modes	Simultaneous and individual modes	Simultaneous and individual modes
Type and size of gesture vocabulary	Pen input, multiple gestures, large vocabulary	Pen input, deictic selection	3D manual input, multiple gestures, small vocabulary	Pen input, multiple gestures, handwriting recognition, small vocabulary	Pen input, deictic selection, handwriting recognition
Size of speech vocabulary[1] and type of linguistic processing	Moderate vocabulary, grammar-based	Large vocabulary, statistical language processing	Small vocabulary, grammar-based	Large vocabulary, grammar-based	Small vocabulary, grammar-based
Type of signal fusion	Late semantic fusion, unification, hybrid symbolic/statistical, MTC framework	Late semantic fusion, frame-based	Late semantic fusion, frame-based	Late semantic fusion, unification, finite state transducers (lattice output)	Late semantic fusion, frame-based
Type of platform and applications	Wireless handheld, varied map and VR applications, digital paper	Desktop computer, word processing	Virtual reality system, aircraft maintenance training	Wireless handheld,[2] map-based city information (restaurants, movies, route planning)	Wireless handheld, catalog ordering
Evaluation status	Proactive user-centered design and iterative system evaluations	Proactive user-centered design	Planned for future	Proactive user-centered design derived from QuickSet and system language evaluation	Planned for future

[1] A small speech vocabulary is up to 200 words, moderate 300–1000 words, and large in excess of 1000 words. For pen-based gestures, deictic selection is an individual gesture, a small vocabulary is 2–20 gestures, moderate 20–100, and large in excess of 100 gestures.

[2] Kiosk version with a talking head is also available.

FIGURE 18.1 Examples of functionality, architectural features, and general classification of different speech and gesture multimodal applications.

(Encarnacao and Hettinger 2003; Flanagan and Huang 2003; Sharma, Pavlovic, and Huang 1998; Pavlovic, Sharma, and Huang 1997). This primarily is because of the significant challenges associated with segmenting and interpreting continuous manual movements, compared with a stream of *x,y* ink coordinates. As a result of this difference, multimodal speech and pen systems have advanced more rapidly in their architectures, and have progressed further toward commercialization of applications. However, a significant cognitive science literature is available for guiding the design of emerging speech and 3D gesture prototypes (Condon 1988; Kendon 1980; McNeill 1992), which will be discussed further in Section 18.5. Among the earlier systems to begin processing, manual pointing or 3D gestures combined with speech were those developed by Koons, Sparrell, and Thorisson (1993), Sharma et al. (1996), Poddar et al. (1998), and Duncan et al. (1999).

Historically, multimodal speech and lip movement research has been driven by cognitive science interest in intersensory audiovisual perception and the coordination of speech output with lip and facial movements (Benoit and Le Goff 1998; Bernstein and Benoit 1996; Cohen and Massaro 1993; Massaro and Stork 1998; McGrath and Summerfield 1985; McGurk and MacDonald 1976; McLeod and Summerfield 1987; Robert-Ribes et al. 1998; Sumby and Pollack 1954; Summerfield 1992; Vatikiotis-Bateson et al. 1996). Among the many contributions of this literature has been a detailed classification of human lip movements (visemes) and the viseme-phoneme mappings that occur during articulated speech. Existing systems that have processed combined speech and lip movements include the classic work by Petajan (1984), Brooke and Petajan (1986), and others (Adjoudani and Benoit 1995; Bregler and Konig 1994; Silsbee and Su 1996; Tomlinson, Russell, and Brooke 1996). Additional examples of speech and lip movement systems, applications, and relevant cognitive science research have been detailed elsewhere (Benoit et al. 2000). Researchers in this area have been actively exploring adaptive techniques for improving system robustness, especially in noisy environmental contexts (Dupont and Luettin 2000; Meier, Hürst, and Duchnowski 1996; Potamianos et al. 2003; Rogozan and Deglise 1998), which is an important future research direction. Although this literature has not emphasized the development of applications, nonetheless its quantitative modeling of synchronized phoneme/viseme patterns has been used to build animated characters that generate text-to-speech output and coordinated lip movements. These new animated characters are being used as an interface design vehicle for facilitating users' multimodal interaction with next-generation conversational interfaces (Cassell et al. 2000; Cohen and Massaro 1993).

While the main multimodal literatures to date have focused on either speech and pen input or speech and lip movements, recognition of other modes also is maturing and beginning to be integrated into new kinds of multimodal systems. In particular, there is growing interest in designing multimodal interfaces that incorporate vision-based technologies, such as interpretation of gaze, facial expressions, head nodding, gesturing, and large body movements (Flanagan and Huang 2003; Morency et al. 2005; Morimoto et al. 1999; Pavlovic, Berry, and Huang 1997; Turk and Robertson 2000; Zhai, Morimoto, and Ihde 1999). These technologies unobtrusively or *passively* monitor user behavior and need not require explicit user commands to a "computer." This contrasts with *active input modes*, such as speech or pen, which the user deploys intentionally as a command issued to the system (see Figure 18.2). Although passive modes may be "attentive" and less obtrusive, active modes generally are more reliable indicators of user intent.

As vision-based technologies mature, one important future direction will be the development of *blended* multimodal interfaces that combine both passive and active modes. These interfaces typically will be *temporally cascaded*, so one goal in designing new prototypes will be to determine optimal processing strategies for using advance information from the first mode (e.g., gaze) to constrain accurate interpretation of the following modes (e.g., gesture, speech). This kind of blended multimodal interface potentially can provide users with greater transparency and control, while also supporting improved robustness and broader application functionality (Oviatt and Cohen 2000; Zhai, Morimoto, and Ihde 1999). As this collection of technologies matures, there also is strong interest in designing new types of pervasive and mobile interfaces, including ones capable of adaptive processing to the user and environmental context.

As multimodal interfaces gradually evolve toward supporting more advanced recognition of users' natural activities in context, they will expand beyond rudimentary bimodal systems to ones that incorporate three or more input modes, qualitatively different modes, and more sophisticated models of multimodal interaction. This trend already has been initiated within biometrics research, which has combined recognition of multiple behavioral input modes (e.g., voice, handwriting) with physiological ones (e.g., retinal scans, fingerprints) to achieve reliable person identification and verification in challenging field conditions (Choudhury et al. 1999; Jain et al. 1999; Jain and Ross 2002; Pankanti, Bolle, and Jain 2000).

Related to passive multimodal interfaces and biometrics, in recent years considerable international multimodal research has focused on the collection and automatic analysis of audiovisual activity patterns during collaborative group meetings. This work included hardware, software, and interface-level research toward improving the robustness of information capture and interpretation using multimodal techniques and machine learning. These projects have included CALO in North America (http://caloproject.sri .com/), the IM2 and AMIDA projects in Europe (http://www.im2.ch/), and others. Although much of this research was aimed at engineering-level advances in detection and analysis of human activity patterns related to surveillance and similar applications, nonetheless other aspects were focused on designing computational meeting assistants for copresent and remote interactions (Lunsford, Oviatt & Arthur, 2006; Lunsford, Oviatt & Coulston, 2005; Oviatt, Swindells, and Arthur 2008), multimodal meeting browsers (Lalanne et al. 2005; Lisowska 2007; Popescu-Belis and Georgescul 2006; Popescu-Belis et al. 2008; Whittaker, *Multimodal interfaces* process two or more combined user input modes—such as speech, pen, touch, manual gestures, gaze, and head and body movements—in a coordinated manner with multimedia system output. They are a new class of interfaces that aim to recognize naturally occurring forms of human language and behavior, and which incorporate one or more recognition-based technologies (e.g., speech, pen, vision).

Active input modes are ones that are deployed by the user intentionally as an explicit command to a computer system (e.g., speech).

Passive input modes refer to naturally occurring user behavior or actions that are recognized by a computer (e.g., facial expressions, manual gestures). They involve user input that is unobtrusively and passively monitored, without requiring any explicit command to a computer.

Blended multimodal interfaces are ones that incorporate system recognition of at least one passive and one active input mode (e.g., speech and lip movement systems).

Temporally cascaded multimodal interfaces are ones that process two or more user modalities that tend to be sequenced in a particular temporal order (e.g., gaze, gesture, speech), such that partial information supplied by recognition of an earlier mode (e.g., gaze) is available to constrain interpretation of a later mode (e.g., speech). Such interfaces may combine only active input modes, only passive ones, or they may be blended.

Mutual disambiguation involves disambiguation of signal or semantic-level information in one error-prone input mode from partial information supplied by another. Mutual disambiguation can occur in a multimodal architecture with two or more semantically rich recognition-based input modes. It leads to recovery from unimodal recognition errors within a multimodal architecture, with the net effect of suppressing errors experienced by the user.

Simultaneous integrator refers to a user who habitually presents two input signals (e.g., speech, pen) in a temporally overlapped manner when communicating multimodal commands to a system.

Sequential integrator refers to a user who habitually separates his or her multimodal signals, presenting one before the other with a brief pause intervening.

Multimodal hypertiming refers to the fact that both sequential and simultaneous integrators will further accentuate their basic multimodal integration pattern when under duress (e.g., as task difficulty or system recognition errors increase).

Visemes refers to the detailed classification of visible lip movements that correspond with consonants and vowels during articulated speech. A *viseme-phoneme mapping* refers to the correspondence between visible lip movements and audible phonemes during continuous speech.

Feature-level fusion is a method for fusing low-level feature information from parallel input signals within a multimodal architecture, which has been applied to processing closely synchronized input such as speech and lip movements.

Semantic-level fusion is a method for integrating semantic information derived from parallel input modes in a multimodal architecture, which has been used for processing speech and gesture input.

Frame-based integration is a pattern-matching technique for merging attribute-value data structures to fuse semantic information derived from two input modes into a common meaning representation during multimodal language processing.

Unification-based integration is a logic-based method for integrating partial meaning fragments derived from two input modes into a common meaning representation during multimodal language processing. Compared with frame-based integration, unification derives from logic programming, and has been more precisely analyzed and widely adopted within computational linguistics.

FIGURE 18.2 Multimodal interface terminology.

Laban, and Tucker 2005), and adaptive human-centered interfaces for collaborative work, problem solving, and educational exchanges (Barthelmess and Oviatt 2007; Lunsford, Oviatt & Arthur, 2006; Lunsford, Oviatt & Coulston, 2005; Oviatt, Swindells, and Arthur 2008). Archivus is one example of a multimodal meeting browser and retrieval system, which users could query with speech, keyboard and mouse, or pen-based natural language queries to obtain information about meeting events (Lisowska 2007). Other research on group multimodal activity patterns established new approaches to detecting floor control, agreement, and decisions during conversation, dominance of group members, and other interaction dynamics (Chen and Harper 2009; Gatica-Perez et al. 2005; Germesin 2009; Hsueh and Moore 2008).

Apart from these developments within research-level systems, multimodal interfaces also are being commercialized as products, especially in areas like personal information access and management on handhelds and cell phones. Microsoft's handheld multimodal interactive notepad (MiPad) for personal information management, (Huang et al. 2000), Kirusa's cell phone interface for directory assistance and messaging, and AT&T's iMOD for searching movies on the iPhone (Johnston 2009) are just three examples of the many mobile commercial products that are being developed with multimodal interfaces. They include spoken language processing and a stylus or touch input for selecting fields to constrain and guide the natural language processing. In some cases, keyboard input is supported as a third option, as well as multimedia output in the form of visualizations and text-to-speech. Another visible growth area for multimodal interfaces involves in-vehicle control of navigation, communication, and entertainment systems, which have emerged in both domestic and import cars. Mobile map-based systems and systems for safety-critical medical and military applications also are being commercialized by companies like Adapx (Adapx, 2011). Which places an emphasis on developing tangible multimodal interfaces that preserve users' existing work practice, minimize cognitive load, and provide backups in case of system failure (Cohen and McGee 2004; McGee 2003). Section 18.9 provides further discussion of trends in the commercialization of multimodal interfaces.

18.3 WHAT ARE THE GOALS AND ADVANTAGES OF MULTIMODAL INTERFACE DESIGN?

Over the past decade, numerous advantages of multimodal interface design have been documented. Unlike a traditional keyboard-and-mouse interface or a unimodal recognition-based interface, multimodal interfaces permit flexible use of input modes. This includes the choice of which modality to use for conveying different types of information, to use combined input modes, or to alternate between modes at any time. Because individual input modalities are well suited in some situations, and less ideal or even inappropriate in others, modality choice is an important design issue in a multimodal system. As systems become more complex and multifunctional, a single modality simply does not permit all users to interact effectively across all tasks and environments.

Because there are large individual differences in ability and preference to use different modes of communication, a multimodal interface permits diverse user groups to exercise selection and control over how they interact with the computer (Fell et al. 1994; Karshmer and Blattner 1998). In this respect, multimodal interfaces have the potential to accommodate a broader range of users than traditional interfaces—including users of different ages, skill levels, native language status, cognitive styles, sensory impairments, and other temporary illnesses or permanent handicaps. For example, a visually impaired user or one with repetitive stress injury may prefer speech input and text-to-speech output. In contrast, a user with a hearing impairment or accented speech may prefer touch, gesture, or pen input. The natural alternation between modes that is permitted by a multimodal interface also can be effective in preventing overuse and physical damage to any single modality, especially during extended periods of computer use (Markinson,* personal communication, 1993).

Multimodal interfaces also provide the adaptability that is needed to accommodate the continuously changing conditions of mobile use. In particular, systems involving speech, pen, or touch input are suitable for mobile tasks and, when combined, users can shift among these modalities from moment to moment as environmental conditions change (Holzman 1999; Oviatt 2000b,c). There is a sense in which mobility can induce a state of temporary disability, such that a person is unable to use a particular input mode for some period of time. For example, the user of an in-vehicle application may frequently be unable to use manual or gaze input, although speech is relatively more available. In this respect, a multimodal interface permits the modality choice and switching that is needed during the changing environmental circumstances of actual field and mobile use.

A large body of data documents that multimodal interfaces satisfy higher levels of user preference when interacting with simulated or real computer systems. Users have a strong preference to interact multimodally, rather than unimodally, across a wide variety of different application domains, although this preference is most pronounced in spatial domains (Hauptmann 1989; Oviatt 1997). For example, 95%–100% of users preferred to interact multimodally, when they were free to use either speech or pen input in a map-based spatial domain (Oviatt 1997). During pen/voice multimodal interaction, users preferred speech input for describing objects and events, sets and subsets of objects, out-of-view objects, conjoined information, past and future temporal states, and for issuing commands for actions or iterative actions (Cohen and Oviatt 1995; Oviatt and Cohen 1991). However, their preference for pen input increased when conveying digits, symbols, graphic content, and especially when conveying the location and form of spatially-oriented information on a dense graphic display such as a map (Oviatt and Olsen 1994; Oviatt 1997; Suhm 1998). Likewise, 71% of users combined speech and manual gestures multimodally, rather than using one input mode, when manipulating graphic objects on a cathode ray tube screen (Hauptmann 1989).

During the early design of multimodal systems, it was assumed that efficiency gains would be the main advantage of designing an interface multimodally, and that this advantage would derive from the ability to process input modes in parallel. It is true that multimodal interfaces sometimes support improved efficiency, especially when manipulating graphical information. In simulation research comparing speech-only with multimodal pen/voice interaction, empirical work demonstrated that multimodal interaction yielded 10% faster task completion time during visual-spatial tasks, but no significant efficiency advantage in verbal or quantitative task domains (Oviatt 1997; Oviatt, Cohen, and Wang 1994). Likewise, users' efficiency improved when they combined speech and gestures multimodally to manipulate 3D objects, compared with unimodal input (Hauptmann 1989). In another early study, multimodal speech and mouse input improved efficiency in a line-art drawing task (Leatherby and Pausch 1992). Finally, in a study that compared task completion times for a graphical interface versus a multimodal pen/voice interface, military domain experts averaged four times faster at setting up complex simulation scenarios on a map when they were able to interact multimodally (Cohen, McGee, and Clow 2000). This latter study was based on testing of a fully functional multimodal system, and it included time required to correct recognition errors.

One particularly advantageous feature of multimodal interface design is its superior error handling, both in terms of error avoidance and graceful recovery from errors (Oviatt and van Gent 1996; Oviatt, Bernard, and Levow 1999; Oviatt 1999a; Rudnicky and Hauptmann 1992; Suhm 1998; Tomlinson, Russell, and Brooke 1996). There are user-centered and system-centered reasons why multimodal systems facilitate error recovery, when compared with unimodal recognition-based interfaces. For example, in a multimodal speech and pen-based gesture interface, users will select the input mode that they judge to be less error prone for particular lexical content, which tends to lead to error avoidance (Oviatt and van Gent 1996). They may prefer speedy speech input, but will switch to pen input to communicate a foreign surname. Second, users' language often is simplified when interacting multimodally, which can substantially reduce the complexity of natural language processing and thereby reduce recognition errors (Oviatt and Kuhn 1998; see Section 18.5 for discussion). In one study, users' multimodal utterances were documented to be briefer, to contain

* R. Markinson, University of California at San Francisco Medical School, 1993.

fewer complex locative descriptions, and 50% fewer spoken disfluencies, when compared with a speech-only interface. Third, users have a strong tendency to switch modes after system recognition errors, which facilitates error recovery. This error resolution occurs because the confusion matrices differ for any given lexical content for the different recognition technologies involved in processing (Oviatt, Bernard, and Levow 1999; Oviatt 2002).

In addition to these user-centered reasons for better error avoidance and resolution, there also are system-centered reasons for superior error handling. A well-designed multimodal architecture with two semantically rich input modes can support *mutual disambiguation* of input signals. For example, if a user says "ditches" but the speech recognizer confirms the singular "ditch" as its best guess, then parallel recognition of several graphic marks can result in recovery of the correct plural interpretation. This recovery can occur in a multimodal architecture even though the speech recognizer initially ranks the plural interpretation "ditches" as a less-preferred choice on its n-best list. Mutual disambiguation involves recovery from unimodal recognition errors within a multimodal architecture because semantic information from each input mode supplies partial disambiguation of the other mode, thereby leading to more stable and robust overall system performance (Oviatt 1999a, 2000a, 2002). Another example of mutual disambiguation is shown in Figure 18.3. To achieve optimal error handling, a multimodal interface ideally should be designed to include complementary input modes, and also the alternative input modes provide duplicate functionality such that users can accomplish their goals using either mode.

PAN

FIGURE 18.3 **(See color insert.)** Multimodal command to "pan" the map, which illustrates mutual disambiguation occurring between incoming speech and gesture information, such that lexical hypotheses were pulled up on both n-best lists to produce a correct final multimodal interpretation.

In two recent studies involving more than 4600 multimodal commands, a multimodal architecture was found to support mutual disambiguation and error suppression ranging between 19% and 41% (Oviatt 1999a, 2000a, 2002). Improved robustness also was greater for "challenging" user groups (accented vs. native speakers) and usage contexts (mobile vs. stationary use). These results indicate that a well-designed multimodal system not only can perform more robustly than a unimodal system, but also in a more stable way across varied real-world users and usage contexts. Finally, during audiovisual perception of speech and lip movements, improved speech recognition also has been demonstrated for both human listeners (McLeod and Summerfield 1987) and multimodal systems (Adjoudani and Benoit 1995; Tomlinson, Russell, and Brooke 1996).

Another recent focus has been on the advantages of multimodal interface design for minimizing users' cognitive load. As task complexity increases, there is evidence that users self manage their working memory limits by distributing information across multiple modalities, which in turn enhances their task performance during both perception and production (Calvert, Spence, and Stein 2004; Mousavi, Low, and Sweller 1995; Oviatt 1997; Oviatt, Flickner, and Darrell 2004; Tang et al. 2005). These predictions and findings are based on Wickens and colleagues' cognitive resource theory and Baddeley's theory of working memory (Baddeley 1992; Wickens, Sandry, and Vidulich 1983). The latter maintains that short-term or working memory consists of multiple independent processors associated with different modes. This includes a visual-spatial "sketch pad" that maintains visual materials such as pictures and diagrams in one area of working memory, and a separate phonological loop that stores auditory-verbal information. Although these two processors are believed to be coordinated by a central executive, in terms of lower-level modality processing, they are viewed as functioning largely independently, which is what enables the effective size of working memory to expand when people use multiple modalities during tasks (Baddeley 1992). So with respect to management of cognitive load, the inherent flexibility of multimodal interfaces is well suited to accommodating the high and changing load conditions typical of realistic mobile use.

One natural human communication mode, pen input, recently has been demonstrated to support better problem solving in science, technology, engineering, mathematics domains than existing keyboard-based graphical interfaces. In two separate studies, when the same high school students solved the same mathematics and science problems, the best performance was supported by a digital pen and paper interface, followed by a pen tablet interface, and lastly a keyboard-based graphical interface (Oviatt, Arthur, and Cohen 2006; Oviatt and Cohen 2010a). Performance advantages due to the pen interface included improved speed, ability to focus attention, solve problems correctly, engage in high-level synthetic thinking, communicate fluently, and remember information just solved (Oviatt 2006; Oviatt, Arthur, and Cohen 2006; Oviatt et al. 2007). In addition, low-performing students experienced elevated cognitive load, with tablet interfaces disrupting their performance more than high-performers, which in turn expanded the achievement gap between groups (Oviatt, Arthur, and Cohen 2006).

Other recent findings have revealed that pen input, a rich communications modality that is capable of expressing different representations (linguistic, symbolic, diagrammatic, numeric), can facilitate people's communicative fluency, ideational fluency, and problem solving to a greater extent than either a keyboard-based graphical interface or nondigital paper and pencil (Oviatt and Cohen, 2010b; Oviatt in press). When biology students, working on hypothesis-generation tasks were compared using different interfaces, they demonstrated greater *nonlinguistic communicative fluency* (numeric, symbolic, diagrammatic) when using pen interfaces than a graphical interface or paper and pencil. In parallel, pen interfaces stimulated 36% more ideational fluency (i.e., appropriate biology hypothesis generation), and regression analyses revealed that interface support for nonlinguistic fluency predicted ideational fluency, as shown in Figure 18.4a (Oviatt in press). In contrast, a keyboard-based graphical interface elicited more *linguistic fluency*, which suppressed ideation, as shown in Figure 18.4b (Oviatt in press). These results challenge us to question the adequacy of existing keyboard-centric graphical interfaces for future educational and professional practice. Pen input capabilities, which often are included in multimodal interfaces, effectively provided a single focused input tool for *fluently expressing both nonlinguistic and linguistic representations*, and for *shifting rapidly and flexibly among them* without impeding thought (Oviatt and Cohen, 2010b; Oviatt in press).

18.4 WHAT METHODS AND INFORMATION HAVE BEEN USED TO DESIGN NOVEL MULTIMODAL INTERFACES?

The design of new multimodal systems has been inspired and organized largely by two things. First, the cognitive science literature on intersensory perception and intermodal coordination during production is beginning to provide a foundation of information for user modeling, as well as information on what systems must recognize and how multimodal architectures should be organized. For example, the cognitive science literature has provided knowledge of the natural integration patterns that typify people's lip and facial movements with speech output (Benoit et al. 1996; Ekman 1992; Ekman and Friesen 1978; Fridlund 1994; Hadar et al. 1983; Massaro and Cohen 1990; Stork and Hennecke 1995; Vatikiotis-Bateson et al. 1996), and their coordinated use of manual or pen-based gestures with speech (Kendon 1980; McNeill 1992; Oviatt, DeAngeli, and Kuhn 1997). Given the complex nature of users' multimodal interaction, cognitive science has and will continue to play an essential role in guiding the design of robust multimodal systems. In this respect, a multidisciplinary perspective will be more central to successful multimodal system design than it has been for traditional GUI design. The cognitive science underpinnings of multimodal system design are described in Section 18.5.

Second, high-fidelity automatic simulations also have played a critical role in prototyping new types of multimodal systems (Dahlbäck, Jëonsson, and Ahrenberg 1992; Oviatt et al. 1992). When a new multimodal system is in the planning stages, design sketches, and low-fidelity mock-ups may initially be used to visualize the new system and plan the sequential flow of HCI. These tentative design plans then are rapidly transitioned into a

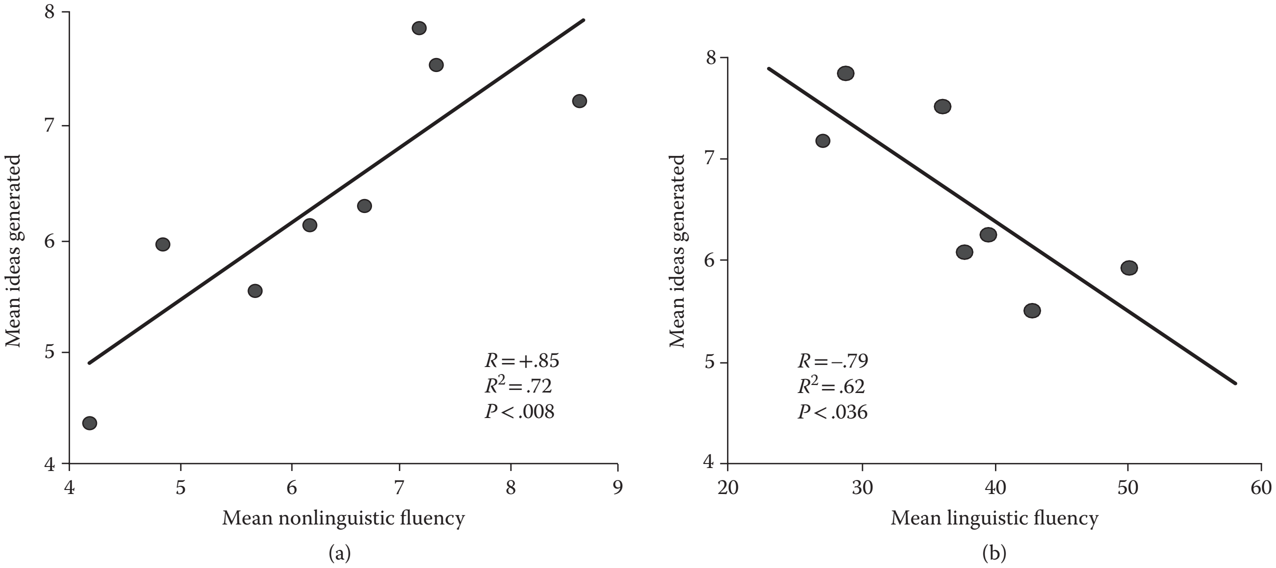

FIGURE 18.4 (a) Regression analysis confirming *positive predictive relation* between interface support for nonlinguistic communicative fluency and ideational fluency as a result of using a richly expressive pen interface. (b) Regression confirming *negative predictive relation* between interface support for linguistic communicative fluency and ideational fluency when using a keyboard-based graphical interface.

higher-fidelity simulation of the multimodal system, which is available for proactive and situated data collection with the intended user population. High-fidelity simulations have been the preferred method for designing and evaluating new multimodal systems, and extensive data collection with such tools preferably is completed before a fully functional system is ever built.

During high-fidelity simulation testing, a user interacts with what she believes is a fully functional multimodal system, although the interface is actually a simulated front end designed to appear and respond as the fully functional system would. During the interaction, a programmer assistant at a remote location provides the simulated system responses. As the user interacts with the front end, the programmer tracks her multimodal input and provides system responses as quickly and accurately as possible. To support this role, the programmer makes use of automated simulation software that is designed to support interactive speed, realism with respect to the targeted system, and other important characteristics. For example, with these automated tools, the programmer may be able to make a single selection on a workstation field to rapidly send simulated system responses to the user during a data-collection session.

High-fidelity simulations have been the preferred method for prototyping multimodal systems for several reasons. Simulations are relatively easy and inexpensive to adapt, compared with building and iterating a complete system. They also permit researchers to alter a planned system's characteristics in major ways (e.g., input and output modes available), and to study the impact of different interface features in a systematic and scientific manner (e.g., type and base-rate of system errors). In comparison, a particular system with its fixed characteristics is a less flexible and suitable research tool, and the assessment of any single system basically amounts to an individual case study. Using simulation techniques, rapid adaptation and investigation of planned system features permits researchers to gain a broader and more principled perspective on the potential of newly emerging technologies. In a practical sense, simulation research can assist in the evaluation of critical performance tradeoffs and in making decisions about alternative system designs, which designers must do as they strive to create more usable multimodal systems.

The most recent high-fidelity simulation tools have been designed to collect data and prototype new multimodal systems that support collaborative group interactions (Arthur et al. 2006). They also are beginning to support real-time processing of the paralinguistic aspects of users' natural speech and pen input signals, such as changes in user amplitude that indicate intended addressee during multiperson exchanges, which is needed to develop new adaptive multimodal systems (Cohen et al. 2008; Oviatt, Swindells, and Arthur 2008). An example of a dual-wizard, high-fidelity simulation environment designed to prototype collaborative multimodal interfaces and also adapt to changes in users' speech and pen amplitude is shown in Figure 18.5. This particular simulation collected speech, visual, and digital pen and paper data from students during three-person collaborative meetings while they used a computational assistant to solve mathematics problems. Two wizards were required in this simulation to process key user data in real time involving the (1) linguistic content of users' requests, and (2) amplitude of their speech or pen communication. Specialized simulation software and wizard training both were needed to support adequately fast and error-free teamwork between the two wizards (Cohen et al. 2008). To support the further development and commercialization of multimodal systems, additional infrastructure that will be needed in the future includes the following: (1) simulation tools for rapidly building and reconfiguring multimodal interfaces, (2) automated tools for collecting and analyzing multimodal corpora, and (3) automated tools for iterating new multimodal systems to improve their performance (see Oviatt et al. 2000, for further discussion).

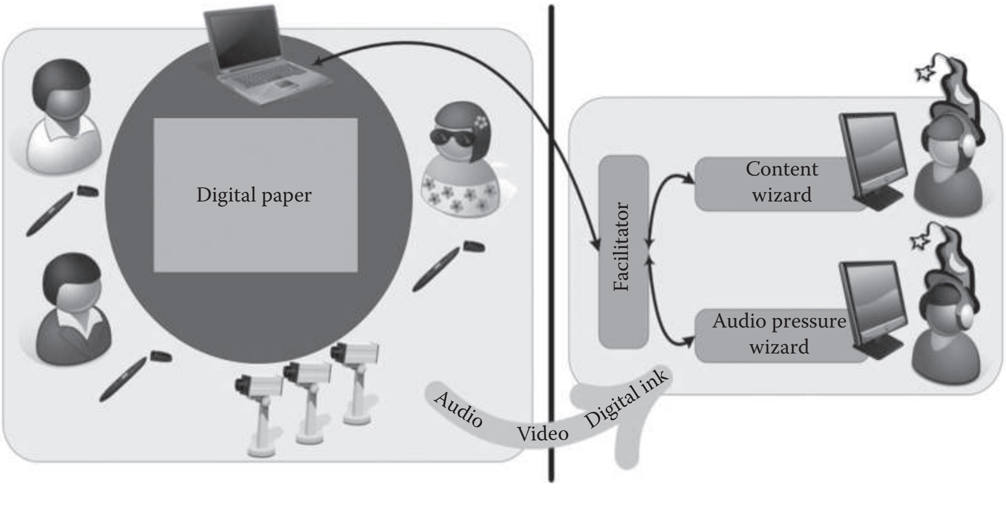

FIGURE 18.5 Dual-wizard simulation environment for prototyping collaborative multimodal interfaces capable of real-time adaptive processing.

18.5 WHAT ARE THE COGNITIVE SCIENCE UNDERPINNINGS OF MULTIMODAL INTERFACE DESIGN?

This section discusses the growing cognitive science literature that provides the empirical underpinnings needed to design next-generation multimodal interfaces. The ability to develop multimodal systems depends on knowledge of the natural integration patterns that typify people's combined use of different input modes. In particular, the design of new multimodal systems depends on intimate knowledge of the properties of different modes and the information content they carry, the unique characteristics of multimodal language and its processability, and the integration and synchronization characteristics of users' multimodal interaction. It also relies on accurate prediction of when users are likely to interact multimodally, and how alike different users are in their specific integration patterns. The relevant cognitive science literature on these topics is very extensive, especially when consideration is given to all of the underlying sensory perception and production capabilities involved in different input modes currently being incorporated in new multimodal interfaces. As a result, this section will be limited to introducing the main cognitive science themes and findings that are relevant to the more common types of multimodal systems.

This cognitive science foundation also has played a key role in identifying computational "myths" about multimodal interaction, and replacing these misconceptions with contrary empirical evidence. Figure 18.6 summarizes 10 common myths about multimodal interaction, which are addressed and discussed in more detail elsewhere (Oviatt 1999b). As such, the literature summarized in this section aims to provide a more accurate foundation for guiding the design of next-generation multimodal systems.

18.5.1 When Do Users Interact Multimodally?

During natural interpersonal communication, people are always interacting multimodally. Of course, in this case, the number of information sources or modalities that an interlocutor has available to monitor is essentially unlimited. However, all multimodal systems are constrained in the number and type of input modes they can recognize. Also, a user can compose active input during human–computer interaction that either is delivered multimodally or that is delivered entirely using just one mode. That is, although users in general may have a strong preference to interact multimodally rather than unimodally, this is no guarantee that they will issue every command to a system multimodally, given the particular type of multimodal interface available. Therefore, the first nontrivial question that arises during system processing is whether a user is communicating unimodally or multimodally.

In the case of speech and pen-based multimodal systems, users typically intermix unimodal and multimodal expressions. In one study involving a visual-spatial domain, users' commands were expressed multimodally 20% of the time, with others just spoken or written (Oviatt et al. 1997). In contrast, in spatial domains, the ratio of users' multimodal interaction often is 65%–70% (Oviatt, Bernard, and Levow 1999). Predicting whether a user will express a command multimodally also depends on the type of action she is performing. In particular, users almost always express commands multimodally when describing spatial information about the location, number, size, orientation, or shape of an object. In one study, users issued multimodal commands 86% of the time when they had to add, move, modify, or calculate the distance between objects on a map in a way that required specifying spatial locations (Oviatt et al. 1997). They also were moderately likely to interact multimodally when selecting an object from a larger array, for example, when deleting a particular object from the map. However, when performing general actions without any spatial component, such as printing a map, users expressed themselves multimodally less than 1% of the time. These data emphasize that future multimodal systems will need to distinguish between instances when users are and are not communicating multimodally, so that accurate decisions can be made about when parallel input streams should be interpreted jointly versus individually. They also suggest that knowledge of the type of actions to be included in an application, such as whether the application entails manipulating spatial information, should influence the basic decision of whether to build a multimodal interface at all.

Myth #1: *If you build a multimodal system, users will interact multimodally.*
Myth #2: *Speech and pointing is the dominant multimodal integration pattern.*
Myth #3: *Multimodal input involves simultaneous signals.*
Myth #4: *Speech is the primary input mode in any multimodal system that includes it.*
Myth #5: *Multimodal language does not differ linguistically from unimodal language.*
Myth #6: *Multimodal integration involves redundancy of content between modes.*
Myth #7: *Individual error-prone recognition technologies combine multimodally to produce even greater unreliability.*
Myth #8: *All users' multimodal commands are integrated in a uniform way.*
Myth #9: *Different input modes are capable of transmitting comparable content.*
Myth #10: *Enhanced efficiency is the main advantage of multimodal systems.*

FIGURE 18.6 Ten myths of multimodal interaction: separating myth from empirical reality.

Findings from a more recent study reveal that multimodal interface users spontaneously respond to dynamic changes in their own cognitive load by shifting to multimodal communication as load increases with task difficulty and communicative complexity (Oviatt, Coulston, and Lunsford 2004). Given a flexible multimodal interface, users' ratio of multimodal (vs. unimodal) interaction increased substantially from 18.6% when referring to established dialog context to 77.1% when required to establish a new context, a +315% relative increase. Likewise, the ratio of users' multimodal interaction increased significantly as the tasks became more difficult, from 59.2% during low-difficulty tasks to 65.5% at moderate difficulty, 68.2% at high difficulty, and 75.0% at very high difficulty, an overall relative increase of +27%. These adaptations in multimodal interaction levels reflect users' effort to self manage limitations in their working memory as discourse-level demands and task complexity increased. As discussed earlier, they accomplished this by distributing communicative information across multiple modalities in a manner compatible with a cognitive load theory of multimodal interaction. This interpretation is consistent with Baddeley's theory of working memory (Baddeley 1992), as well as the growing literatures within education (Mousavi, Low, and Sweller 1995; Sweller 1988), linguistics (Almor 1999), and multisensory perception (Calvert, Spence, and Stein 2004; Ernst and Bulthoff 2004). Recent work on visual and haptic processing under workload also indicates that presentation of haptic feedback during a complex task can augment users' ability to handle visual information overload (Tang et al. 2005).

In a multimodal interface that processes passive or blended input modes, there always is at least one passively-tracked input source providing continuous information (e.g., gaze tracking, head position). In these cases, all user input would by definition be classified as multimodal, and the primary problem would become segmentation and interpretation of each continuous input stream into meaningful actions of significance to the application. In the case of blended multimodal interfaces (e.g., gaze tracking and mouse input), it still may be opportune to distinguish active forms of user input that might be more accurately or expeditiously handled as unimodal events.

18.5.2 What Are the Integration and Synchronization Characteristics of Users' Multimodal Input?

The past literature on multimodal systems has focused largely on simple selection of objects or locations in a display, rather than considering the broader range of multimodal integration patterns. Because the development of Bolt's (1980) "Put That There" system, speak-and-point has been viewed as the prototypical form of multimodal integration. In Bolt's system, semantic processing was based on spoken input, but the meaning of a deictic term such as "that" was resolved by processing the *x*, *y* coordinate indicated by pointing at an object. Since that time, other multimodal systems also have attempted to resolve deictic expressions using a similar approach, for example, using gaze location instead of manual pointing (Koons et al. 1993).

Unfortunately, this concept of multimodal interaction as point-and-speak makes only limited use of new input modes for *selection* of objects—just as the mouse does. In this respect, it represents the persistence of an old mouse-oriented metaphor. In contrast, modes that transmit written input, manual gesturing, and facial expressions are capable of generating symbolic information that is much more richly expressive than simple pointing or selection. In fact, studies of users' integrated pen/voice input indicate that a speak-and-point pattern only comprises 14% of all spontaneous multimodal utterances (Oviatt et al. 1997). Instead, pen input more often is used to create graphics, symbols and signs, gestural marks, digits, and lexical content. During interpersonal multimodal communication, linguistic analysis of spontaneous manual gesturing also indicates that simple pointing accounts for less than 20% of all gestures (McNeill 1992). Together, these cognitive science and user-modeling data highlight the fact that any multimodal system designed exclusively to process speak-and-point will fail to provide users with much useful functionality. For this reason, specialized algorithms for processing deictic-point relations will have only limited practical use in the design of future multimodal systems. It is clear that a broader set of multimodal integration issues needs to be addressed in future work. Future research also should explore typical integration patterns between other promising modality combinations, such as speech and gaze.

It also is commonly assumed that any signals involved in a multimodal construction will co-occur temporally. The presumption is that this temporal overlap then determines which signals to combine during system processing. In the case of speech and manual gestures, successful processing of the deictic term "that square" in Bolt's original system relied on interpretation of pointing when the word "that" was spoken in order to extract the intended referent. However, one empirical study indicated that users often do not speak deictic terms at all, and when they do the deictic frequently is not overlapped in time with their pointing. In fact, it has been estimated that as few as 25% of users' commands actually contain a spoken deictic that overlaps with the pointing needed to disambiguate its meaning (Oviatt et al. 1997).

Beyond the issue of deixis, a series of studies has shown that users' input frequently does not overlap at all during multimodal commands to a computer (Oviatt 1999b; Oviatt et al. 2003; Xiao, Girand, and Oviatt 2002; Xiao et al. 2003). In fact, there are two distinct types of user with respect to integration patterns—*simultaneous* integrators and *sequential* ones. A user who habitually integrates his or her speech and pen input in a *simultaneous* manner overlaps them temporally, whereas a sequential integrator finishes one mode before beginning the second. These two types of user integration pattern occur across the lifespan from children through the elderly (Oviatt, Lunsford et al. 2005; Xiao, Girand, and Oviatt 2002; Xiao et al. 2003). They also can be detected almost immediately during multimodal interaction, usually on the very first input. Users' habitual integration pattern remains strikingly highly consistent during a session, as well as resistant to change following explicit instructions or attempts at training (Oviatt et al. 2003; Oviatt, Lunsford et al. 2005). This bimodal distribution of user integration patterns has been observed in different task domains (e.g., map-based real estate selection, crisis management, educational applications with animated characters), and also when using different types of interface (e.g., conversational, command style) (Darves and Oviatt 2004; Oviatt 1999b; Xiao, Girand, and Oviatt 2002; Xiao et al. 2003). In short, empirical studies have demonstrated that this bimodal distinction between users in their fundamental integration pattern generalizes widely across different age groups, task domains, and types of interface.

One interesting discovery in recent work is the phenomenon of *multimodal hypertiming*, which refers to the fact that both sequential and simultaneous integrators will entrench further or accentuate their habitual multimodal integration pattern (i.e., increasing their intermodal *lag* during sequential integrations, or *overlap* during simultaneous integrations) during system error handling or when completing increasingly difficult tasks. In fact, users will progressively increase their degree of entrenchment by 18% as system errors increase and by 59% as task difficulty increases (Oviatt et al. 2003). As such, changes in the degree of users' multimodal hypertiming provides a potentially sensitive means of evaluating their cognitive load during real-time interactive exchanges. In the context of system error handling, the phenomenon of multimodal hypertiming basically replaces the hyperarticulation that is typically observed in users during error-prone speech-only interactions.

Given the bimodal distribution of user integration patterns, *adaptive temporal thresholds* potentially could support more tailored and flexible approaches to fusion. Ideally, an adaptive multimodal system would detect, automatically learn, and adapt to a user's dominant multimodal integration pattern, which could result in substantial improvements in system processing speed, the accuracy of interpretation, and also synchronous interchange with the user. For example, it has been estimated that system delays could be reduced to approximately 40%–50% of what they currently are by adopting user-defined thresholds (Oviatt, Lunsford et al. 2005; Gupta 2004). Recent research has begun comparing different learning-based models for adapting a multimodal system's temporal thresholds to an individual user in real time (Huang and Oviatt 2006).

Unfortunately, users' multimodal integration patterns have not been studied as extensively or systematically for other input modes, such as speech and manual gesturing. Linguistics research on interpersonal communication patterns has revealed that both spontaneous gesturing and signed language often precede their spoken lexical analogs during human communication (Kendon 1980; Naughton 1996), when considering word-level integration pattern. In fact, the degree to which gesturing precedes speech is greater in topic-prominent languages such as Chinese than it is in subject-prominent ones like Spanish or English (McNeill 1992). Even in the speech and lip movement literature, close but not perfect temporal synchrony is typical, with lip movements occurring a fraction of a second before the corresponding auditory signal (Abry, Lallouache, and Cathiard 1996; Benoit 2000). However, when considering the whole user utterance as the unit of analysis, some other studies of speech and manual gesturing have found a higher rate of simultaneity for these modes (Epps, Oviatt, and Chen 2004). Learning-based approaches that are capable of accurately identifying and adapting to different multimodal integration patterns, whether due to differences among users, modality combinations, or applications and usage contexts, will be required in order to generalize and speed up multimodal system development in the future.

In short, although two input modes may be highly interdependent and synchronized during multimodal interaction, synchrony does not imply simultaneity. The empirical evidence reveals that multimodal signals often do not co-occur temporally at all during human–computer or natural human communication. Therefore, multimodal system designers cannot necessarily count on conveniently overlapped signals in order to achieve successful processing in the multimodal architectures they build. Future research needs to explore the integration patterns and temporal cascading that can occur among three or more input modes, such as gaze, gesture, and speech, so that more advanced multimodal systems can be designed and prototyped.

In the design of new multimodal architectures, it is important to note that data on the order of input modes and average time lags between input modes has been used to determine the likelihood that an utterance is multimodal versus unimodal, and to establish temporal thresholds for fusion of input. In the future, weighted likelihoods associated with different utterance segmentations, for example, that an input stream containing speech, writing, speech should be segmented into [S / W S] rather than [S W / S], and with intermodal time lag distributions, will be used to optimize correct recognition of multimodal user input (Oviatt 1999b). In the design of future time-critical multimodal architectures, data on users' integration and synchronization patterns will need to be collected for other mode combinations during realistic interactive tasks, so that temporal thresholds can be established for performing multimodal fusion.

18.5.3 What Individual Differences Exist in Multimodal Interaction, and What Are the Implications for Designing Systems for Universal Access?

There are large individual differences in users' multimodal interaction patterns, beginning with their overall preference to interact unimodally versus multimodally, and also which mode they generally prefer (e.g., speaking vs. writing) (Oviatt, Coulston, and Lunsford 2004). As outlined in Section 18.5.2, there likewise are striking differences among users' in adopting either a sequential or simultaneous multimodal integration pattern. Recent research has revealed that these two patterns are associated with behavioral and linguistic differences between the groups (Oviatt, Lunsford et al. 2005). Although in an interactive task context their performance speed was comparable, sequential integrators were far less error prone and excelled during new or complex tasks. Although their speech rate was no slower, sequential integrators also had more precise articulation (e.g., fewer disfluencies). Finally, sequential integrators were more likely to adopt terse and direct command-style language, with a smaller and less varied vocabulary, which appeared focused on achieving error-free communication. These user differences in interaction pattern have been interpreted as deriving from fundamental differences among users in their reflective-impulsive cognitive style (Oviatt, Lunsford et al. 2005). Based on this work, one goal of future multimodal interface design will be to support the poorer attention span and higher error rate of impulsive users—especially for mobile in-vehicle, military, and similar application contexts in which the cost of committing errors is unacceptably high.

Apart from these individual differences, cultural differences also have been documented between users in modality integration patterns. For example, substantial individual differences have been reported in the temporal synchrony between speech and lip movements (Kricos 1996) and, in addition, lip movements during speech production are known to be less exaggerated among Japanese speakers than Americans (Sekiyama and Tohkura 1991). In fact, extensive interlanguage differences have been observed in the information available from lip movements during audiovisual speech (Fuster-Duran 1996). These findings have implications for the degree to which disambiguation of speech can be achieved through lip movement information in noisy environments or for different user populations. Finally, non-native speakers, the hearing impaired, and elderly listeners all are more influenced by visual lip movement than auditory cues when processing speech (Fuster-Duran 1996; Massaro 1996). These results have implications for the design and expected value of audiovisual multimedia output for different user groups in animated character interfaces. With respect to support for universal access, recent work also has shown the advantage of combined audiovisual processing for recognition of impaired speech (Potamianos and Neti 2001).

Finally, gender, age, and other individual differences are common in gaze patterns, as well as speech and gaze integration (Argyle 1972). As multimodal interfaces incorporating gaze become more mature, further research will need to explore these gender and age-specific patterns, and to build appropriately adapted processing strategies. In summary, considerably more research is needed on multimodal integration and synchronization patterns for new mode combinations, as well as for diverse and disabled users for whom multimodal interfaces may be especially suitable for ensuring universal access.

18.5.4 Is Complementarity or Redundancy the Main Organizational Theme That Guides Multimodal Integration?

It frequently is claimed that the propositional content conveyed by different modes during multimodal communication contains a high degree of redundancy. However, the dominant theme in users' natural organization of multimodal input actually is complementarity of content, not redundancy. For example, speech and pen input consistently contribute different and complementary semantic information—with the subject, verb, and object of a sentence typically spoken, and locative information written (Oviatt et al. 1997). In fact, a major complementarity between speech and manually oriented pen input involves visual-spatial semantic content, which is one reason these modes are an opportune combination for visual-spatial applications. Although spatial information is uniquely and clearly indicated through pen input, the strong descriptive capabilities of speech are better suited for specifying temporal and other nonspatial information. Even during multimodal correction of system errors, when users are highly motivated to clarify and reinforce their information delivery, speech and pen input express redundant information less than 1% of the time. Finally, during interpersonal communication, linguists also have documented that spontaneous speech and manual gesturing involve complementary rather than duplicate information between modes (McNeill 1992).

Other examples of primary multimodal complementarities during interpersonal and human–computer communication have been described in past research (McGurk and MacDonald 1976; Oviatt and Olsen 1994; Wickens, Sandry, and Vidulich 1983). For example, in the literature on multimodal speech and lip movements, natural feature-level complementarities have been identified between visemes and phonemes for vowel articulation, with vowel rounding better conveyed visually, and vowel height and backness better revealed auditorally (Massaro and Stork 1998; Robert-Ribes et al. 1998).

In short, actual data highlight the importance of complementarity as a major organizational theme during multimodal communication. Furthermore, recent research has documented an increase in the ratio of complementary to redundant multimodal constructions as users' cognitive load increases (Ruiz, Oviatt, and Chen, 2010). The designers of next-generation multimodal systems therefore should not expect to rely on duplicated information when processing multimodal language, although in certain contexts such as teaching a higher percentage of redundant content may exist because of the tutorial context.

In multimodal systems involving both speech and pen-based gestures and speech and lip movements, one explicit goal has been to integrate complementary modalities in a manner that yields a synergistic blend, such that each mode can be capitalized upon and used to overcome weaknesses in the other mode (Cohen et al. 1989). This approach to system design has promoted the philosophy of using modes and component technologies to their natural advantage, and of combining them in a manner that permits mutual disambiguation. One advantage of achieving such a blend is that the resulting multimodal architecture can function more robustly than an individual recognition-based technology or a multimodal system based on input modes lacking natural complementarities.

18.5.5 What Are the Primary Features of Multimodal Language?

Communication channels can be tremendously influential in shaping the language transmitted within them. From past research, there now is cumulative evidence that many linguistic features of multimodal language are qualitatively very different from that of spoken or formal textual language. In fact, it can differ in features as basic as brevity, semantic content, syntactic complexity, word order, disfluency rate, degree of ambiguity, referring expressions, specification of determiners, anaphora, deixis, and linguistic indirectness. In many respects, multimodal language is simpler linguistically than spoken language. In particular, comparisons have revealed that the same user completing the same map-based task communicates significantly fewer words, briefer sentences, and fewer complex spatial descriptions and also disfluencies when interacting multimodally, compared with using speech alone (Oviatt 1997). One implication of these findings is that multimodal interface design has the potential to support more robust future systems than a unimodal design approach. The following is an example of a typical user's spoken input while attempting to designate an open space using a map system: *"Add an open space on the north lake to b—include the north lake part of the road and north."* In contrast, the same user accomplished the same task multimodally by encircling a specific area and saying: *"Open space."*

In previous research, hard-to-process disfluent language has been observed to decrease by 50% during multimodal interaction with a map, compared with a more restricted speech-only interaction (Oviatt 1997). This drop occurs mainly because people have difficulty speaking spatial information, which precipitates disfluencies. In a flexible multimodal interface, they instead use pen input to convey spatial information, thereby avoiding the need to speak it. Further research is needed to establish whether other forms of flexible multimodal communication also generally ease users' cognitive load, which may be reflected in a reduced rate of disfluencies.

During multimodal pen/voice communication, the linguistic indirection that is typical of spoken language frequently is replaced with more direct commands (Oviatt and Kuhn 1998). In the following example, a study participant made a disfluent indirect request using speech input while requesting a map-based distance calculation: "What is the distance between the Victorian Museum and the, uh, the house on the east side of Woodpecker Lane?" When requesting distance information multimodally, the same user encircled the house and museum while speaking the following brief direct command: "Show distance between here and here." In this research, the briefer and more direct multimodal pen/voice language also contained substantially fewer referring expressions, with a selective reduction in coreferring expressions that instead were transformed into deictic expressions. This latter reduction in coreference would simplify natural language processing by easing the need for anaphoric tracking and resolution in a multimodal interface. Also consistent with fewer referring expressions, explicit specification of definite and indefinite reference is less common in multimodal language (Oviatt and Kuhn 1998). Current natural language-processing algorithms typically rely heavily on the specification of determiners in definite and indefinite references in order to represent and resolve noun phrase reference. One unfortunate by-product of the lack of such specifications is that current language-processing algorithms are unprepared for the frequent occurrence of elision and deixis in multimodal HCI.

In other respects, multimodal language clearly is different than spoken language, although not necessarily simpler. For example, users' multimodal pen/voice language departs from the canonical English word order of S-V-O-LOC (i.e., subject-verb-object-locative constituent), which is observed in spoken language and also formal textual language. Instead, users' multimodal constituents shift to an LOC-S-V-O word order. A recent study reported that 95% of locative constituents were in sentence-initial position during multimodal interaction. However, for the same users completing the same tasks while speaking, 96% of locatives were in sentence-final position (Oviatt et al. 1997). It is likely that broader analysis of multimodal communication patterns, which could involve gaze and manual gesturing to indicate location rather than pen-based pointing, would reveal a similar reversal in word order.

One implication of these many differences is that new multimodal corpora, statistical language models, and natural language-processing algorithms will need to be established before multimodal language can be processed optimally. Future research and corpus collection efforts also will be needed on different types of multimodal communication, and in other application domains, so that the generality of previously identified multimodal language differences can be explored.

18.6 WHAT ARE THE BASIC WAYS IN WHICH MULTIMODAL INTERFACES DIFFER FROM GRAPHICAL USER INTERFACES?

Multimodal research groups currently are rethinking and redesigning basic user interface architectures because a whole new range of architectural requirements has been posed. First, GUIs typically assume that there is a single event stream that controls the underlying event loop, with any processing sequential in nature. For example, most GUIs ignore typed input when a mouse button is depressed. In contrast, multimodal interfaces typically can process continuous and simultaneous input from parallel incoming streams. Second, GUIs assume that the basic interface actions, such as selection of an item, are atomic and unambiguous events. In contrast, multimodal systems process input modes using recognition-based technologies, which are designed to handle uncertainty and entail probabilistic methods of processing. Third, GUIs often are built to be separable from the application software that they control, although the interface components usually reside centrally on one machine. In contrast, recognition-based user interfaces typically have larger computational and memory requirements, which often makes it desirable to distribute the interface over a network so that separate machines can handle different recognizers or databases. For example, cell phones and networked PDAs may extract features from speech input, but transmit them to a recognizer that resides on a server. Finally, multimodal interfaces that process two or more recognition-based input streams require time-stamping of input, and the development of temporal constraints on mode fusion operations. In this regard, they involve uniquely time-sensitive architectures. As discussed in Section 18.5.2, recent research has been working toward the development of adaptive rather than fixed temporal thresholds, which can be tailored to specific modalities or a given user (Oviatt, Lunsford et al. 2005; Huang and Oviatt 2006). Adaptive temporal thresholds have not yet been implemented, but they could substantially improve multimodal processing speed, system usability, and portability of general processing modules across different types of multimodal systems.

18.7 WHAT BASIC ARCHITECTURES AND PROCESSING TECHNIQUES HAVE BEEN USED TO DEVELOP MULTIMODAL SYSTEMS?

Many early multimodal interfaces that handled combined speech and gesture, such as Bolt's "Put That There" system (Bolt 1980), have been based on a control structure in which multimodal integration occurs during the process of parsing spoken language. As discussed in Section 18.5.2, when the user speaks a deictic expression such as "here" or "this," the system searches for a synchronized gestural act that designates the spoken referent. Although such an approach is viable for processing a point-and-speak multimodal integration pattern, multimodal systems must be able to process richer input than just pointing, including gestures, symbols, graphic marks, lip movements, meaningful facial expressions, and so forth. To support more broadly functional multimodal systems, general processing architectures have been developed since Bolt's time. Some of these recent architectures handle a variety of multimodal integration patterns, as well as the interpretation of both unimodal and combined multimodal input. This kind of architecture can support the development of multimodal systems in which modalities are processed individually as input alternatives to one another, or those in which two or more modes are processed as combined multimodal input.

For multimodal systems designed to handle joint processing of input signals, there are two main subtypes of multimodal architecture. First, there are ones that integrate signals at the *feature level* (i.e., "early fusion") and others that integrate information at a *semantic level* (i.e., "late fusion"). Examples of systems based on an early feature-fusion processing approach include those developed by Bregler et al. (1993), Vo et al. (1995), and Pavlovic, Berry, and Huang (1997, 1998). In a feature-fusion architecture, the signal-level recognition process in one mode influences the course of recognition in the other. Feature fusion is considered more appropriate for closely temporally synchronized input modalities, such as speech and lip movements (Stork and Hennecke 1995; Rubin et al. 1998).

In contrast, multimodal systems using the late semantic fusion approach have been applied to processing multimodal speech and pen input or manual gesturing, for which the input modes are less closely coupled temporally. These input modes provide different but complementary information that typically is integrated at the utterance level. Late semantic integration systems use individual recognizers that can be trained using unimodal data, which are easier to collect and already are publicly available for speech and handwriting. In this respect, systems based on semantic fusion can be scaled up easier in number of input modes or vocabulary size. Examples of systems based on semantic fusion include Put That There (Bolt 1980), Shoptalk (Cohen et al. 1989), QuickSet (Cohen et al. 1997), CUBRICON (Neal and Shapiro 1991), Virtual World (Codella et al. 1992), Finger-Pointer (Fukumoto, Suenaga, and Mase 1994), VisualMan (Wang 1995), Human-Centric Word Processor, Portable Voice Assistant (Bers et al. 1998), the VR Aircraft Maintenance Training System (Duncan et al. 1999), Jeanie (Vo and Wood 1996), and MATCH (Bangalore and Johnston 2009).

As an example of multimodal information processing flow in a late-stage semantic architecture, Figure 18.7 illustrates two input modes (e.g., speech and manual or pen-based gestures) recognized in parallel and processed by an understanding component. The results involve partial meaning representations that are fused by the multimodal integration component, which also is influenced by the system's dialog management and interpretation of current context. During the integration process, alternative lexical candidates for the final multimodal interpretation are ranked according to their probability estimates on an n-best list. The best-ranked multimodal interpretation then is sent to the application invocation and control component, which transforms this information into a series of commands to one or more back-end application systems. System feedback typically includes multimedia output, which may incorporate text-to-speech and nonspeech audio, graphics and animation, and so forth. For examples of feature-based multimodal processing flow and architectures, especially as applied to multimodal speech and lip movement systems, see Benoit et al. (2000).

There are many ways to realize this information processing flow as an architecture. One common infrastructure that has been adopted by the multimodal research community involves *multiagent architectures*, such as the open agent

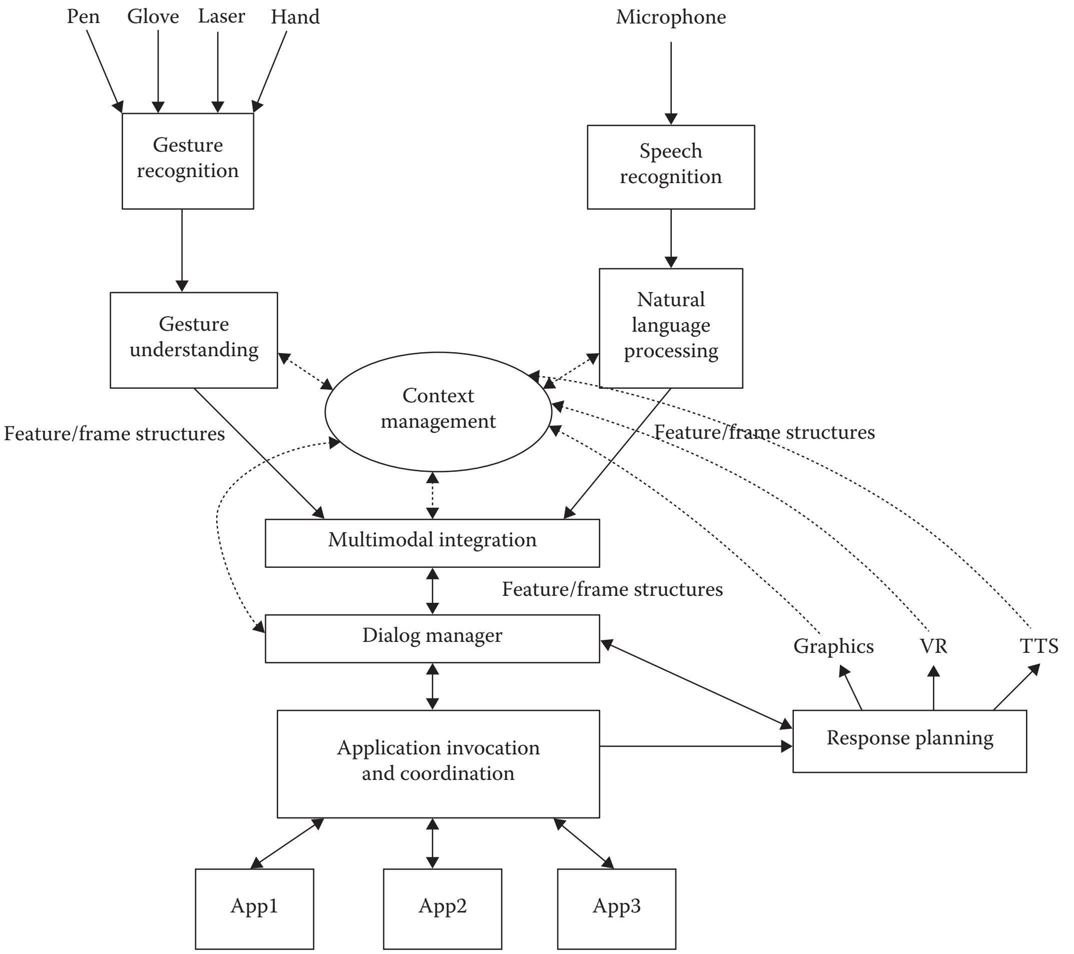

FIGURE 18.7 Typical information processing flow in a multimodal architecture designed for speech and gesture.

architecture (Cohen et al. 1994; Martin, Cheyer, and Moran 1999) and adaptive agent architecture (Kumar and Cohen 2000). In a multiagent architecture, the many components needed to support the multimodal system (e.g., speech recognition, gesture recognition, natural language processing, multimodal integration) may be written in different programming languages, on different machines, and with different operating systems. Agent communication languages are being developed that can handle asynchronous delivery, triggered responses, multicasting and other concepts from distributed systems, and that are fault-tolerant (Kumar and Cohen 2000). Using a multiagent architecture, for example, speech and gestures can arrive in parallel or asynchronously through individual modality agents, with the results recognized and passed to a facilitator. These results, typically an n-best list of conjectured lexical items and related time stamp information, then are routed to appropriate agents for further language processing. Next, sets of meaning fragments derived from the speech and pen signals arrive at the multimodal integrator. This agent decides whether and how long to wait for recognition results from other modalities, based on the system's temporal thresholds. It fuses the meaning fragments into a semantically- and temporally-compatible whole interpretation before passing the results back to the facilitator. At this point, the system's final multimodal interpretation is confirmed by the interface, delivered as multimedia feedback to the user, and executed by any relevant applications. In summary, multiagent architectures provide essential infrastructure for coordinating the many complex modules needed to implement multimodal system processing, and they permit doing so in a distributed manner that is compatible with the trend toward mobile computing.

When statistical processing techniques are combined with a symbolic unification-based approach that merges feature structures, then the multimodal architecture that results is a *hybrid symbolic/statistical* one. Hybrid architectures represent one major new direction for multimodal system development. Multimodal architectures also can be hybrids in the sense of combining Hidden Markov Models and Neural Networks. New hybrid architectures potentially are capable of achieving very robust functioning, compared with either an early- or late-fusion approach alone. For example, the Members-Teams-Committee hierarchical recognition technique, which is a hybrid symbolic/statistical multimodal integration framework trained over a labeled multimodal corpus, recently achieved 95.26% correct recognition performance, or within 1.4% of the theoretical system upper bound (Wu, Oviatt, and Cohen 1999). Other architectural approaches and contributions to processing multimodal information have been summarized elsewhere (Oliver and Horvitz 2005; Potamianos et al. 2003). Finally, in recent years, machine learning techniques have been applied to several aspects of multimodal systems, including individual modality recognition, early or late modality fusion, dialog management, and recognition and adaptation to users' multimodal communication integration patterns. This research has been spearheaded largely by European Union projects, and reported in a series of workshops on machine learning for multimodal interaction (Bengio 2004; Popescu-Belis, Renals, and Bourlard 2008).

18.8 WHAT BASIC LANGUAGE-PROCESSING TECHNIQUES AND STANDARDS HAVE BEEN USED TO DEVELOP MULTIMODAL SYSTEMS?

The core of multimodal systems based on semantic fusion involves algorithms that integrate common meaning representations derived from speech, gesture, and other modalities into a combined final interpretation. The semantic fusion operation requires a common meaning representation framework for all modalities, and a well-defined operation for combining partial meanings that arrive from different signals. To fuse information from different modalities, various research groups have independently converged on a strategy of recursively matching and merging attribute/value data structures, although using a variety of different algorithms (Vo and Wood 1996; Cheyer and Julia 1995; Pavlovic and Huang 1998; Shaikh et al. 1997). This approach is considered a *frame-based integration* technique. An alternative logic-based approach derived from computational linguistics (Carpenter 1990, 1992; Calder 1987) involves the use of *typed feature structures* and *unification-based integration*, which is a more general and well-understood approach. Unification-based integration techniques also have been applied to multimodal system design (Cohen et al. 1997; Johnston et al. 1997; Wu, Oviatt, and Cohen 1999). Feature-structure unification is considered well suited to multimodal integration because unification can combine complementary or redundant input from both modes, but it rules out contradictory input.

The unification-based approaches to multimodal language processing recently have been extended using finite-state transducers with lattice output (Bangalore and Johnston 2009). Multimodal language processing using these methods involve a one-stage interleaved grammar-processing approach, rather than separating speech parsing and multimodal integration. They also enable gesture aggregation, visual parsing, and more flexible and declarative encoding of temporal and spatial constraints (Bangalore and Johnston 2009). This approach, used in the MATCH system (see Figure 18.1), is efficient and enables tight coupling of more complex speech and gesture processing. Basically, the grammar is directly compiled into a cascade of finite-state transducers, which can compose with lattices from speech recognition and gesture recognition components (Bangalore and Johnston 2009). However, more research still is needed on the development of canonical meaning representations that are common among different input modes, which will need to be represented in new types of multimodal systems.

Because developing new multimodal interfaces remains a complex and specialized task, attention has turned to the establishment of W3C EMMA standards to provide a representation language for input to multimodal systems. This focus aims to facilitate plug-and-play components and rapid prototyping of new multimodal interfaces (Johnston 2009; Johnston et al. 2009). The new W3C EMMA standard addresses this problem by providing a standardized XML representation language for encapsulating and annotating input to multimodal systems. EMMA provides mechanisms for capturing and annotating the various stages of input processing. There are two key aspects to the language: a series of elements (e.g., emma:group, emma:one-of, emma:interpretation) that are used as containers for interpretations of the user input, and a series of annotation attributes and elements that are used to provide pieces of metadata associated with those inputs, such as time stamps (emma:start, emma:end) and confidence score values (emma:confidence). These standards currently are being used to develop new mobile applications, such as iMOD movies on demand for the iPhone and iMATCH for map-based searches of local restaurants (Johnston 2009). Both of these mobile systems involve processing of speech input with touch selection or pen gestures.

18.9 WHAT ARE THE TRENDS IN COMMERCIALIZING MULTIMODAL SYSTEMS?

Multimodal interfaces are a major and innovative departure from existing keyboard-and-mouse graphical interfaces. They represent a long-term interface redesign agenda and are challenging to build for many reasons outlined in this chapter. Section 18.3 provides a detailed summary of what is at stake in pushing forward to develop the next level of multimodal interfaces, and the advantages are overwhelmingly compelling. For this reason, multimodal interfaces have emerged during the last decade as a major worldwide trend for funding agencies, journal special issues, and also commercialization of new products.

The primary impetus for developing commercial multimodal interfaces to date has been accommodation of the practical aspects of usability while people are mobile and in field contexts, where a conventional keyboard interface is a poor or untenable option. To date, most of these commercialized multimodal interfaces have multimodal input-processing capabilities that are limited to (1) one natural and expressive mode (e.g., speech) plus simple pointing or selection in a second mode (e.g., touch or pen, as on Microsoft's MiPad), and (2) one keyboard-based input mode, and a second more natural and expressive mode (e.g., touch-based gestures, as on Apple's iPhone and iPad). Processing in these cases either takes place on alternative input modes individually, or the pointing or selection act simply constrains information processing involving the richer input mode, but requires no real fusion of the two information sources as discussed in Sections 18.6 and 18.7.

In other cases, current commercially available multimodal interfaces provide multimodal output, while input remains unimodal (e.g., animated characters with lifelike synchronized visual movements and text-to-speech output, now used in television commercials, kiosks, on the web, and elsewhere). In other cases, the multimodal input involves synchronized digital ink with recorded speech, but no coprocessing of the language content from these modes (e.g., Livescribe's digital pen). In Livescribe's case, processing is focused on recognition of written content in users' notes so it can be retrieved from past notes (Liverscribe, 2011). Temporally-associated verbatim audio recordings captured at the same time also can be played back.

Together, these illustrations highlight that commercially available multimodal interfaces primarily have been developed for mobile use, including cell phones, small PDA handhelds, and new digital pens. Second, they have avoided coprocessing and interpreting the linguistic meaning of two or more natural input streams. In this regard, they lag substantially behind far more powerful research-level prototypes, and have yet to reach their most valuable commercial potential. Third, in some cases, these systems simply have emphasized capture and reuse of synchronized human communication signals (e.g., verbatim speech, pen ink), rather than interpretation and processing of linguistic meaning at all. Finally, these system illustrations highlight the diverse meanings of what has been called "multimodal," which in recent years has become well recognized as a marketing strategy and advantage.

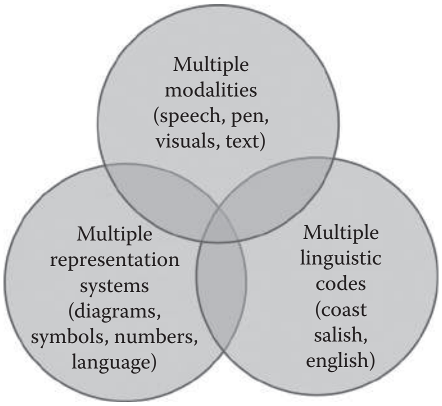
18.10 WHAT ARE THE MAIN FUTURE DIRECTIONS FOR MULTIMODAL INTERFACE DESIGN?

The computer science community is just beginning to understand how to design well-integrated and robust multimodal systems. To date, most multimodal systems remain bimodal, and recognition technologies related to several human senses (e.g., haptics, smell, taste) have yet to be well represented within multimodal interfaces. The successful design and development of new types of systems that include such modes will not be achievable through intuition. Rather, it will continue to require guidance from cognitive science on the coordinated human perception and production of natural modalities. In this respect, multimodal systems only can flourish through multidisciplinary cooperation, as well as teamwork among those representing expertise in the component technologies. In the future, further theoretical work also will be needed to account more coherently for diverse types of multimodal interaction patterns. New or refined theoretical frameworks could be invaluable for proactively guiding the design of new multimodal interfaces that are compatible with human capabilities and limitations. Current work in cognitive neuroscience and multisensory perception are beginning to provide an empirical and theoretical basis for this future interface design (Calvert, Spence, and Stein 2004; Ernst and Bulthoff 2004).

Most of the systems outlined in this chapter have been built during the past 15 years, and they are research-level systems. However, in some cases, they have developed well beyond the prototype stage, and are being integrated with other software at academic and federal sites, or appearing as newly shipped products. To achieve wider commercialization of multimodal interfaces, such systems will need to develop more powerful and general methods of natural language and dialog processing, and also temporal modeling and processing of incoming signals. In addition, multimodal data sets and tools are very much needed to build applications more rapidly in a wide range of domains, including for newly emerging collaborative multimodal applications such as meeting support and education (Barthelmess et al. 2005; Cohen and McGee 2004; Danninger et al. 2005; Gatica-Perez et al. 2005; McGee 2003; Pentland 2005). The many mobile multimodal interfaces currently being built also will require active adaptation to the user, task, ongoing dialog, and environmental context, which is another area of recent work (Gorniak and Roy 2005; Gupta 2004; Huang and Oviatt 2006; Jain and Ross 2002; Lunsford, Oviatt & Arthur, 2006; Lunsford, Oviatt & Coulston, 2005; Potamianos et al. 2003; Xiao et al. 2003). To facilitate the speed and generality of multimodal interface adaptation to these important variables, future work will need to integrate new machine learning techniques that are now being developed to handle asynchronous and heterogeneous data (Bengio 2004; McCowan et al. 2005).

New multimodal interfaces are just now beginning to appear on platforms such as collaborative table surfaces (Brandl et al. 2008; Leitner et al. 2009; Liwicki and El-Neklawy 2009). Tabletop interfaces previously have included multitouch input and virtual keyboards, but the latest versions now include more flexible and expressively powerful multimodal touch and write capabilities incorporating Anoto-based pen input (Anoto, 2009). Given these developments, high-resolution pen input now can be used on collaborative interfaces for marking, drawing, or writing directly on displayed documents, photographs, or simulations. This substantially expands possibilities for application functionality in education and other areas hoping to benefit from collaborative table interfaces. Another very recent change is the emergence of mobile digital book interfaces. They also are beginning to incorporate pen-based annotation capabilities for active learning and information reuse, along with graphical interface capabilities and touch gestures for pagination and similar actions. Both of these interface platforms are expected to change rapidly in the near future.

Ultimately, multimodal interfaces are just one part of the larger movement to establish richer communications interfaces, ones that can expand existing computational functionality and also improve support for human cognition and performance. Figure 18.8 shows this longer-term direction of establishing communications interfaces that are more



Multiple modalities (speech, pen, visuals, text)
Multiple representation systems (diagrams, symbols, numbers, language)
Multiple linguistic codes (coast salish, english)

FIGURE 18.8 Richly expressive communications interfaces that support multiple modalities, representation systems, and linguistic codes.

capable of supporting people's ability to communicate fluently as they think and work using: (1) multiple modalities (pen, speech, touch, visual, text), (2) multiple representation systems (diagrams, symbols, numbers, language, informal marking), and (3) multiple linguistic codes (western, Asian, indigenous), which may represent one's native language or bilingual/multilingual communication patterns. One major goal of such interfaces is to reduce cognitive load and improve communicative and ideational fluency, as discussed at the end of Section 18.3. Recent results on the cognitive advantages of pen interfaces during real-world problem solving seriously challenge the adequacy of keyboard-centric graphical interfaces, and encourage us to prototype new multimodal systems that incorporate pen input for our education and professional lives (Oviatt in press). An additional goal of developing richer communications interfaces is preservation of the world's diverse heritage languages, many of which are poorly supported by western-European keyboards.

In conclusion, multimodal interfaces are just beginning to model human-like sensory perception and communication patterns. They are recognizing and identifying actions, language, and people that have been seen, heard, or in other ways experienced in the past. They literally reflect and acknowledge the existence of human users, empower them in new ways, and create for them a "voice." They also can be playful and self-reflective interfaces that suggest new forms of human identity as we interact face-to-face with animated personas representing our own kind. In all of these ways novel multimodal interfaces, as primitive as their early bimodal instantiations may be, represent a new multidisciplinary science, a new art form, and a sociopolitical statement about our collective desire to humanize the technology we create.

ACKNOWLEDGMENTS

I thank the National Science Foundation for their support, which enabled me to pursue basic exploratory research on many aspects of multimodal interaction, interface design, and system development. The preparation of this chapter has been supported by NSF Grants IRI-9530666, IIS-0117868, and NSF Special Extension for Creativity (SEC) Grant IIS-9530666, as well as by Incaa Designs nonprofit (www.incaadesigns.org). This work also has been supported by contracts DABT63-95-C-007, N66001-99-D-8503, and NBCHD030010 from DARPA's Information Technology and Information Systems Office, and Grant No. N00014-99-1-0377 from ONR. Any opinions, findings, or conclusions expressed in this chapter are those of the author and do not necessarily reflect the views of the federal agencies sponsoring this work.

I also thank Phil Cohen and others in the Center for Human–Computer Communication for many insightful discussions, and Dana Director and Rachel Coulston for expert assistance with manuscript preparation. Finally, I wish to acknowledge LEA, Inc. for giving permission to reprint Figure 18.7, and to acknowledge ACM for allowing the reprint of Figures 18.3 through 18.6.

19 Systems That Adapt to Their Users

Anthony Jameson and Krzysztof Z. Gajos

CONTENTS

19.1 INTRODUCTION

This chapter covers a broad range of interactive systems which have one idea in common: that it can be worthwhile for a system to learn something about individual users and adapt its behavior to them in some nontrivial way.

A representative example is shown in Figure 19.1: the CommunityCommands recommender plug-in for AutoCAD (introduced by Matejka et al. [2009] and discussed more extensively by Li et al. [2011]). To help users deal with the hundreds of commands that AutoCAD offers—of which most users know only a few dozen—CommunityCommands

(1) gives the user easy access to several recently used commands, which the user may want to invoke again soon; and (2) more proactively suggests commands that this user has not yet used but may find useful, given the type of work they have been doing recently.

19.1.1 Concepts

A key idea embodied in CommunityCommands and the other systems discussed in this chapter is that of *adaptation to the individual user*. Depending on their function and form, particular types of systems that adapt to their users have been given labels including *adaptive user interfaces*, *software agents*, *recommender systems*, and *personalization*. To be able to discuss the common issues that all of these systems raise, we will refer to them with a term that describes their common property explicitly: *user-adaptive systems*. Figure 19.2 introduces some concepts that can be applied to any user-adaptive system; Figure 19.3 shows the form that they take in recommendations generated by CommunityCommands.

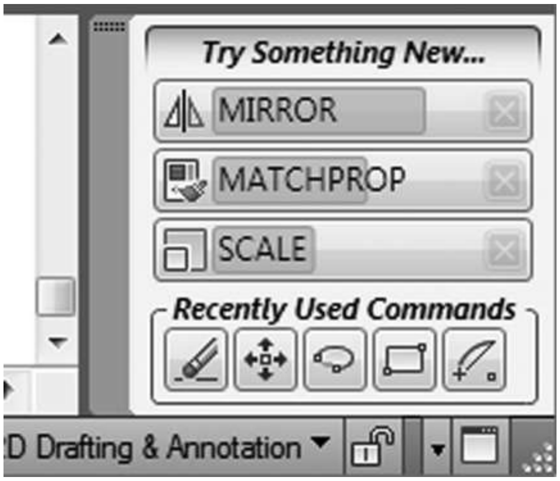

FIGURE 19.1 Screenshot showing how CommunityCommands recommends commands to a user. (Image supplied by Justin Matejka. The length of the darker bar for a command reflects its estimated relevance to the user's activities. When the user hovers over a command in this interface, a tooltip appears that explains the command and might show usage hints provided by colleagues. See also http://www.autodesk.com/research.)

A user-adaptive system makes use of some type of information about the current individual user, such as the commands that the user has executed. In the process of *user model acquisition*, the system performs some type of learning and/or inference on the basis of the information about the user to arrive at some sort of *user model*, which in general concerns only limited aspects of the user (such as their pattern of command use). In the process of *user model application*, the system applies the user model to the relevant features of the current situation to determine how to adapt its behavior to the user; this process may be straightforward, or it can involve some fairly sophisticated decision making on the part of the system.

A user-adaptive system can be defined as an interactive system that adapts its behavior to individual users on the basis of processes of user model acquisition and application that involve some form of learning, inference, or decision making.

The second half of the definition is necessary because otherwise any interactive system could be said to "adapt" to its users, even if it just responds straightforwardly to key presses. It is the processes of user model acquisition and application that raise many common issues and challenges that characterize user-adaptive systems.

This definition also distinguishes user-adaptive systems from purely *adaptable* systems: ones that offer the user an opportunity to configure or otherwise influence the system's longer term behavior (e.g., by choosing options that determine the appearance of the user interface [UI]). Often, what works best is a carefully chosen combination of adaptation and adaptability. For example, if the user of CommunityCommands is not interested in the command MATCHPROP, they can click on the "close" button next to it to specify that it should not be recommended again. Keeping

the user "in the loop" in this way can be an essential part of effective and well-accepted adaptation.

19.1.2 Chapter Preview

Sections 19.2 and 19.3 address the question "What can user-adaptivity be good for?" They examine in turn a number of different functions that can be served by user adaptivity, giving examples ranging from familiar commercially deployed systems to research prototypes. Section 19.4 discusses some usability challenges that are especially important in connection with user-adaptive systems, challenges which stimulated much of the controversy that surrounded these systems when they first began to appear in the 1980s and 1990s. Section 19.5 considers a key design decision: what types of information about each user should be collected? The chapter concludes with a reflection on the current state of the art and the future challenges for user-adaptive systems.*

19.2 FUNCTIONS: SUPPORTING SYSTEM USE

Some of the ways in which user adaptivity can be helpful involve support for a user's efforts to operate a system successfully and effectively. This section considers four types of support.

19.2.1 Adaptively Offering Help

The first form is the one illustrated by the CommunityCommands recommender: in cases where it is not sufficiently obvious to users how they should operate a given application, a help system can adaptively offer information and advice about how to use it—and perhaps also execute some actions on behalf of the user. That is, the system can act like a helpful friend who is looking over the user's shoulder—a service which users often greatly appreciate but which is not in general easy to automate effectively. The adaptation can make the help that is offered more relevant to the user's needs than the more commonly encountered user-independent help.

The main way in which CommunityCommands helps the user is by recommending possibly useful commands that the user has not yet used. The basic recommendation technique is *collaborative filtering*, which is discussed later in this chapter in connection with systems that recommend products. The central idea is: "People who use commands like the ones that you have been using also use the following commands, which you may not be familiar with: . . . ."

Matejka et al. (2009) explain how the basic collaborative filtering algorithm had to be adapted and supplemented to yield good performance for command recommendation. For example, if a user already knows the command *A*, it makes little sense to recommend a command *B*, which is just a similar or less efficient way of achieving the same effect; so handcrafted rules were added to prevent such recommendations.

Experience with the deployment of CommunityCommands as an AutoCAD plug-in has indicated that this approach appears to have general feasibility and usefulness for systems that offer a large number of commands. This case study can also be seen as a successful application of the strategy of looking for a relatively lightweight approach to adaptation that still offers considerable added value. Attention to the details of the adaptive algorithms and of the UI design appears to be more important here than the use of more complex adaptation technology.

Systems that offer help in an adaptive way have a long history. Perhaps the most obvious—but also the most difficult—scenario is one in which a user is trying to achieve a particular goal (e.g., align the objects in a drawing in a particular way) but does not know how to achieve the goal with the system. A helper could in principle automatically recognize the user's difficulty and suggest a way of solving the problem. A good deal of research into the development of systems that can take the role of a knowledgeable helper was conducted in the

* Interested readers may also want to consult the chapters on this topic in the first two editions of this handbook (Jameson 2003, 2008), which include discussions of earlier user-adaptive systems that can still serve as instructive examples, as well as discussions of typical issues and methods associated with empirical studies of user-adaptive systems.

1980s, especially in connection with the complex operating system Unix.* During the 1990s, such work became less frequent, perhaps partly because of a recognition of the fundamental difficulties involved: it is in general hard to recognize what goal a user is pursuing when the user is not performing actions that serve their goal. And spontaneously offering help can be distracting, since the system cannot be sure that the user is interested in getting help. The Office Assistant, an ambitious attempt at adaptive help introduced in Microsoft Office 97, was given a mixed reception, partly because of the inherent difficulty of its task but especially because of its widely perceived obtrusiveness (cf. Section 19.4).

For these reasons, more recent research has focused on less ambitious but still potentially useful ways of adaptively offering help. A strategy in this category—one which is quite different from that of CommunityCommands—is to view the process of offering help as involving collaboration and dialog with the user. A representative of this paradigm is the DiamondHelp system, which assists users in the operation of complex consumer devices (see, e.g., Rich et al. [2005]). DiamondHelp is somewhat reminiscent of the (nonadaptive) "wizards" that walk users through procedures such as the configuration of new software; but is more flexible and adaptive in that it applies a *mixed-initiative* paradigm, allowing the user to perform sequences of actions on their own if they like and trying to keep track of what they are doing. Rich (2009) offers a recent discussion of this general paradigm.

19.2.2 Taking Over Parts of Routine Tasks

Another function of adaptation involves taking over some of the work that the user would normally have to perform herself—routine tasks that may place heavy demands on a user's time, though typically not on their intelligence or knowledge. Two traditionally popular candidates for automation of this sort (discussed briefly below) have been the sorting of e-mail and the scheduling of appointments and meetings.

The system TaskTracer (Figure 19.4) illustrates a number of typical functionalities of systems in this category.† The tedious work that is taken over by TaskTracer is not a single, separate chore but rather parts of many of the routine subtasks that are involved in everyday work with a normal desktop (or laptop) computer. The central insight is that a user is typically multitasking among a set of *projects*, each of which is associated with a diverse set of *resources*, such as files, web pages, and e-mail messages. Since these resources tend to be stored in different places and used by different applications, a significant proportion of everyday computer work involves locating and accessing the resources that are relevant to the project that is currently in the focus of attention.

The user of TaskTracer creates a structured list of projects that they sometimes work on; once they have done so, the system does two things largely autonomously: (1) By observing the user, it learns which resources are associated with which projects; (2) It tries to figure out which project the user is working on at any given moment (see, e.g., Shen et al. [2009]). As can be seen in Figure 19.5, these two functions constitute the adaptive aspects of the system.

Even if these inferences by the system are not entirely accurate, they can help the user in various ways: for example, when the user wants to save a document that they have created, TaskTracer can save them some mouse clicks by suggesting two or three folders associated with the current project in which they might like to store the new file. And

* A collection of papers from this period appeared in a volume edited by Hegner et al. (2001).

† See Dietterich et al. (2010), for a recent comprehensive discussion of TaskTracer and http://eecs.oregonstate.edu/TaskTracer/ for further information and references.

FIGURE 19.5 Overview of adaptation in TaskTracer.

when a user switches to a project, TaskTracer can offer a list of the resources associated with the current project, sorted by recency of access, so that the user can quickly locate them again (see, e.g., Figure 19.4).

A more difficult form of support that still represents a challenge involves supporting the user in executing *workflows* (see, e.g., Shen, Fitzhenry, and Dietterich [2009]). That is, instead of just recognizing that the user is working on the project "quarterly report," the system (1) learns by observation what steps are involved in the preparation of a quarterly report; (2) keeps track of how much of the quarterly report workflow the user has executed so far; and (3) supports the user in remembering and executing subsequent steps. The tendency of users to multitask makes this type of support potentially valuable, but it also makes it challenging for systems to do the necessary learning and activity tracking.

Two traditionally popular candidates for automation of this general type have been sorting or filtering e-mail and scheduling appointments and meetings. Classic early research on these tasks included the work of Pattie Maes's group on "agents that reduce work and information overload" (see, e.g., Maes [1994]). The scheduling of meetings and appointments has been addressed over the years by (among many others) Mitchell et al. (1994); Horvitz (1999); and Gervasio et al. (2005): by learning the user's general preferences for particular meeting types, locations, and times of day, a system can tentatively perform part of the task of entering appointments in the user's calendar.

Systems of this sort can actually take over two types of work from the user: (1) choosing what particular action is to be performed (e.g., which folder a file should be saved in); and (2) performing the mechanical steps necessary to execute that action (e.g., clicking in the file selector box until the relevant folder has been reached). Adaptation to the user is required only for the first type of work; but the second type of work cannot be performed without the first type.

In the ideal case, the system could make the correct choice with such confidence that it would not even be necessary to consult the user, and the entire task would be automated, with the user perhaps not even being aware that it was being performed. In many cases, though, the user does have to be involved in the choice process, because the system can only help to make the choice, not make it autonomously. In these cases, the amount of mental and physical work saved is much lower. Hence, there is a trade-off between the amount of control that the user has over the choices being made and the amount of effort they save. Users can differ as to where they want to be on this trade-off curve at any given time, depending on factors like the importance of making a correct choice and the amount of other work that is competing for their attention. The typical pattern is for users to begin by exercising careful control over the performance of the task and then to relinquish control gradually to the system, as the system's competence increases (because of learning) and/or the user becomes better able to predict what the system will be able to do successfully. Patterns of this sort will be discussed in the Section 19.4.

19.2.3 Adapting the Interface to Individual Tasks and Usage

A different way of helping a person to use a system more effectively is to adapt the presentation and organization of the interface so that it fits better with the user's tasks and usage patterns. The potential benefit of this type of adaptation is that it can improve the user's motor performance by bringing functionality that is likely to be used closer or making interface elements larger; improve perceptual performance by making relevant items easier to find; or improve cognitive performance by reducing complexity.

An example of this type of adaptive interface that will be familiar to most readers is the font selection menus available in popular productivity software. Figure 19.6a illustrates the basic mechanism: the most recently selected items are copied to the top part of the menu. This top part, clearly visually separated from the rest of the menu, holds the adaptive content. If a desired font is present in the top section, the user can select it either from that section or from its usual location in the lower part of the menu.

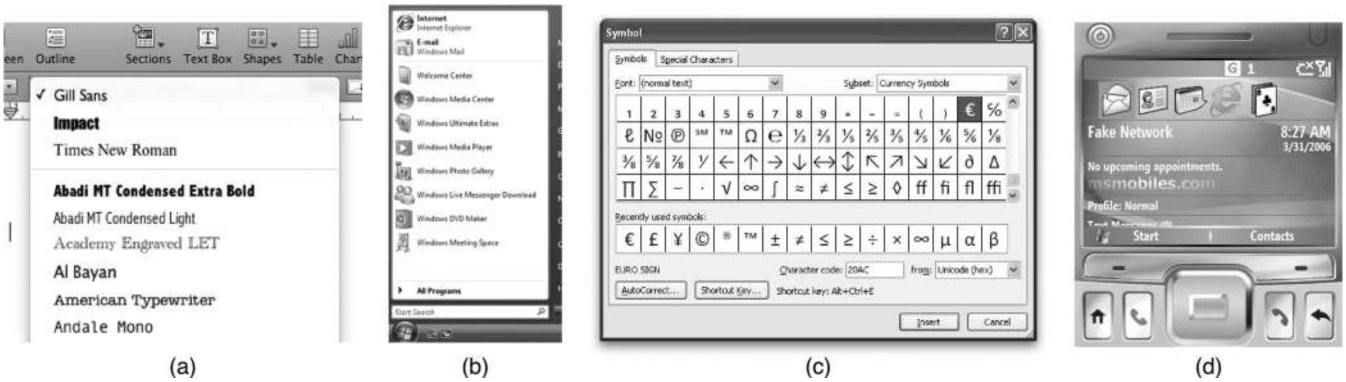

FIGURE 19.6 Examples of modern implementations of adaptive split interfaces. (a) The most recently used fonts are copied to the clearly designated adaptive top part of the menu in Apple Pages. A user wishing to select the Times New Roman font has the option of either taking advantage of the adaptation or following the familiar route to the usual location of that font in the main part of the menu. (b) Recently or frequently used programs are copied to the main part of the Windows 7 Start menu while also remaining accessible through the "All Programs" button. (c) Recently used special symbols are copied to a separate part of the dialog box in the symbol chooser in MS Office 2007. (d) Recently used applications are easily accessible on a Windows Mobile phone.

FIGURE 19.7 Overview of adaptation in split interfaces.

The concept generalizes beyond menus; it can be used to adapt many different types of UI component, as is illustrated in Figure 19.6. We use the term *split interfaces* to refer to the successful general design pattern in which adaptation is used to copy functionality predicted to be most relevant to the user to a designated adaptive part of the UI (see Figure 19.7).

Several studies have demonstrated that split interfaces reliably improve both satisfaction and performance (Findlater and McGrenere 2008; Gajos et al. 2006). What makes split interfaces successful is that they offer an effort saving to those users who are willing to take advantage of the adaptation while not upsetting the familiar routine for those who prefer to use the basic interface consistently.

Designs that require users to alter their behavior are often resisted. A widely known example of an early adaptive interface that elicited mixed reactions from users is the Smart Menus that Microsoft introduced in Windows 2000 (Figure 19.8; see McGrenere, Baecker, and Booth [2007] for a comparison of this type of adaptation with user-controlled customization). To reduce the apparent complexity of the software, these menus were designed to show only a subset of the features—the most basic ones and those that the user used frequently or recently. The remaining features were shown if the user dwelled on a menu without selecting anything or if he or she clicked on a downward pointing arrow at the bottom of the menu. The design had the promise of simplifying the interaction most of the time for most users, but for some users, the additional mental effort required to find infrequently used functionality outweighed the potential benefits.

An early illustrative example involves automatically reordering menu items on the basis of the frequency of use (Mitchell and Shneiderman 1989). This approach resulted in poorer performance and lower user satisfaction than the nonadaptive baseline. In this case, the lack of success of the adaptive strategy can be attributed to the fact that because of the constantly changing order of menu items, users could never reach the expert level of visual search efficiency that is achievable with unchanging familiar interfaces.

A radically different approach to menu adaptation—called *ephemeral adaptation*—was introduced recently by Findlater et al. (2009). In ephemeral adaptation, the menu items that are predicted to be most likely to be selected by the user are displayed immediately when the menu is opened,

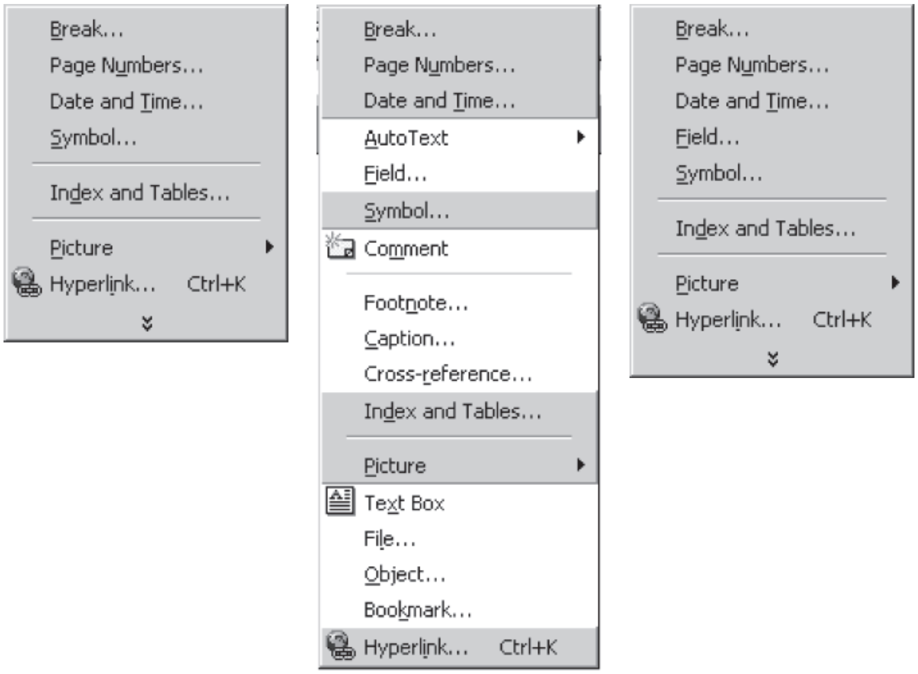

FIGURE 19.8 In Microsoft Smart Menus, rarely used items are removed from the menu thus reducing the apparent complexity of the application. (Hovering over the menu or clicking on the double arrow below the last item causes the menu to be expanded showing the elided items. If a hidden item is selected by the user, it is immediately visible on the subsequent visits to that menu.)

whereas the remaining items fade in gradually over a short period of time (e.g., 500 milliseconds). This adaptation takes advantage of the fact that an abrupt appearance of a new object involuntarily captures our attention, while its gradual onset does not. Because the user's attention is drawn to the small subset of items that are shown immediately when the menu opens, it is easy for users to locate these items quickly. This adaptive mechanism focuses entirely on users' visual search performance. It has been demonstrated to improve overall performance without increasing selection times for the items that are gradually faded in.

A user-driven alternative to the class of adaptive approaches described in this section is customization. Customization, however, requires significant upfront effort on user's part and consequently very few people choose to customize their interfaces (Mackay 1991; Palen 1999) and even fewer recustomize them as their needs change (McGrenere et al. 2007). Mixed-initiative approaches (e.g., Bunt, Conati, and McGrenere 2007) that combine the two approaches show promise for providing good balance between efficiency and user control.

The adaptive designs discussed in this section were prototyped and evaluated mostly with menus and toolbars, but the underlying concepts can be generalized to a broader range of settings. Findlater and Gajos (2009) provide a more in-depth exploration of the design space of UIs that adapt to users' tasks.

19.2.4 Adapting the Interface to Individual Abilities

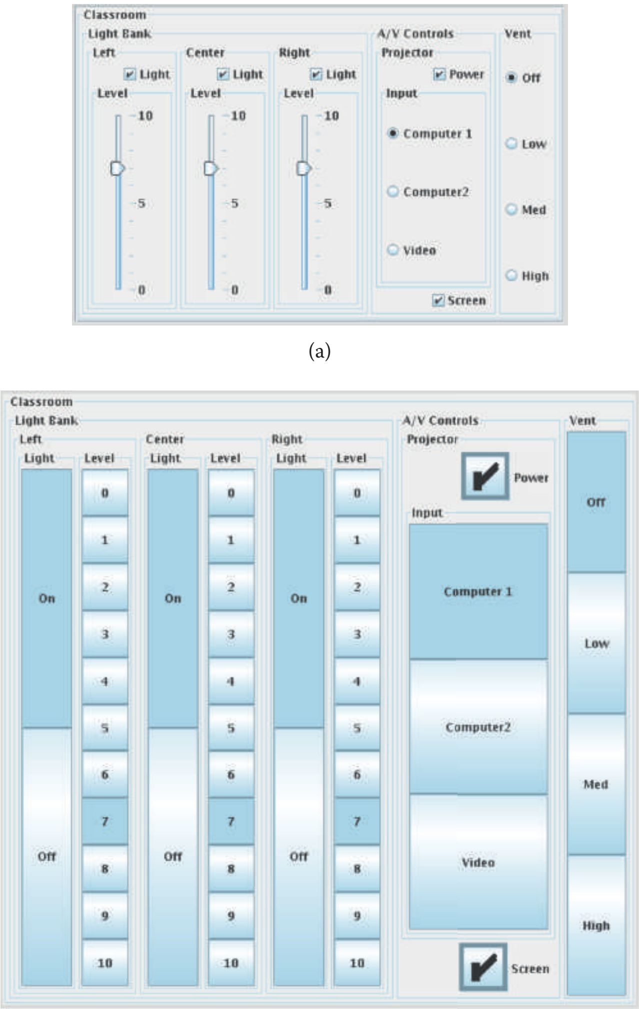
Next, we consider systems that adapt their UIs to the *abilities* of their users.

The promise of this type of adaptation is that it can provide personalized experience to people whose needs with respect to the UI are unique, variable over time, or hard to anticipate. This is precisely the situation of many users with impairments. Not only are these users different from the "average" user, they are also significantly different from each other: even people with very similar diagnoses can have very different actual abilities (Bergman and Johnson 1995; Hwang et al. 2004; Keates et al. 2002; Law, Sears, and Price 2005). Currently, these users have to adapt themselves—often using specialized assistive technologies—to the existing UIs. Adaptive systems offer the possibility to reverse this situation: Why not adapt UIs to the unique needs and abilities of people with impairments?

Impairments do not have to be permanent or a result of a medical condition. For example, environmental factors such as temperature may temporarily impair a person's dexterity; a low level of illumination will impact reading speed; and ambient noise will affect hearing ability. These factors are particularly relevant to mobile computing. Indeed, studies have shown that in relation to standing still, walking results in lower pointing speed and accuracy, as well as decreased reading speed and comprehension (Barnard et al. 2007; Lin et al. 2007). These results suggest that there is both a need and an opportunity to adapt mobile interaction to the momentary effective abilities of users.

The Supple system (Gajos, Wobbrock, and Weld 2007, 2008; Gajos, Weld, and Wobbrock 2010) provides an example of ability-based adaptation for people with motor impairments. Supple requires each user to perform a one-time set of diagnostic tasks so that the system can build a model of that person's unique motor abilities. After that, for any application that the user wants to interact with, Supple uses optimization methods to automatically generate UIs that are predicted to be the fastest to use for this person. Figure 19.9 shows an example of a dialog box automatically generated by Supple for a user with impaired dexterity due to a spinal cord injury; see also Figure 19.10. The results of an experiment involving 11 participants with a variety of motor impairments demonstrate that the automatically generated interfaces that were adapted to users' individual motor abilities resulted in significantly improved speed, accuracy, and satisfaction (see Gajos, Wobbrock, and Weld [2008]). On the average, these interfaces helped close over 60% of the performance gap between able-bodied users and users with motor impairments.

The Walking UI prototype (Kane, Wobbrock, and Smith 2008) shown in Figure 19.11 provides an example of what an adaptation to the changing abilities of mobile users might look like. The UI has two versions, one for when the user is stationary and one for when they are in motion. The two versions follow a very similar design to ensure that the users do not have to learn two separate UIs. The walking variant has larger interactors to compensate for users' impaired dexterity, larger fonts for song titles to accommodate reduced reading ability, and a more visually salient presentation for song titles than for secondary information to mitigate the effects of fragmented attention.



(a)

(b)

FIGURE 19.9 Example of the ability-based adaptation in Supple. (a) The default interface for controlling lighting and A/V equipment in a classroom. (b) A user interface for the same application automatically generated by Supple for a user with impaired dexterity based on a model of her actual motor abilities.

These types of systems have been evaluated in laboratory studies, but since they have not yet been widely deployed, we cannot yet provide empirical evidence showing what the main challenges to adoption of these systems are. But several such challenges can be anticipated: Obtaining useful models of users' abilities while placing minimum burden on the users is clearly one such challenge. The studies evaluating the Supple system demonstrated that models created from direct measurements of users' abilities resulted in significantly more successful interfaces than those that were based on users' expressed preferences, but those direct measurements of abilities required users to go through a one-time but hour-long set of diagnostic tasks. Another factor that seems likely to have an impact on adoption of interfaces like that of Figure 19.11 is the method for controlling the switch between different UI variants. A fully manual approach is likely to be found too inefficient, whereas one that is fully automated may cause confusion.

Wobbrock et al. (2011) present several other examples of ability-based interfaces, discuss the rationale for ability-based design, and propose a set of guiding principles.

19.3 FUNCTIONS: SUPPORTING INFORMATION ACQUISITION

Even back in the days when computers were chained to desktops, people were complaining about information overload and clamoring for tools that would help them to focus their attention on the documents, products, and people that really mattered to them. Since then, the flood has grown to a tsunami. Two of the most conspicuous developments have been (1) mobile devices that enable people to produce and consume information wherever they are; and (often in combination with these) (2) social networks, which are increasingly replacing face-to-face communication.

This information overload constitutes a powerful motivation for the development of systems that adapt to their users: computers have the technical capability to reduce the information tsunami to a trickle that people can manage; but since people are generally not interested in the same trickle, computers can do so effectively only by taking into account properties of the user such as their interests, current tasks, and context.

19.3.1 Helping Users to Find Information

We will first look at the broad class of systems that help the user to find relevant electronic documents, which may range from brief news stories to complex multimedia objects.

One type of document that has become more pervasive over the past several years comprises news reports of the type traditionally found in printed newspapers. With so many

news sources now available online, the amount of choice available to a person who wants to read a few interesting news reports has increased drastically, even when we take into consideration the fact that one report may turn up in a number of variations in different news sources.

One news website that addresses this problem is GOOGLE NEWS. One of the solutions offered by the site is a section of "recommended" stories that are selected on the basis of the users' previous clicks on other news stories within the same site (see Figures 19.12 and 19.13). The first personalization algorithms used for this purpose by GOOGLE were based on collaborative filtering, which is found in several other systems discussed in this chapter. But as is described by Liu, Dolan, and Pedersen (2010), it proved necessary to include some *content-based* filtering as well, recommending stories related to general themes that the current user had previously shown an interest in. In particular, it is otherwise hard to recommend hot-off-the-press news stories that have not yet attracted many clicks from other users. Roughly speaking, in this application, the content-based filtering helps by revealing what topics the current user is generally interested in, whereas the collaborative filtering helps to keep track of temporary trends (e.g., a surge of interest in the newly released iPad) that apply to larger groups of users and that are likely to be followed to some extent by any given individual user as well.

More generally speaking, user-adaptive systems that help users find information* typically draw from the vast repertoire of techniques for analyzing textual information (and to a lesser but increasing extent, information presented in other media) that have been developed in the field of information retrieval. The forms of adaptive support are in part different in three different situations, the first two of which can arise with Google News.

19.3.1.1 Support for Browsing

In the world wide web and other hypermedia systems, users often actively search for desired information by examining information items and pursuing cross-references among them. A user-adaptive hypermedia system can help focus the user's browsing activity by recommending or selecting promising items or directions of search on the basis of what the system has been able to infer about the user's information needs. An especially attractive application scenario is that of mobile information access, where browsing through irrelevant pages can be especially time consuming and expensive. In this context, the best approach may be for the system to omit entirely links that it expects to be less interesting to the individual user. Billsus and Pazzani (2007) describe a case study of an adaptive news server that operated in this way. Stationary systems with greater communication bandwidth tend to include all of the same links that would be presented by a nonadaptive system, highlighting the ones that they consider most likely to be of interest or presenting separate lists of recommended links. As is argued and illustrated by Tsandilas and schraefel (2004), this approach makes it easier for the user to remedy incorrect assessments of the user's interests on the part of the system.

* Surveys of parts of this large area are provided by, among others, Kelly and Teevan (2003) and several chapters in the collection edited by Brusilovsky, Kobsa, and Nejdl (2007).

19.3.1.2 Support for Query-Based Search

When a user is just checking the latest news or casually browsing for interesting information, the user is not in general expressing a specific information need. Hence, it is relatively easy for a user model to help noticeably by presenting information that is especially likely to be of interest to this particular user. In contrast, when a user formulates an explicit query, as in a web search engine, it is less obvious how a user model can help to identify relevant information. And in fact, the *potential for personalization* (Teevan, Dumais, and Horvitz 2010) has been found to vary considerably from one query to the next. If just about all of the users who issue a given query end up choosing the same documents from those returned by the system, there is little that an individual user model can do to increase the usefulness of the search results. But for queries that tend to result in very different selections for different users (e.g., the query "chi"), *personalized search* can add value. The basic idea is that the list of search results that would normally be returned is reordered (or *biased*) on the basis of a user model, which is in turn based on some aspects of the user's previous behavior with the system. GOOGLE has offered personalized search on its main search engine for several years—though many users are probably unaware of the personalization, which tends not to change the ranking of the search results in an immediately noticeable way for most queries.

The idea of assessing the potential for personalization is worth considering with other forms of adaptation as well: if we can estimate in advance the possible benefits of adaptation, perhaps before designing or implementing any adaptive mechanism, we can more efficiently identify situations in which the benefits of adaptation will outweigh the costs.

19.3.1.3 Spontaneous Provision of Information

A number of systems present information that may be useful to the user even while the user is simply working on some task, making no effort to retrieve information relevant to it from external sources. An illustrative recent example* is the AMBIENT HELP system (Matejka, Grossman, and Fitzmaurice 2011), which can also be seen as an approach to the problem of offering adaptive help that was discussed at the beginning of this chapter: while a user works with a complex application on one computer monitor, AMBIENT HELP uses a second monitor to display videos and texts with tutorial material that has some relevance to the user's current working context. A central design issue for this and similar systems concerns the methods for making the retrieved information available to the user. Presentation of results via means like pop-up windows risks being obtrusive (cf. Section 19.4); but if the presentation is too subtle, users will often ignore the information that is offered and derive little or no benefit from the system. AMBIENT HELP expands the space of design solutions by introducing an unobtrusive way of showing what a video has to offer (with a dimmed image, a reduced frame rate, and muted volume) and a scheme for allowing users quickly to explore the content of the available videos. Previous work in the same vein (e.g., by Billsus, Hilbert, and Maynes-Aminzade [2005]) suggests allowing users to adjust the relative obtrusiveness of the proactively offered information to suit their individual taste.

19.3.2 RECOMMENDING PRODUCTS

One of the most practically important categories of user-adaptive systems today comprises the product recommenders that are found in many commercial websites. The primary benefit of these systems is that they assist users in finding personally interesting (but not previously known) items in large collections of products.

An example that will look familiar to most readers is shown in Figure 19.14. A visitor to NETFLIX has just explicitly requested recommendations, without having specified a particular type of a movie. During the user's past visits, NETFLIX has learned about his or her interests, on the basis of movies he or she has watched and ratings he or she has made. Therefore, the system can make recommendations that are especially likely to appeal to this particular user.

The recommendations of NETFLIX embody many design decisions that contribute to the success of this type of adaptation. First, as can be inferred from the brief explanation that accompanies the recommendation in Figure 19.14, the system takes as a starting point the information it has about the user's prior viewing history and ratings. It then compares these with the ratings of other users to generate predictions for the current user. That is, the recommendations are based on a statistical analysis of ratings made by many users, an approach known as *collaborative filtering* (see, e.g., Schafer et al. [2007], for a general overview and Figure 19.15).[†] The products recommended in this way may also happen to be similar in the sense of belonging to the same genre or having the same director, but similarities of this sort can also be conspicuously absent: In the example shown in Figure 19.14, a nature documentary is recommended to a customer partly on the basis of his past enjoyment of Kurosawa's lighthearted samurai story *Yojimbo*. The power of collaborative filtering comes from the fact that many features relevant to our choices are hard to capture. In the movie domain, for example, the mood, the particular style of humor, or the details of the camera work may be as relevant as the more easily describable properties such as genre, director, or cast.

Second, the explanations accompanying the recommendation are another important design feature: for example, taking into account the fact that what is "good" often depends on context (e.g., a user may enjoy a complex drama one day while preferring a less demanding action movie after a long work day), the explanations help users better predict if a particular film is what they are looking for at a given moment. As in the example in Figure 19.14, many sites use other items

[*] Influential early systems in this category include those of Rhodes (2000) and Budzik, Hammond, and Birnbaum (2001).

[†] Interested readers will also find many documents available on the web about the highly publicized efforts of NETFLIX to encourage improvement of its algorithms by sponsoring the NETFLIX Prize.

the user has rated in the past as a basis for generating an explanation. But very different types of information can also be used for explanations, such as user-generated tags (Vig, Sen, and Riedl 2009). A recent discussion of the many forms that explanations can take and the functions that they can serve has been provided by Tintarev and Masthoff (2010).

Finally, movie recommendations in NETFLIX complement rather than replace the normal searching and browsing capabilities. This property allows users to decide which mode of interaction is most appropriate in their situation.

Because many products, such as movies, vacations, or restaurant meals, are often enjoyed by groups rather than individuals, so a number of systems have been developed that explicitly address groups (see Jameson and Smyth [2007] for an overview). The need to address a group rather than an individual has an impact on several aspects of the recommendation process: Users may want to specify their preferences in a collaborative way; there must be some appropriate and fair way of combining the information about the various users' preferences; the explanations of the recommendations may have to refer to the preferences of the individual group members; and it may be worthwhile for the system to help the users negotiate to arrive at a final decision on the basis of the recommendations.

Another design challenge for recommender systems has to do with the availability of information about the users' preferences. Collaborative filtering is less effective for supporting infrequent decisions such as a digital camera purchase, which can involve one-time considerations that are not closely related to previous choices by the same user. Since the 1980s, researchers have worked on systems that explicitly elicit information about the user's needs (and the trade-offs among them) and help the user identify products that best meet their needs. One particularly effective interaction paradigm for such systems is *example critiquing* (see, e.g., Burke, Hammond, and Young [1997], for an early exposition, and Pu and Chen [2008] for a discussion of some recent advances). The distinguishing feature is an iterative cycle in which the system proposes a product (e.g., a restaurant in a given city), the user criticizes the proposal (e.g., asking for a "more casual" restaurant), and the system proceeds to propose a similar product that takes the critique into account.

Finally, a highly pervasive and economically vital form of product recommendation is advertising. Over the last decade, online advertising has shifted largely from attention-grabbing banners and pop-ups to subtler *personalized* ads. Rather than relying on users' explicit feedback in the form of purchases and product ratings (as is the case with recommender systems), online personalized advertising relies on implicit input such as the search terms, contents of an e-mail message (in the case of GMAIL ads), the topics of the pages visited, and the browsing history. There are many good reasons to prefer such personalized advertising: it tends to be presented in a less intrusive way (e.g., the text-only ads used by GOOGLE), and it has the promise of being more relevant to the users. Indeed, a recent study found that of people who clicked on personalized ads, twice as many were likely to actually make a purchase than people who clicked on nonpersonalized ads (Beales 2010).

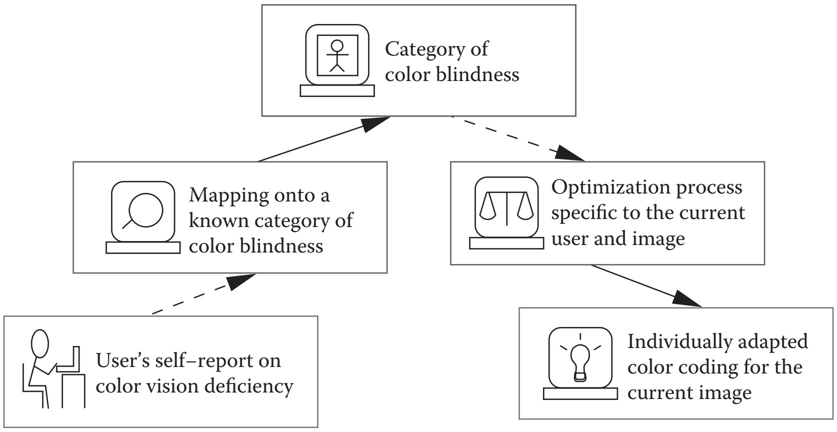
However, because online behavioral data (such as searches the people perform and sites that they visit) are considered sensitive personal information, and because the users do not have clear and effective means of controlling what information they divulge to advertisers and when, privacy concerns about personalized advertising are common (Federal Trade Commission 2009). The Canadian Marketing Association (2009) has found that only about 30% of North Americans are comfortable with advertisers tracking their browsing behavior for the purpose of providing more targeted advertising, even though nearly half like seeing ads for coupons and promotions from online stores and brands that they have purchased from before. Improving the comprehensibility of and user control over data collection are therefore important challenges for the long-term success of personalized advertising (cf. in Section 19.4).

19.3.3 Tailoring Information Presentation

Sections 19.3.1–2 discussed systems that help users decide *what* information (such as news items or product descriptions) to consider. We now turn to systems that adapt *how* information is presented.

A striking and practically important example is found in the work of Jefferson and Harvey (2006, 2007), which uses personalized models of color perception abilities of color-blind users to adapt the presentation of graphical information in a way that preserves the saliency and readability of color-encoded information. A major challenge in adapting content to an individual's color perception abilities is that complex color-encoded information needs to be conveyed through a reduced color palette. One possible approach is to generate a fixed mapping that tries to "squeeze" the full spectrum of visible colors into a range that is distinguishable by a particular individual. This approach inevitably reduces perceptual differences among the colors in the transformed palette. Instead, Jefferson and Harvey (2006) compute these mappings for each image individually (see Figure 19.16). Their approach takes advantage of the fact that most images use only a limited number of colors for salient information. Their algorithm automatically identifies these salient colors and computes a mapping from the original palette to one that is appropriate for the user. The mapping is computed in a way that preserves the perceptual differences among the important colors.

Unfortunately, because the process of computing an optimal color mapping is computationally expensive—up to several minutes may be required—it is not feasible for interactive use. Jefferson and Harvey (2007) have developed an alternative approach where the computer quickly generates a small set of possible mappings that may be appropriate for a particular individual and the user can quickly select the appropriate one with a slider, while getting an immediate preview of the effect. By splitting the adaptation burden



Category of color blindness
Mapping onto a known category of color blindness
Optimization process specific to the current user and image
User's self–report on color vision deficiency
Individually adapted color coding for the current image

FIGURE 19.16 Overview of Jefferson and Harvey's method of adaptation to color blindness.

between the computer and the user, this particular system provides users with a solution that is effective and fast, and requires only a minimal amount of user effort.

The remaining challenge is that of quickly creating accurate models of individual color perception abilities. Fortunately, most users can be helped adequately by being stereotyped into one of a small number of discrete color blindness categories. However, some types of color blindness (the *anomalous trichromacies*) form a spectrum from almost normal color perception to almost complete inability to distinguish certain pairs of colors. Although there exist some methods for building models of individual color perception abilities (e.g., Brettel, Viénot, and Mollon [1997]; Gutkauf, Thies, and Domik [1997]), they require that users engage in an explicit diagnostic task, and one that may need to be repeated for different display devices. A faster, unobtrusive method is still needed.

Tailoring often concerns information in textual form. An important application area here comprises systems that present medical information to patients, who may differ greatly in terms of their interest in and their ability to understand particular types of information (see, e.g., Cawsey, Grasso, and Paris [2007], for an overview).

Properties of users that may be taken into account in the tailoring of documents include: the user's degree of interest in particular topics; the user's knowledge about particular concepts or topics; the user's preference or need for particular forms of information presentation; and the display capabilities of the user's computing device (e.g., web browser vs. cell phone).

Even in cases where it is straightforward to determine the relevant properties of the user, the automatic creation of adapted presentations can require sophisticated techniques of natural language generation (see, e.g., Bontcheva and Wilks [2005]) and/or multimedia presentation generation. Various less complex ways of adapting hypermedia documents to individual users have also been developed (see Bunt, Carenini, and Conati [2007] for a broad overview).

19.3.4 Bringing People Together

One of the most striking changes in computer use over the past several years has been the growth of social networks. Whereas people used to complain about being overwhelmed by the number of e-mails and other documents that they were expected to read, they can now also be overwhelmed by the number of comments posted on their social network home page, the number of people who would like to link up with them—and even the suggestions that they get from sites like Facebook and LinkedIn concerning possible social links. Accordingly, personalized support for decisions about whom to link up with has become a practically significant application area for user-adaptive systems.

Figure 19.17 shows how an internal social networking site used at IBM called SocialBlue (formerly Beehive) recommends a colleague who might be added to the user's network (see also Figure 19.18).

As the example illustrates, SocialBlue makes extensive use of information about social relationships to arrive at recommendations: not just information about who is already explicitly linked with whom in the system (which is used, for example, on Facebook) but also types of implicit information that are commonly available within organizations, such as organizational charts and patent databases.

As described by Chen et al. (2009), SocialBlue also uses information about the similarity between two employees (e.g., the overlap in the words used in available textual descriptions of them).

These authors found that these two types of information tend to lead to different recommendations, which in turn are accepted or rejected to differing extents and for different reasons. For example, information about social relationships works better for finding colleagues that the current user already knows (but has not yet established a link to in the system), while information about similarity is better for finding promising unknown contacts.

Taking the analysis of the same data a step further, Daly, Geyer, and Millen (2010) showed that different algorithms can also have different consequences for the structure of the social network in which they are being used. For example, a system that recommends only "friends of friends" will tend to make the currently well-connected members even better connected. This result illustrates why it is often worthwhile to consider not only how well an adaptive algorithm supports a user in a typical individual case but also what its broader, longer-term consequences may be.

Given that the various contact recommendation algorithms can be used in combination in various ways, a natural conclusion is that designers of systems of this sort should consider what mix of the algorithm types makes most sense for their particular system and application scenario.

Other contexts in which some sort of social matching has proved useful include the following:

- Expert finding, which involves identifying a person who has the knowledge, time, and social and spatial proximity that is necessary for helping the user to solve a particular problem (see, e.g., Shami et al. [2007]; Ehrlich, Lin, and Griffiths-Fisher [2007]; Terveen and McDonald [2005]).
- Recommendation of user communities that a user might like to join—or at least use as an information resource (see, e.g., Chen, Zhang, and Chang [2008], Carmagnola, Vernero, and Grillo [2009], and Vasuki et al. [2010] for early contributions to this relatively novel problem).
- Collaborative learning, which has become a popular approach in computer-supported learning environments (see, e.g., Soller [2007]).

19.3.5 Supporting Learning

Some of the most sophisticated forms of adaptation to users have been found in tutoring systems and learning environments: systems designed to supplement human teaching by

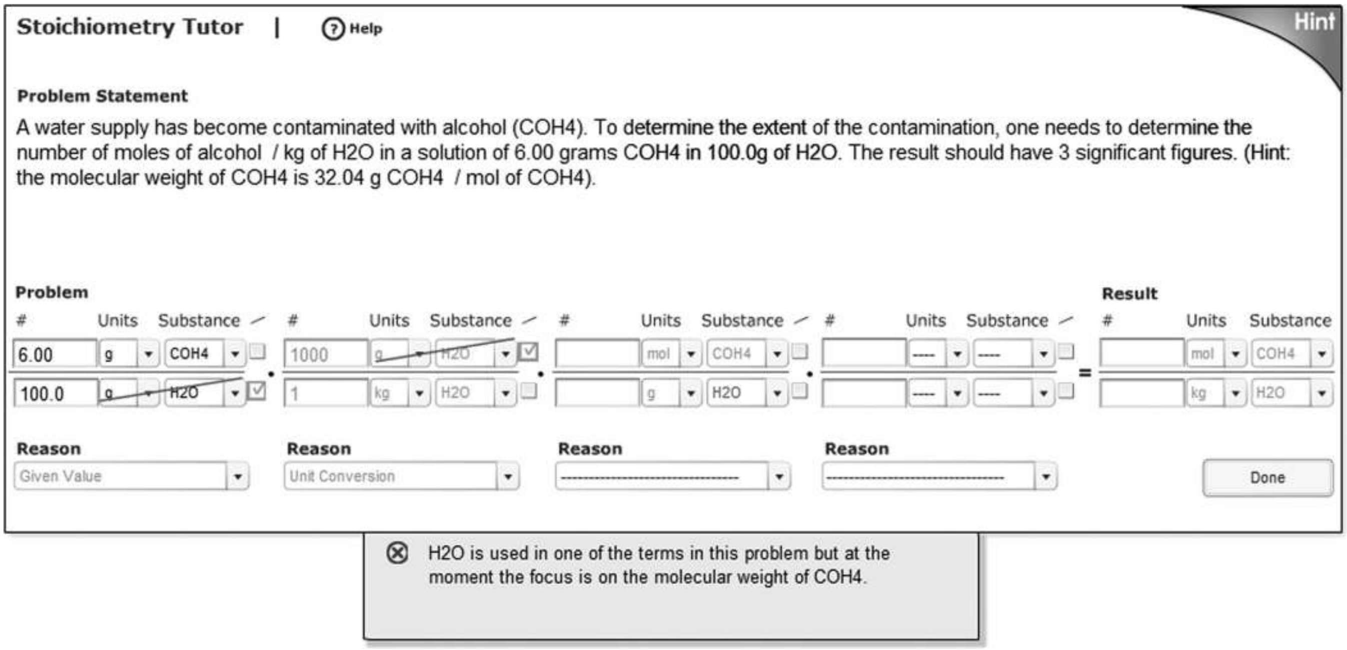
enabling students to learn and practice without such teaching while still enjoying some of its benefits.*

An illustrative recent example is the web-based Stoichiometry Tutor (Figures 19.19 and 19.20; McLaren, DeLeeuw, and Mayer 2011a,b), which helps students to practice solving elementary chemistry problems using basic mathematics. In the example shown, the student must perform a unit conversion and take into account the molecular weight of alcohol. The interface helps to structure the student's thinking, but it is still possible to make a mistake, as the student in the example has done by selecting "H20" instead of "COH4" in the lower part of the middle column. Part of the system's adaptation consists in hints that it gives when the student makes a mistake (or clicks on the "Hint" link in the upper right). The key knowledge that underlies the adaptation is a *behavior graph* for each problem: a representation of acceptable paths to a solution of the problem, along with possible incorrect steps. Essentially, the tutor is like a navigation system that knows one or more ways of getting from a specified starting point to a destination; but instead of showing the student a "route" to follow, it lets the user try to find one, offering hints when the student makes a wrong turn or asks for advice. This approach enables the system to adapt

* General sources of literature on this type of system include the *International Journal of Artificial Intelligence in Education* and the proceedings of the alternating biennial conferences on *Artificial Intelligence in Education* and on *Intelligent Tutoring Systems*. The integrative overview by VanLehn (2006) can also serve as an introduction.



Stoichiometry Tutor | ? Help

Hint

Problem Statement

A water supply has become contaminated with alcohol (COH4). To determine the extent of the contamination, one needs to determine the number of moles of alcohol / kg of H2O in a solution of 6.00 grams COH4 in 100.0g of H2O. The result should have 3 significant figures. (Hint: the molecular weight of COH4 is 32.04 g COH4 / mol of COH4).

Problem

#	Units	Substance	⁄		#	Units	Substance	⁄		#	Units	Substance	⁄		#	Units	Substance	⁄		#	Units	Substance
6.00	g	COH4	☐	•	1000	~~g~~	~~H2O~~	☑	•		mol	COH4	☐	•		----	----	☐	=		mol	COH4
100.0	~~g~~	~~H2O~~	☑		1	kg	H2O	☐			g	H2O	☐			----	----	☐			kg	H2O

Result (last three columns)

Reason	Reason	Reason	Reason	
Given Value	Unit Conversion	------------------------------	------------------------------	Done

☒ H2O is used in one of the terms in this problem but at the moment the focus is on the molecular weight of COH4.

FIGURE 19.19 Example of error feecback provided by the Stoichiometry Tutor. (The message below the main panel is the feedback on the student's incorrect selection of "H2O" as the "Substance" in the middle column, shown in red in the interface. with some flexibility: It can deal with multiple strategies for solving the problem and entertain multiple interpretations about the student's behavior.

This relatively recent approach to tutoring is called *example tracing* (Aleven et al. 2009), because it involves tracing the student's progress through the behavior graph, which in turn represents, in generalized form, a set of examples of how a problem can be solved. For authors of tutoring systems, providing such examples is a relatively easy, practical way to give the system the knowledge that it needs to interpret the student's behavior. In the long history of systems that adaptively support learning, most systems have used more complex representations of the to-be-acquired knowledge and of the student's current state of knowledge (e.g., in terms of sets of rules or constraints). Example tracing is an instance of a general trend to look for simpler but effective ways of achieving useful adaptation, relative to the often complex ground-breaking systems that are developed in research laboratories.

Giving feedback and hints about steps in solving a problem is an example of *within-problem guidance*, sometimes called the *inner loop* of a tutoring system (VanLehn 2006). Adaptation can also occur in the *outer loop*, where the system makes or recommends decisions about what problems the student should work on next. Outer-loop adaptation can use coarse- or fine-grained models of the student's knowledge, which are typically constructed on the basis of observation of the student's behavior.

19.4 USABILITY CHALLENGES

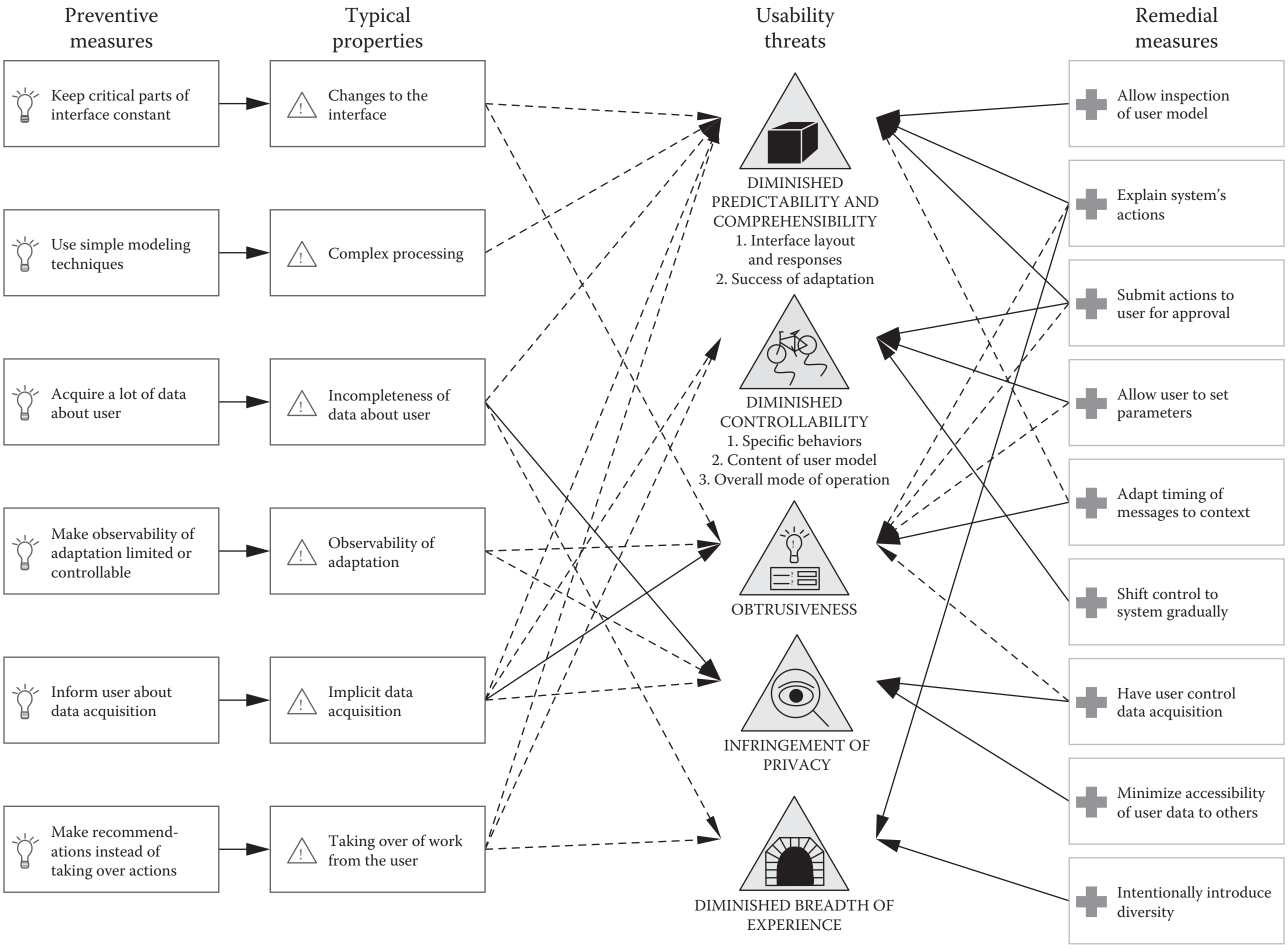
One of the reasons why the systems discussed in the first part of this chapter have been successful is that they have managed to avoid some typical usability side effects that can be caused by adaptation. These side effects were quite pronounced in some of the early user-adaptive systems that came out of research laboratories in the 1980s and 1990s, and they led to some heated discussion about the general desirability of adaptation to users (see the references given later in this section). By now, designers of user-adaptive systems have learned a good deal about how to avoid these side effects, but it is still worthwhile to bear them in mind, especially when we design new forms of adaptation that go beyond mere imitation of successful existing examples.

Figure 19.21 gives a high-level summary of many of the relevant ideas that have emerged in discussions of usability issues raised by user-adaptive systems and interactive intelligent systems more generally (see, e.g., Norman [1994]; Wexelblat and Maes [1997]; Höök [2000]; Tsandilas and Schraefel [2004]; Jameson [2009]). The figure uses the metaphor of signs that give warnings and advice to persons who enter a potentially dangerous terrain.

The *usability threats* shown in the third column characterize the five most important potential side effects. A first step toward avoiding them is to understand why they can arise; the column *typical properties* lists some frequently encountered (though not always necessary) properties of user-adaptive systems, each of which has the potential of creating particular usability threats.

Each of the remaining two columns shows a different strategy for avoiding or mitigating one or more usability threats: Each of the *preventive measures* aims to ensure that one of the *typical properties* is not present in such a way that it would cause problems. Each of the *remedial measures* aims to ward off one or more threats once it has arisen. The classes of preventive and remedial measures are open ended, and in fact advances in design and research often take the form of new measures in these classes. Therefore, Figure 19.21 can be used not only as a summary of some general lessons but also as a way of structuring thinking about a specific user-adaptive system; in the latter case, some of the boxes and arrows will be replaced with content that is specific to the system under consideration.

A discussion of all of the relationships indicated in Figure 19.21 would exceed the scope of this chapter, but some remarks will help to clarify the main ideas.



Preventive measures
Typical properties
Usability threats
Remedial measures
Keep critical parts of interface constant
Changes to the interface
Use simple modeling techniques
Complex processing
Acquire a lot of data about user
Incompleteness of data about user
Make observability of adaptation limited or controllable
Observability of adaptation
Inform user about data acquisition
Implicit data acquisition
Make recommendations instead of taking over actions
Taking over of work from the user
DIMINISHED PREDICTABILITY AND COMPREHENSIBILITY
1. Interface layout and responses
2. Success of adaptation
DIMINISHED CONTROLLABILITY
1. Specific behaviors
2. Content of user model
3. Overall mode of operation
OBTRUSIVENESS
INFRINGEMENT OF PRIVACY
DIMINISHED BREADTH OF EXPERIENCE
Allow inspection of user model
Explain system's actions
Submit actions to user for approval
Allow user to set parameters
Adapt timing of messages to context
Shift control to system gradually
Have user control data acquisition
Minimize accessibility of user data to others
Intentionally introduce diversity

FIGURE 19.21 Overview of usability challenges for user-adaptive systems and of ways of dealing with them. (Dashed arrows denote threats and solid arrows mitigation of threats, respectively; further explanation is given in the text.)

19.4.1 Threats to Predictability and Comprehensibility

The concept of *predictability* refers to the extent to which a user can predict the effects of his or her actions. *Comprehensibility* is the extent to which the user can understand system actions and/or has a clear picture of how the system works.* These goals are grouped together here because they are associated with largely the same set of other variables.

Users can try to predict and understand a system on two different levels of detail as follows:

1. *Exact layout and responses*. Especially detailed predictability is important when interface elements are involved that are accessed frequently by skilled users—for example, icons in control panels or options in menus (cf. the discussion of interface adaptation in Sections 19.2.2–3). In particular, the extreme case of predictability—remaining identical over time—has the advantage that after gaining experience users may be able to engage in *automatic processing* (see, e.g., Hammond [1987]; or, for a less academic discussion, Krug [2006]): They can use the parts of the interface quickly, accurately, and with little or no attention. In this situation, even minor deviations from constancy on a fine-grained level can have the serious consequence of making automatic processing impossible or error-prone. But even a lower degree of predictability on this detailed level can be useful for the user's planning of actions. Suppose that a person who regularly visits the website for this year's CHI conference knows that, if he or she types "chi" into the search field of his or her browser, the conference's home page will appear among the first few search results (possibly because the search is personalized and he or she has visited the conference page in the past): This knowledge will enable him or her to access the page more quickly than if the search engine's results were less predictable.
2. *Success of adaptation*. Often, all the user really needs to be able to predict and understand is the general level of success of the system's adaptation. For example, before spending time following up on a system's recommendations, the user may want to know how likely they are to be accurate. And if they turn out to be inaccurate, the user may want to understand why they were not satisfactory in this particular case, so as to be able to judge whether it will be worthwhile to consult the recommendations in the future.

19.4.2 Threats to Controllability

Controllability refers to the extent to which the user can bring about or prevent particular actions or states of the system if the user has the goal of doing so. It is an especially important issue if the system's adaptation consists of actions that have significant consequences, such as changing the UI or sending messages to other people. A widely used way of avoiding controllability problems is simply to have the system make recommendations, leaving it up to the user to take the actions in question. Or the system can take an action after the user has been asked to approve it. Both of these tactics can raise a threat of *obtrusiveness* (see Section 19.4.3); so it is important to find a way of making recommendations or asking for approval in an unobtrusive fashion but still in a noticeable fashion (see, e.g., the discussion of Ambient Help in Section 19.3.1.3).

Like predictability and comprehensibility, controllability can be achieved on various levels of granularity. Especially since the enhancement of controllability can come at a price, it is important to consider what kinds of control will really be desired. For example, there may be little point in submitting individual actions to the user for approval if the user lacks the knowledge or interest required to make the decisions. Jameson and Schwarzkopf (2002) found that users sometimes differ strikingly in their desire for control over a given aspect of adaptation, because they attach different weight to the advantages and disadvantages of controllability, some of which are situation-specific. This observation corroborates the recommendation of Wexelblat and Maes (1997) to make available several alternative types of control for users to choose from.

19.4.3 Obtrusiveness

We will use the term *obtrusiveness* to refer to the extent to which the system places demands on the user's attention, which reduces the user's ability to concentrate on his or her primary tasks. This term—and the related words *distracting* and *irritating*—were often heard in connection with early user-adaptive systems that were designed with inadequate attention to this possible side effect. Figure 19.21 shows that (1) there are several different reasons why user-adaptive systems may be obtrusive and (2) there are equally many strategies for minimizing obtrusiveness.

19.4.4 Threats to Privacy

Until a few years ago, threats to privacy were associated with user-adaptive systems more than with other types of systems, because adaptation implied a greater need to collect and store data about individual users (see, e.g., Cranor [2004]). Nowadays, where so much of everyday life has moved to the web, people have many reasons for storing personally sensitive information (including, e.g., their e-mail, personal photos, and work documents) on computers over which they have no direct control. So, the threat of privacy and security violations due to unauthorized access to or inappropriate use of personal data is now less strongly associated with the modeling of individual users. A comprehensive general discussion of privacy issues in human–computer interaction has been provided by Iachello and Hong (2007).

* The term *transparency* is sometimes used for this concept, but it can be confusing, because it also has a different, incompatible meaning.

A privacy threat that is still specifically associated with user-adaptive systems concerns the visibility of adaptation. For example, consider a reader of GOOGLE NEWS who suffers from a particular disease and has been reading news stories related to it. If the user is not eager for everyone to know about his or her disease, he or she may take care not to be seen reading such news stories when other people are present. But if he or she visits the personalized section of the news site when someone else is looking and a story about the disease appears there unexpectedly, the observer may be able to infer that the user is interested in the topic: The stories that are displayed implicitly reflect the content of the user model that the system has acquired. As Figure 19.21 indicates, a preventive measure is to give the user ways of limiting the visibility of potentially sensitive adaptation.

19.4.5 Diminished Breadth of Experience

When a user-adaptive system helps the user with some form of information acquisition (cf. Section 19.3), much of the work of examining the individual documents, products, and/or people involved is typically taken over by the system. A consequence can be that the user ends up learning less about the domain in question than the user would with a nonadaptive system (cf. Lanier [1995] for an early discussion of this issue).

Findlater and McGrenere (2010) investigated this type of trade-off in depth in connection with personalized UIs that limit the number of features that a user is exposed to. Their results confirmed that this type of personalization can both increase users' performance on their main tasks and reduce their awareness of features that might be useful with other tasks. The authors discuss a number of considerations that need to be taken into account when this type of trade-off is encountered.

As Figure 19.21 indicates, a general preventive measure is to ensure that users are free to explore the domain in question freely despite the adaptive support that the system offers. For example, recommender systems in e-commerce do not in general prevent the user from browsing or searching in product catalogs.

If a user does choose to rely heavily on the system's adaptations or recommendations, reduction of the breadth of experience is especially likely if the system relies on an incomplete user model (e.g., knowing about only a couple of the tasks that the user regularly performs or a couple of topics that the user is interested in). Some systems mitigate this problem by systematically proposing solutions that are *not* dictated by the current user model (see, e.g., Ziegler et al. [2005] for a method that is directly applicable to recommendation lists such as those of NETFLIX; and Linden, Hanks, and Lesh [1997] and Shearin and Lieberman [2001], for methods realized in different types of recommenders).

19.4.6 The Temporal Dimension of Usability Side Effects

The ways in which a user experiences a particular usability side effect with a given adaptive system can evolve as the user gains experience with the system. For example, adaptations that initially seem unpredictable and incomprehensible may become less so once the user has experienced them for a while. And a user may be able to learn over time how to control adaptations. In some cases, therefore, usability side effects represent an initial obstacle rather than a permanent drawback. On the other hand, since an initial obstacle may prompt the user to reject the adaptive functionality, it is worthwhile even in these cases to consider what can be done to improve the user's early experience. The remedial measure shown in Figure 19.21 of enabling the user to control the system closely at first and shift control to the system gradually is an example of such a strategy.

In general, though, the temporal evolution of the usability of an adaptive system is more complex than with nonadaptive systems, because the system tends to evolve even as the user is learning about it. A systematic way of thinking about the complex patterns that can result is offered by Jameson (2009).

19.5 OBTAINING INFORMATION ABOUT USERS

Any form of adaptation to an individual user presupposes that the system can acquire information about that user. Indeed, one reason for the recent increase in the prevalence of user-adaptive systems is the growth in possibilities for acquiring and exploiting such data.

Sections 19.5.1 and 19.5.2 will look, respectively, at (1) information that the user supplies to the system explicitly for the purpose of allowing the system to adapt and (2) information that the system obtains in some other way.

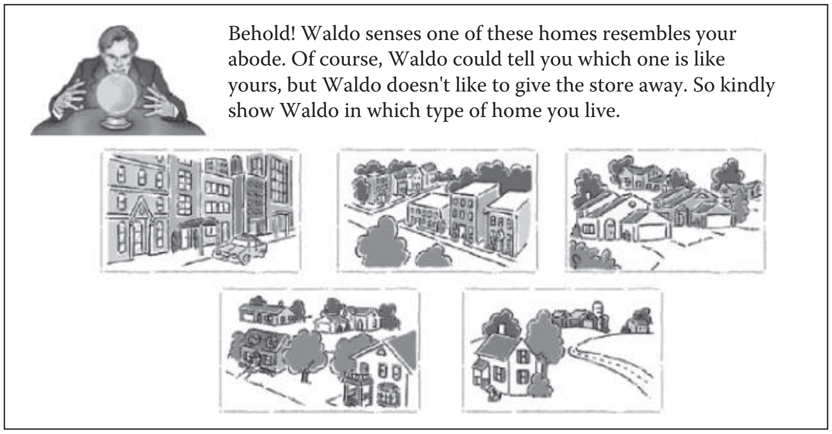
19.5.1 Explicit Self-Reports and -Assessments

19.5.1.1 Self-Reports about Objective Personal Characteristics

Information about objective properties of the user (such as age, profession, and place of residence) sometimes has implications that are relevant for system adaptation—for example, concerning the topics that the user is likely to be knowledgeable about or interested in. This type of information has the advantage of changing relatively infrequently. Some user-adaptive systems request information of this type from users, but the following caveats apply:

1. Specifying information such as profession and place of residence may require a fair amount of tedious menu selection and/or typing.
2. Since information of this sort can often be used to determine the user's identity, a user may justifiably be concerned about privacy. Even in cases where such concerns are unfounded, they may discourage the user from entering the requested information.

A general approach is to (1) restrict requests for personal data to the few pieces of information (if any) that the system really requires; and (2) explain the uses to which the data will be put. A number of suggestions about how the use of personally identifying data can be minimized are given by Cranor



Behold! Waldo senses one of these homes resembles your abode. Of course, Waldo could tell you which one is like yours, but Waldo doesn't like to give the store away. So kindly show Waldo in which type of home you live.

FIGURE 19.22 Example of a screen with which the LifeStyle Finder elicits demographic information. (Figure 19.3 of “Lifestyle Finder: Intelligent user profiling using large-scale demographic data,” by Krulwich, B. 1997. *AI Mag* 18(2):37–45. Research conducted at the Center for Strategic Technology Research of Andersen Consulting [now Accenture Technology Labs].) (Copyright 1997 by the American Association for Artificial Intelligence. Adapted with permission.)

(2004). An especially creative early approach appeared in the web-based Lifestyle Finder prototype (Figure 19.22; Krulwich 1997), which was characterized by a playful style and an absence of requests for personally identifying information. Of the users surveyed, 93% agreed that the Lifestyle Finder’s questions did not invade their privacy.

19.5.1.2 Self-Assessments of Interests and Knowledge

It is sometimes helpful for a user-adaptive system to have an assessment of a property of the user that can be expressed naturally as a position on a particular general dimension: the level of the user’s interest in a particular topic, the level of his or her knowledge about it, or the importance that the user attaches to a particular evaluation criterion. Often an assessment is arrived at through inference on the basis of indirect evidence, as with the assessments of the user’s interest in news items in the personalized section of Google News. But it may be necessary or more efficient to ask the user for an explicit assessment. For example, shortly before this chapter went to press and after the discussion of Google News in Section 19.3.1 had been completed, Google News began providing a form (shown in Figure 19.23) on which users could specify their interests explicitly.

Because of the effort involved in this type of self-assessment and the fact that the assessments may quickly become obsolete, it is in general worthwhile to consider ways of minimizing such requests, making responses optional, ensuring that the purpose is clear, and integrating the self-assessment process into the user’s main task (see, e.g., Tsandilas and Schraefel [2004], for some innovative ideas about how to achieve these goals).

19.5.1.3 Self-Reports on Specific Evaluations

Instead of asking a user to describe his or her interests explicitly, some systems try to infer the user’s position on the basis of his or her explicitly evaluative responses to specific items. Familiar examples include rating scales on which a user can award one to five stars and the now-ubiquitous thumbs-up “like” icon of Facebook. The items that the user evaluates can be (1) items that the user is currently experiencing directly (e.g., the current web page); (2) actions that the system has just performed, which the user may want to encourage or discourage (see, e.g., Wolfman et al. [2001]); (3) items that the user must judge on the basis of a description (e.g., the abstract of a talk; a table listing the attributes of a physical product); or (4) the mere name of an item (e.g., a movie) that the user may have had some experience with in the past. The cognitive effort required depends in part on how directly available the item is: In the third and fourth cases just listed, the user may need to perform memory retrieval and/or inference to arrive at an evaluation.

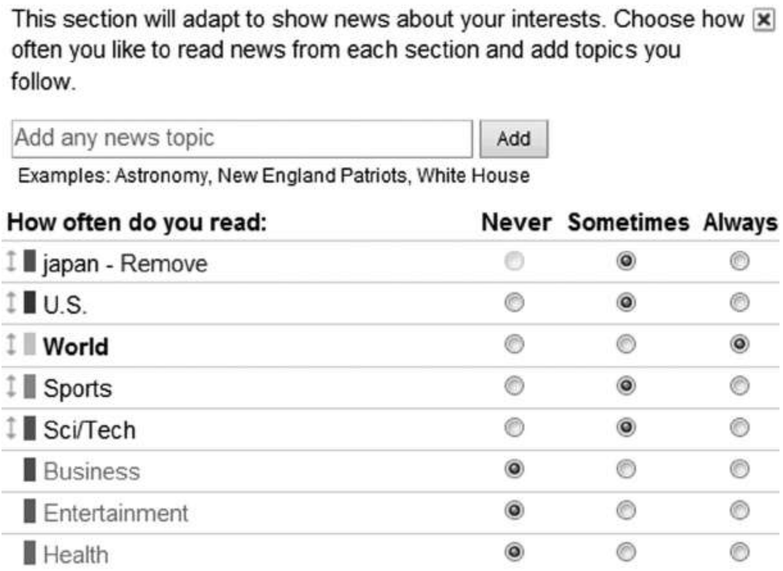
19.5.1.4 Responses to Test Items

In systems that support learning, it is often natural to administer tests of knowledge or skill. In addition to serving their normal educational functions, these tests can yield valuable information for the system’s adaptation to the user. An advantage of tests is that they can be constructed, administered, and interpreted with the help of a large body of theory, methodology, and practical experience (see, e.g., Wainer [2000]).

Outside of a learning context, users are likely to hesitate to invest time in tests of knowledge or skill unless these can be presented in an enjoyable form (see, e.g., the color discrimination test used by Gutkauf et al. [1997] to identify perceptual limitations relevant to the automatic generation of graphs). Trewin (2004) reports on experience with a brief typing test that was designed to identify helpful keyboard adaptations: Some users who turned out to require no adaptations were disappointed that their investment in the test had yielded no benefit. As a result, Trewin decided that adaptations should be based on the users’ naturally occurring typing behavior.

19.5.2 Nonexplicit Input

Section 19.5.1 has given some examples of why designers often look for ways of obtaining information about the user that does not require any explicit input by the user.



This section will adapt to show news about your interests. Choose how often you like to read news from each section and add topics you follow.

FIGURE 19.23 A form in which a user of GOOGLE NEWS can characterize her interests in particular types of news.

19.5.2.1 Naturally Occurring Actions

The broadest and most important category of information of this type includes all of the actions that the user performs with the system that do not have the purpose of revealing information about the user to the system. These may range from major actions like purchasing an expensive product to minor ones like scrolling down a web page. The more significant actions tend to be specific to the particular type of system that is involved (e.g., e-commerce sites vs. learning environments).

In their pure form, naturally occurring actions require no additional investment by the user. The main limitation is that they are hard to interpret; for example, the fact that a given web page has been displayed in the user's browser for 4 minvutes does not reveal with certainty which (if any) of the text displayed on that page the user has actually read. Some designers have tried to deal with this trade-off by designing the UI in such a way that the naturally occurring actions are especially easy to interpret. For example, a web-based system might display just one news story on each page, even if displaying several stories on each page would normally be more desirable.

19.5.2.2 Information from Social Networks

One type of information about users that has grown explosively during the last several years is information that can be found in the increasingly ubiquitous social networks (e.g., FACEBOOK, LINKEDIN, and ORKUT, but also media-sharing sites such as FLICKR). Much of this information is similar in nature to information that can in principle be found elsewhere—for example, on a user's personal home page or in their e-mail messages—but social networking sites encourage people to create and expose more of this information than they otherwise would. One type of information is specific to social networks: explicit links connecting people (e.g., as "friends," professional collaborators, or members of the same online community). The most obvious way of exploiting link information was illustrated by the SOCIALBLUE system (Section 19.3.4): helping people to create additional links of the same types. But the fact that a given user is a friend of another person or a member of a given community can enable the system to make many other types of inference about that user by examining the persons to whom he or she is linked (see, e.g., Brzozowski, Hogg, and Szabo [2008]; Mislove et al. [2010]; Schifanella et al. [2010]; Zheleva and Getoor [2009]). In effect, much of the information that can be acquired in other ways summarized in this section can be propagated to other users via such links—although the nature of the inferences that can be made depends on the nature of the links and the type of information that is involved.

19.5.2.3 Other Types of Previously Stored Information

Even before the advent of social networking platforms, there were ways in which some user-adaptive systems could access relevant information about a user which was acquired and stored independently of the system's interaction with the user:

1. If the user has some relationship (e.g., patient, customer) with the organization that operates the system, this organization may have information about the user that it has stored for reasons unrelated to any adaptation, such as the user's medical record (see Cawsey et al. [2007] for examples) or address.
2. If there is some other system that has already built up a model of the user, the system may be able to access the results of that modeling effort and try to apply them to its own modeling task. There is a line of research that deals with *user modeling servers* (see, e.g., Kobsa [2007]): systems that store information about users centrally and supply such information to a number of different applications.

Related concepts are *ubiquitous user modeling* (see, e.g., Heckmann [2005]) and *cross-system personalization* (Mehta 2009).

19.5.2.4 Low-Level Indices of Psychological States

The next two categories of information about the user started to become practically feasible in the late 1990s with advances in the miniaturization of sensing devices.

The first category of sensor-based information (discussed at length in the classic book of Picard [1997]) comprises data that reflect aspects of a user's psychological state.

Two categories of sensing devices have been used: (1) devices attached to the user's body (or to the computing device itself) that transmit physiological data, such as electromyogram signals, the galvanic skin response, blood volume pressure, and the pattern of respiration (see Lisetti and Nasoz [2004], for an overview); and (2) video cameras and microphones that transmit psychologically relevant information about the user, such as features of his or her facial expressions (see, e.g., Bartlett et al. [2003]), speech (see, e.g., Liscombe, Riccardi, and Hakkani-Tür [2005]), or eye movements (see, e.g., Conati and Merten [2007]).

With both categories of sensors, the extraction of meaningful features from the low-level data stream requires the application of pattern recognition techniques. These typically make use of the results of machine learning studies in which relationships between low-level data and meaningful features have been learned.

One advantage of sensors is that they supply a continuous stream of data, the cost to the user being limited to the physical and social discomfort that may be associated with the carrying or wearing of the devices. These factors have been diminishing steadily in importance over the years with advances in miniaturization.

19.5.2.5 Signals Concerning the Current Surroundings

As computing devices become more portable, it is becoming increasingly important for a user-adaptive system to have information about the user's current surroundings. Here again, two broad categories of input devices can be distinguished (see Krüger et al. [2007], for a discussion of a number of specific types of devices).

1. Devices that receive explicit signals about the user's surroundings from specialized transmitters. The use of GPS (global positioning system) technology, often in conjunction with other signals, to determine a user's current location is familiar to most users of modern smartphones, and one of the purposes is to personalize the provision of information (e.g., about local attractions). More specialized transmitters and receivers are required, for example, if a portable museum guide is to be able to determine which exhibit the user is looking at.
2. More general sensing or input devices. For example, Schiele et al. (2001) describe the use of a miniature video camera and microphone (each roughly the size of a coin) that enable a wearable computer to discriminate among different types of surroundings (e.g., a supermarket vs. a street). The use of general-purpose sensors eliminates the dependence on specialized transmitters. On the other hand, the interpretation of the signals requires the use of sophisticated machine learning and pattern recognition techniques.

19.6 CONCLUDING REFLECTIONS

During the past few years, an increasing range of systems have been put into widespread use that exhibit some form of adaptation to users; in Section 19.2–3 have presented a representative sample. This increasing pervasiveness can be explained in part in terms of advances that have increased the feasibility of successful adaptation to users: better ways of acquiring and processing relevant information about users and increases in computational capacity for realizing the adaptation. But there has also been a growth in understanding of the forms of adaptation that fit with the ways in which people like to use computing technology, providing added value while avoiding the potential usability side effects discussed in Section 19.4.

One general design pattern has emerged which has been applied successfully in various forms and which might be considered the default design pattern to consider for any new form of adaptation: the nonadaptive interaction with an application is supplemented with recommendations that the user can optionally consider and follow up on.

The earliest widely used examples of this general pattern included product recommenders for e-commerce, such as Amazon.com's recommendations. As was illustrated by the examples in Sections 19.2–3, the pattern has also been appearing with other functions of adaptation, such as personalized news, recommendations of people to link up with, and support for the discovery and learning of useful commands in a complex application. In tutoring systems that include an "outer loop," recommendations can concern the suggestions of learning material and exercises. Even some forms of adaptation that would not normally be called "recommendation," such as split interfaces and TaskTracer's support for the performance of routine tasks shown in Figure 19.4, fit the same basic pattern.

The general appeal of this design pattern is understandable in that it involves making available to users some potentially helpful options which they would have had some difficulty in identifying themselves or which at least would have taken some time for them to access. This benefit is provided with little or no cost in terms of usability side effects: provided that the available display space is adequate, the additional options can be offered in an unobtrusive way. The fact that the user is free to choose what to do with the recommended options—or to ignore them—means that any difficulty in predicting or understanding them need not cause significant problems; that the system does not take any significant action that is beyond the user's control; and that the user's experience does not have to be restricted.

This relatively straightforward and generally successful paradigm cannot be applied to all forms of adaptation to users. Adaptation to abilities and impairments often requires the provision of an alternative interface (cf. Section 19.2.4). And some types of system—such as small mobile devices, smart objects embedded in the environment, and telephone-based spoken dialog systems—may lack sufficient display space to offer additional options unobtrusively or a convenient way for users to select such options. Achieving effective and widely used adaptation where the general recommendation-based design pattern cannot be applied remains a challenge for researchers and designers.

ACKNOWLEDGMENTS

The following colleagues provided valuable assistance in the form of comments on earlier drafts, supplementary information about their research, and/or graphics depicting their systems: Jilin Chen, Thomas Dietterich, Werner Geyer, Shaun Kane, Bruce Krulwich, Justin Matejka, and Bruce McLaren. The contribution of the first author was supported in part by the 7th Framework EU Integrating Project GLOCAL: *Event-based Retrieval of Networked Media* (http://www.glocal-project.eu/) under grant agreement 248984.

20 Mobile Interaction Design in the Age of Experience Ecosystems

Marco Susani

CONTENTS

20.1 MOBILE EXPERIENCE

20.1.1 Interacting with Networked Ecosystems

The parallel evolution of network technologies and social behaviors is transforming the character of interactive systems.

The conventional model of the individual working in front of a personal computer is challenged by innovative ways of accessing content and communication: networked mobile wireless devices grow their functionality, handheld interfaces become richer, mobile-distributed delivery of content will be fully integrated with conventional media, and entirely new social forms of communication are emerging.

The mobile component of this system of interactions, centered on "the device formerly known as the cell phone," has been among the most impressive technocultural phenomena of the past 10 years, and its evolution is still changing drastically the way human interaction is conceived. Mobility is only one aspect of this revolution: mobile devices also happen to be much more related to the individuals who use them and follow constantly both their private and work life. Thus, the interaction with these tools is characterized by a combination of functional and emotional aspects.

Present interaction models, even the ones developed respecting the rules of usability, often lack fundamental emotional qualities that are needed to support and increase existing social behaviors and rituals.

The paradigm of pervasive and ubiquitous networking, instead of gravitating around the personal computer, is taking the shape of an ecosystem of mobile and static platforms, for individual and collective use, all connected to the network, and their coordination is taking the shape of a choreography of interactions to provide access to integrated content and communication.

"Convergence" seems finally to take shape, centered on three platforms that dominate this experience ecosystem:

- Virtually all personal computers are on the net, and most of them can access the net via mobile wireless technologies. Some of them, netbooks, become lean clients and access both documents and apps from the "cloud" (internet-based servers).

- Tablets fill the space between mobile ‘pocketable’ devices, such as phones, and ‘static’ devices, like computers. Tablets open an enormous opportunity to interact with digital content both at home and while mobile, and evolve the touch-based interaction paradigm and high quality graphics to a higher level.
- Almost 5 billion cell phones and smartphones, most of them capable to network both voice and net access, are in the hands of people of all cultures and statuses.
- The transition from cable and broadcast TV to Internet Protocol (IP) networked TV is transforming the paradigm of interacting with video, movies, and TV content. Around the TV, other distributed devices introduce new sizes and form factors to increase the mobility within the home.
- Embedded networking capabilities are growing in other “appliances,” such as cars, or in any “thing” (via the radio frequency identification [RFID] technology), and in active environments.
- All the above is going to be connected with a multiplicity of technologies; the integration of wired and wireless, and the integration of different technologies within each one of these domains (e.g., cellular networks talking to local wireless networks at different scales, from Bluetooth to Wi-Fi to RFID), transforms the picture of a network into a flexible, capable, seamless, “opportunistic” infrastructure that can take advantage of any available connectivity.

Similar social and cultural disruptions are happening in parallel with this fully developed technology disruption:

- Format and genres of communication integrate and hybridize, and social networking becomes mainstream.
- Content becomes deconstructed and pervasive.
- Based on the intersection of the two aspects above, new types of communities are emerging, and new social models growing around the generation and distribution of content explore the space between one-to-one communication (the evolution of the telephone) and broadcast (the evolution of mass media).

Devices of different types, sizes, and context of use become multiple points of access to the network, and the net is much more embedded in the everyday reality, both because it is more integrated with spaces and artifacts of everyday life and because it influences more and more human activities and social systems.

20.1.2 Content, Communication, and Control

The original interaction with personal computers focused on doing (writing a document, making calculations on a spread sheet, etc.), and its physical context was a single individual user sitting in front of his computer, isolated from the surrounding physical space. Today, the merging of computer technologies with telecommunication technologies and wireless network access calls for a completely different paradigm: computers, mobile devices, and networks are a complex set of tools not only to ‘do’ things to performing tasks. Instead, they are above all gates to communication media that connect people, hybrid physical and digital collaborative spaces to meet others, and tools to access published, dynamic, and ubiquitous content.

The interfaces of these devices are no longer exclusively mediators between a machine and an individual but much more often they are the interfaces that structure the user’s communication mental model or interfaces that organize, contextualize, and categorize in an accessible way the vast space of networked content.

Simplicity, the key attribute that allowed in the past easy access to the functionality of a “machine,” becomes today a much more sophisticated concept, because a “simple” access to the user’s sphere of communication and content cannot come only from a functional, efficient organization of the interaction, but is much more rooted in subjective and cultural aspects, such as the ability to handle speed and quantity of connections or the mental construct of the user’s social universe. The success of sociotechnical phenomena like Twitter, for example, demonstrates that communication at a pace that would be defined as overwhelming by the average adult is totally acceptable for younger generations.

In this chapter, we will investigate the specifics of interaction with a multiplicity of mobile networked devices, and we will see how the whole paradigm of networked reality changes the way we think about human–computer interaction (HCI). We will look at any networked device, whether monofunctional or multifunctional, such as cell phones, networked photo-cameras, networked digital music players, digital TV, and so on, as points of access to this vast ecosystem of networked content, communication, and control.

20.1.3 From Interaction to Experience

In a networked universe that has no center, we will use the human user as a subjective viewer of the whole experience ecosystem.

Around this hypothetical user, we will describe different concentric “spheres” of interaction. The first “sphere,” closest to the user, corresponds to what usually is taken in consideration when designing a computer system: the physical interaction with a device. The other “spheres,” growing progressively to include multiple elements of this experience ecosystem, will include topics related to human-to-human communication, or access to content in the “cloud,” or interacting with objects in a space.

When mobile devices are enriched by multiple functions and applications, this entire ecosystem is what actually influences the overall experience of the user. This is the new territory for designers to act and define the character of a product, the features of a service, or the identity of a medium.

20.2 SPHERES OF INTERACTION

20.2.1 Sphere 1: Of Humans and Devices

The first sphere of interaction, the most intimate connection between a human and a device, is the physical manipulation.

The very nature of handheld devices makes this manipulation a key component of the relationship between user and system. Although handheld devices like mobile phones, whether they have conventional keypads or a touch screen, sometimes mimic the navigation in the graphical user interface (GUI) of a computer, the overall experience is extremely different from using a PC. The manipulation and relation with the hand, and in some respect with the rest of the body (such as through placing the device in a bag or in the pocket), roots these objects in the history of tools that are real extensions of the hand, such as pens. Also, the handheld nature of mobile devices highlights social aspects, such as the proxemic role of the object, like handing over a phone to show a picture to a friend, for example. In this context, rich and sophisticated sociocultural aspects complement the basic ergonomic components of the interaction.

20.2.1.1 Cars and Motorcycles

If you talk to a passionate biker, you will most often hear a comparison between the emotional aspects of driving a motorcycle compared with the "dullness" of driving a car: riding a bike is a richer sensorial experience that involves the whole body. Although one drives a car by "codified" controls, proper interfaces that act on the machine, riding a bike involves an *extension* of the body.

Actually, riding a bike is a hybrid between some coded controls (such as clutch and brakes) and "natural" proprioceptive controls (such as moving the body while making a turn).

Consequently, a car may be perceived as passive, whereas riding a bike is perceived as an active and engaging experience. Furthermore, riding a bike puts you in direct, immediate connection with the surrounding environment. From a certain point of view, the same can be said of personal computers and cell phones or tablets. Computers' only relationship with the body is the flat space of the desk, the movements of fingers on the keyboard, and the hand on the mouse. We use computers while sitting alone at a desk, our bodies still, and our minds isolated from the surrounding environment. Mobile devices such as cell phones are handheld, and the relationship with the hands is a fundamental character of the interaction. A PC provides an experience that atrophies our body to minuscule movements of the fingers and the wrist, whereas handling a cell phone is an experience that may involve larger gestures and has a richer relationship with the body. We use mobile phones while walking, sitting, standing, and driving. We use them in isolation or in a crowd. The experience of communicating via a mobile phone is only partially immersive: the environmental noise and the distractions of the environment balance this immersion and provide meaningful context to our activity. Cell phones have transformed the way we approach others and the power of the context enriches the communication: rather than asking, "How are you?" when we start a conversation, we ask, "Where are you?" as if the environment was an integral part of the conversation. The limited size of the device, which is in some respects a limit to the interaction because the screen is small and crowded, actually helps provide a further element of context: with such a small screen, we are forced to see what is around it, and the interaction is always peripheral, never immersive, and always hybridized by the "real" experience of the world around.

20.2.1.2 Ritual Power of Hands

Consider the way people take pictures with a cell phone. Sometimes the camera phone is pointed toward the subject of the photo like a camera, and sometimes the phone is used in a very different way to take pictures that are much more spontaneous and transient. To be fair, the way camera phones are used had been anticipated by a phenomenon grown around very conventional film-based cameras. In the early 1990s, users of a camera called Lomo started to take very spontaneous pictures by not aiming in the viewfinder. The Lomo phenomenon transformed the genre of photography with a disruption that was purely "behavioral": a new gesture, such as handling the camera without bringing it near the eye, revolutionized photography, and made the images much more "instantaneous" and genuine. This gave birth to a new photographic genre that was called Lomography. In Lomography, the gesture *is* the photo. The way people manipulate camera phones is very similar. In this case, the instantaneous photo genre is reinforced by the fact that photos are taken to be shared, not to be kept. Although, in origin, photography was conceived as a way of "conserving" reality by documenting it, networked photos are transient, not perennial. And the informality of the gesture of "catching" them is a fundamental part of both the interaction and the narratives of this genre of photography. Designing a form that facilitated or denied this spontaneity would be for a designer a way of confirming, or denying, this behavior and, as a consequence, a way of influencing the genre of photographs taken with such a device. In this case, the whole form and shape of the device, rather than an interface or a control, is the fundamental component of the interaction. Better, the shape of the device *is* the interface. Although this is relatively new in the history of HCI, it is not new in the history of objects.

20.2.1.3 Form Follows Gesture

In the history of material culture, a history that includes, for example, ancient cooking utensils and working tools, the relationship between objects and hands is fundamental and ends up defining the ritual relationship between humans and their tools. We are facing a kind of "calligraphic" use of an object. The idea of calligraphy, etymologically a "beautiful way of drawing or writing," is very much related to the idea of dignity and richness of gesture. Touch-screen devices with multitouch and swipe leverage this idea by adopting gestures that go beyond the mere tap-to-select: they imply much more articulated gestures, and movements that discern pressure, acceleration, and chords, and react with the same rich articulation by providing visual dynamic feedback that include physics-like bounce, float, mass, inertia, and so on.

In addition to being a fundamental component of the use of the device, the overall shape, proportions, and mechanics of the object are also establishing the "character" of the object, and with that they influence the social dynamics around the usage of the object. The way John Travolta pulls the antenna of his flip phone with his teeth in Pulp Fiction (in the topical moment when his friend just shot a guy by error in a car) is integral part of his character, and of the violence in that scene. How different is this from the way Anna Magnani "hugs" the handset in a cinema rendition of Jean Cocteau's theatrical piece "La Voix Humaine," a love monologue "designed" around the relationship between the woman—a desperate lover who has been abandoned by her partner—and the handset of her phone, the only thread left between her and her lover.

The manipulation of handheld devices also has a social role: sharing a photo sometimes means also grabbing the digital camera or the phone and handing it to somebody to watch at the screen. Even if the screen is small, sharing it with a friend is a rich social act. Handheld devices are part of the proxemic relationship between humans, other humans, and the social space that surrounds them.

When devices such as cell phones are becoming so miniaturized that their shape is no more influenced by their technical components, their form would rather be defined by the way people manipulate them. And, as we described previously, the manipulation is only in part delimited by the mere rules of usability. With the multiplication of networked devices of different form and size, for example, different devices define their identity not just through their usability per se, but through their ability to find the right place in the context of use: touch-screen-based tablets like the iPad mimic the size of a magazine and they cover the interaction space between the "one-foot" interaction of a handheld and the "10-foot" interaction of TV.

20.2.1.4 Sense of Touch

The diffusion of keyboards and keypads has led to a kind of "buttonification" of the human being. This is definitely a reduction of the power of the sense of touch. Our senses are way more sophisticated than the basic on/off controls that they operate. In the case of handheld devices, this sensorial atrophy is more evident for at least two reasons. The first one is that, while we hold the device with the full hand, five fingers plus the palm, we only use one finger to actually operate the keypad and receive tactile feedback. The second one is that, for the "peripheral" nature of the interaction with handhelds that we mentioned before, our interaction with a keypad has in the past ignored other fundamental spatial and proprioceptual clues, such as the horizon, our wrist position, and gravity. The recent advances in sensing and feedback technologies have finally fought back this kind of sensorial deprivation that keypads have provoked. The introduction of accelerometers and gravity sensors allows the device to be "conscious" of its absolute position in space and its relative position to the hand of the user. This allows users to take full advantage of the proprioceptual character of handheld manipulation and provides a fuller tactile stimulation as a feedback to this manipulation. Similarly, with the introduction of haptics, the primitive vibrators used originally just to replace the ringer tone of phones are used to provide a broader tactile feedback. Haptic actuators amplified by the resonance of the whole mass of the handheld can stimulate the whole palm of the hand or they could be used in a denser "resolution" to provide localized feedback and a more meaningful haptic "message" to parts of the hand. When combined with a proper reflection of the proprioceptual character of the GUI, the overall combination of enriched tactile and visual contextualized experience finally takes full advantage of the handheld nature of mobile devices. Localized buttons seem to have disappeared completely from touch-based devices, and combining touch with these additional proprioceptual sensory messages will provide a much richer sensorial experience.

20.2.1.5 Product Species

Even when the interaction with devices is properly designed and based on the principles of usability, sometimes there seems to be an additional difficulty in understanding the functions of an object, a subtler barrier to its adoption. An object may fail to deliver a clear message of its functionality to the user. The issue in this case is not "How easy is it to perform a task with this device?" but "What does this device do?" or, even more, "What is this?". In the past, a good rule to introduce a new object has been to leverage an analogy with a known, familiar object.

The reference to familiar devices and interactions could still apply today, but can also become too big of a limitation, a restriction of new functionalities or richer paradigms that simply do not have any parallel with anything familiar. Too many references are challenged: networked TV has no channels; mobile phones and house phones hybridize; e-mail and instant messaging integrate; camera, telephone, and video functionalities converge in the same device. Communication paradigms such as social networking and blogging, or content distribution models such as podcasting, simply do not have any reference to past, established, familiar models.

Inventing new object archetypes, as much as it is an oxymoron, may be the only way out of this impasse—developing new product types and new interaction paradigms when playing analogy to existing archetypes is just not applicable. The same applies to monofunctional devices in comparison with multifunctional ones; the history of interaction design is full of successes of simple, monofunctional devices that leveraged this analogy.

From the Palm PDA to the iPod, all fall in the category of devices that "do one thing and do it right." In the future, however, reducing the functionality to achieve simplicity of use may be no longer possible. Multifunctionality may offer too much of an advantage to be compromised, and new generations of users, younger hyper-taskers, would not necessarily appreciate oversimplification.

So, the challenge for a designer is to ensure that an object would be "understood" while preserving multifunctionality and richness of experience. Designers would, on the one side, develop a richer perspective on visual affordances, one that could accommodate multiple and partially ambiguous affordances related to different usages. On the other side, beyond affordances, designers need to develop a better understanding of what constitutes a recognizable, understandable "species" of objects. That is to say, rather than seeking the familiarity with a known object or function "as-is," developing a more sophisticated understanding of how familiarity(ies), or just components of this, can be carried over along the evolution of an object, or carried across a discontinuity in the evolution of such an object or functionality. This tactic seems to have been adopted by the designers of the iPad, which uses the familiarity of the book, or newspaper, as a Trojan horse to enter in our houses with the purpose, in future, to introduce new behaviors and spurt the growth of a completely new species of devices, which may put the familiar book into oblivion. The result will be the transformation of the simple concept of affordance into a richer notion of "objecthood," defined as the ability of humans to recognize and perceive correctly the world of objects, and the mutual ability of objects to be understandable and to overtly disclose their functionality. That is, for both humans and objects to develop their relationship around a sixth sense, the "sense of meaning."

20.2.2 Sphere 2: Mental Models (and Their Representation)

20.2.2.1 Mental Models

In personal computers, the metaphor of the "desktop" and the "point and click" in that digital space starts to feel the "competition" of other models of interaction, namely the information architectures organized around e-mail and social networking, which today are often dominant compared with the desktop access to files and folders.

The mental construct of the interaction with mobile wireless media is intrinsically centered on communication; the phonebook, and its extension to include presence, status, and location, is often the master mental model that represents our communication universe. The phonebook acts as a point of departure for a broad series of actions: starting a call, generating a message, initiating a textual chat, posting our status or checking the ones of our "buddies," or sharing a picture. However, with the diffusion of other ways of contextualizing the interaction, such as location detection, a user may decide to switch to a different model and, for example, "view by location" and reorganize the communication, mapping it over the actual physical surroundings. In this model, a user may reorganize the phonebook to check first "who's around me" in that moment. Even if the idea of communicating in physical proximity may seem paradoxical, cell phones are often used to create an additional communication channel (e.g., texting or sharing images) with people who are not remote or to manage meetings with people in physical proximity (e.g., a group of friends in the same city arranging a dinner together).

Other mental models use incoming events as an organizational context: an incoming call may trigger a reorganization of the interface around the person who calls (bringing in the foreground previous messages or pictures exchanged with that person); or walking in front of a place may trigger some location-based content and contextual actions around that content; or an approaching event, such as a meeting, can trigger other information such as the names of the participants, their status, and their location.

Although the taxonomies arranged around the sphere of communication may work better for phone-first devices, the proliferation of functions (imaging, video, music management, e-mail, etc.) could suggest taxonomies based around a clear distinction of applications or around categories of content (my photos, my music, my phonebook, etc.).

The dominance of the former model (centered on communication) or the latter (centered on content or applications) is not yet clear. For a long time, we will probably continue to have hybrids with the copresence of multiple categorizations.

What is common to both these models and different from the old desktop metaphor is that they have a less direct analogy with an interaction space—such as the physical space of the desktop—and they have more reference to mental constructs. As such, these models could be referred to as "cosmographies." Although a metaphor like the desktop implies having a reference with something that exists, a cosmography is a "general description of the world or universe," and this could embrace descriptions of both the material world and of abstract concepts—a mental model of something that eventually does not have any relation with the material reality.

20.2.2.2 Greater Than Infinity

Aggregation seems to be one of the best techniques to manage large quantities of contacts or content. Many recent interfaces and services, for example, help users manage the exponential growth of social networking messages by aggregating them around a revisited version of the contact book. The "view by person" allows in this case accessing all the social updates and managing all the multiple identities of an individual. This confirms the validity of a mental model based on communication and content rather than a task-oriented approach that would split access to e-mails, phone calls, and social updates from an individual within different applications. Aggregation, however, falls victim of quantity: when all friends, and friends of friends, using different communication formats (e-mails, phone calls, social updates, content sharing, etc.) are aggregated into one single view, their quantity may become unmanageable. The aggregated contact book of a last-generation smartphone can easily exceed thousands of contacts, and the benefit of having them "at hand" in one place is hindered by the difficulty of managing such an almost-infinite list. For this reason, it is fundamental to develop techniques to manage quantities of data, whether contacts in a phonebook or videos in a channel lineup, that risk becoming a cognitive burden. Innovative mental models are among such techniques. In the example of an ever-growing phonebook, finding an alternative to the alphabetic A-to-Z structure is fundamental. This can be achieved by adopting innovative information structures (i.e., closer friends first, then friends of friends, in a concentrical, progressive logical geometry that would replace the linear, nonhierarchical

A-to-Z structure), or visualization techniques (i.e., visualizing the above mentioned structure in a center-periphery zoomable diagram), or relying on context to filter information (i.e., showing contacts relevant to the moment of the day or an upcoming calendar event).

20.2.3 Sphere 3: Context

20.2.3.1 Physical Context

Mobile interaction cannot be isolated from its context. Although the interaction between a user and a personal computer tends to be immersive and central and is agnostic of the physical context of the user, the interaction with mobile devices is typically contextual and peripheral.

Primitive graphic menus and icons arranged in the small screen, a kind of translation of the conventional PC, are still the dominant GUI paradigm in wireless mobile media, but they are only the most superficial aspect of the interaction with devices like cell phones. Multiple other aspects of interaction with cell phones are less tangible, yet more important, than the keypad-and-screen, or touch-based, user interface. The whole experience ecosystem of the interaction with wireless media includes the combination of the interaction with the physical device, with its services, and with the physical environment.

Context is what makes mobile interaction much richer than computer interaction. Mobility means to be *more connected* to the physical place, not *more disconnected* from it; communication relates to *where* we are and *who* is around us. Location-based services, mobile imaging, and mobile blogging extend this concept to content itself: content accessed and generated from a mobile platform has the potential to be heavily contextualized over the physical environment. The convergence of all these aspects leads toward the paradigm of augmented reality, where information is shown on the actual physical space. The full implementation of such paradigm would be the ultimate celebration of the contextual power of mobile interaction.

20.2.3.2 Smart Objects and Active Ambient

Smart tags are very tiny, low-cost, wireless microcomputers. They only cost a few cents and they can be attached to anything—items of clothing, food cans, spare parts for cars, electric irons, and so on. The tags can be programmed to provide information about the items to which they are attached. They are able to identify a product and network this information and can also take note of their environment, recording changes in temperature, and so on. Their broad adoption is changing the way logistics are organized around raw materials and products traveling to transformation and to markets.

Smart tags also enable a minute level of interaction with the physical space. Cell phones equipped with RFID tags are already enabling financial transactions such as paying a ticket on the underground or replacing a credit card. The extension of this level of interaction may further enrich the augmented reality paradigm by supporting the paradigm of "point and click at real environments." Handheld devices could be used to trigger contextual information when pointed at other objects or parts of the environment.

Finally, the connection of these tags to an integrated information system able to tell, at any moment, everything about the life of an item of produce, for example, may allow the quality, the origin, or the value to be tracked in real time. Produce that is fresh or older, in-season or off-season, near or far from its origin, with or without a track record of its growth will have a different value. In this scenario, smart tags may enable the creation of *digital word-of-mouth*, similar to the spreading of information and knowledge by human word-of-mouth, connected to the system of goods. Attached to items will be information and knowledge. It is possible to describe this as a *knowledge aura*, and this is the most interesting aspect of future material-knowledge systems. Experiments on connecting *collective wisdom* with digital systems on the field have been undertaken in India since the 1990s. The fully fledged scenario will allow replication in a digital environment of the wisdom of word-of-mouth know-how.

The whole idea of using advertisement before the purchase, and separate from the purchase experience, could be revolutionized by the presence of an aura of information that follows the product until the point of purchase. Through this aura of digital information, the product would "advertise itself" from the shelves of a shop. Even more intriguing is the idea that deeper information about a product, connected to similar experiences of purchase and use—what is known as a recommendation on a website—will be readily available at any moment a product is encountered. The lure and temptations that attract a buyer will come directly from the product, from the background voices of people who bought and used it, and by the life history of the product—a kind of very detailed, dynamic, digital certificate of authenticity.

20.2.4 Sphere 4: Communities

20.2.4.1 Interacting with Social Networks

Networked media are characterized by the hybridization of a multiplicity of communication genres. Although 20 years ago, the evolution of telephone technologies seemed to go toward hyperrealism—technologies focused on replicating, at best, face-to-face communication—the actual evolution of telecommunication has denied this trend and pointed toward mediating communication in a form *different* from face-to-face. Text messaging via SMS created a communication channel that was simply impossible to achieve with face-to-face—often more intimate, more enigmatic, than face-to-face, and complementary to that. Instant messaging has added the management of multiple one-to-one communications, also not possible in real face-to-face, and later, blogging created a hybrid between one-to-one expression and broadcast. Social networks put constant connection in a new light: they catalyze a permanent flow of status updates, a kind of collective *stream of consciousness*, that was unimaginable with old media.

Finally, the multimedia capabilities of devices like camera phones allow the integration between communication and content sharing, making it possible to share experiences in an almost permanent way.

Mobile wireless media are also the ideal platform to support tribal social structures: mobile phones have favored the birth of tribal forms of few-to-few and few-to-many communication, and they revitalize the scale of the small circle of friends, of groups of people who are in constant touch, exchanging information and passions, and sharing images and music.

Different from both an individual that communicates one-to-one with his interlocutor and from a broadcaster with a passive mass audience, tribal models of communication define a dense flow of exchanges within a restricted circle of friends. The space for tribal relations, superimposition of the physical space and of the "digital territory of belonging," also amplifies information and messages while building a shared memory. The permanence of content in a shared space creates not a simple exchange of messages but the sedimentation, the memory, and the construction of a shared permanent experience.

20.2.5 Sphere 5: Content

"Convergence" between media, for long just a buzzword, is happening for real, and this means a much richer interaction for the user. Richer communication—messaging, voice, and so on—is more and more integrated with content access, such as sharing music, videos, and images.

20.2.5.1 Deconstructed Content

Mobile imaging is an already-established form of hybridization between communication and content capture. Camera and video capture phones as an imaging platform are fully integrated with both the PC and the TV. Video and music content have already migrated to "the cloud," and this, combined with the integration of web content with TV productions, has created yet another "triple point" (mobile, PC, and TV and home systems) interaction with content.

The first consequence this will have from an interaction point of view will be the separation of content creation from content delivery and the consequent "deconstruction" of content. The possibility of capturing images with different devices (camera phones or digital cameras) and accessing them in different modalities (in the device itself, shared with others or published on the web, or printed or accessed from a PC or a TV) are already evident signs of separation between creation and access and examples of truly networked access to content. Mobile TV will not be an exact replica of TV delivered to home. The latter has already been transformed by Digital Video Recorders, and broadcasts have been separated from real time. Mobile TV will be even more disconnected from the real time of broadcast—often decomposed in smaller fragments, buffered, and stored locally or in the cloud—and reassociated with the "relative" time of the user; the possibility of caching content on a mobile device, combined with the need for "snacking" shorter versions of the same content during leftover time while commuting, for example, has made the idea of a personal, adapted palimpsest more realistic. Content is deconstructed in different multiple formats (filling up many lengths, between the short trailer and the full-length movie) and consumed from different platforms.

20.2.5.2 Narrowcast

Social networks, podcasting, and blogging are the signal of a larger trend that opens the possibility for everybody to become a publisher. In both cases, the broadcast paradigm evolves from one-to-many (where the one is an author, an institutional publisher such as a TV station) to any-to-many (where anybody, with a limited investment and a much leaner technology, can become a publisher). But there is more. Both blogging and podcasting are creating communities of adepts that do not behave like a conventional passive audience of broadcast mass media. They feed back, comment, re-tweet, and create a closer circle of communication that constitutes an actual "narrowcast" environment, a scale of publishing unheard of before. There is no solution of continuity between the one-to-one paradigm of telephony that extends to the larger scale of a tribe of friends and the blogging and podcasting narrowcast that takes broadcast to a smaller scale. Also, communication and content are so hybridized that they become indistinguishable.

20.3 SEAMLESS EXPERIENCE ECOSYSTEMS

Today, no interaction can be isolated in the confined space of HCI: any consideration on the interaction between a user and a mobile device cannot ignore the complexity of the relational "ecosystems" that exist around this interaction.

The components of this complex networked experience are as follows:

1. A social ecosystem, because mobile devices go beyond the one-to-one communication to mediate very rich and complex system of social relationships.
2. A content ecosystem, since mobile devices allow access to images, music, and videos, and peer-to-peer content generation and sharing introduce a completely new perspective of content authoring.
3. A spatial ecosystem, because location-based services and communication strongly "ground" the interaction via mobile devices in the physical space.
4. A business ecosystem, because no single company or designer can control the overall experience, but can only shape the interaction from a partial point of control.
5. A platform ecosystem, since mobile interaction is integrated with interaction with other platforms, such as personal computers and digital TV.

The complexity of these ecosystems puts additional challenges to designers who want to shape the interaction.

Among these challenges are the following:

Adapting experiences to evolving behaviors. Convergence will change drastically the way users perceive their sphere of content and communication and, sometimes, giving up familiar models to embrace new paradigms may actually facilitate the ease of use. This is in apparent contrast with one of the rules of user-centered design, which is to refer to familiar models and avoid disruptions. For example, the potential elimination of "channels" when TV content moves over IP may help embrace a new paradigm that has no reference to the old "zapping." In the same way, embracing the paradigm of one-phone-number-per-person may confuse users at first, but will actually facilitate the transition to a communication paradigm where the user, not the device, is the one to be reached. A well-crafted, user-oriented approach may distinguish between the respect of familiarities that are structurally embedded in human perception and pushing back resistance of old mental habits that may actually hinder innovation and cause disruptions.

Shaping an experience without controlling the full ecosystem. The design culture has long insisted on the protection of the brand and on establishing a "signature" experience to a device or a service. In the future, it will be very rare, however, that a single brand, thus a single designer, would control the full experience ecosystem. Two approaches to this are possible: one is a resistance to sharing components of the experience with other brands; another is embracing the complexity of the system and finding lean, smart ways to shape the experience without actually owning and controlling all the elements. The latter seems to be a more open-minded, relaxed way to accept changes in the environment a designer operates, whereas the former may end up in a stubborn, desperate attempt to protect a territory that simply cannot be protected anymore. In other words, it is better to adapt and shape an experience by seeding signature elements in few key areas rather than working on a more rigid model and risking losing all the control.

Embracing the idea of human-to-human (and human-to-content) mediation rather than HCI. The HCI discipline is rooted in the interaction between a human and a machine (or a system) and focused on the shift from a mechanical interaction to a logical one. Although this competence remains true for the broad majority of devices we are designing today, it is also true that another aspect, the one of designing interfaces to access other humans and content via a mediating interface, is becoming more and more dominant. A deeper understanding of human patterns of communication, and of the interactions between interfaces of devices and genres of communication, is needed. In the same way, the understanding of how innovative ways of interacting with content may shape new types and formats of content is also needed. Media studies were born in a condition in which the media genre (e.g., the TV programs), the transport technology (via aerial or cable TV), the device of access (the TV set), the method of interaction (zapping through channels), the method of delivery (broadcast), and the interaction environment (a couch potato in a living room) of a given medium were linked and homogeneous. Today, a certain type of content (e.g., a TV program) may be delivered in a multiplicity of formats (real time or cached, in snippets, or in a linear fashion) to extremely different platforms and environments (at home or while mobile, to a passive individual or annotated and redistributed within a community). This poses new challenges to designers that need to shape at the same moment an innovative interaction and an innovative medium genre.

Experience ecosystems are reshaping the way human knowledge is grown and diffused. Interaction designers have the responsibility of both shaping a pleasurable, meaningful experience and of facilitating the chain of innovations that flows through new behaviors, new business models, and new technologies. Designers need to be the first to drive innovation in their own disciplines.

21 Tangible User Interfaces

Hiroshi Ishii and Brygg Ullmer

CONTENTS

21.1 INTRODUCTION

Where the sea meets the land, life has blossomed into a myriad of unique forms in the turbulence of water, sand, and wind. At a different seashore, between the sea of bits and land of atoms, we are now facing the challenge of reconciling our dual citizenships in the physical and digital worlds. Our visual and auditory senses are steeped in the sea of digital information, but our bodies remain deeply rooted in the physical world. Windows to the digital world are confined within flat square screens and pixels, or "painted bits." Digital information remains caged apart from our visceral engagement, from enduring embodiments we can directly engage with our hands and bodies.

Imagine an iceberg, a floating mass of ice in the ocean. This is one metaphor of tangible user interfaces (TUIs). A TUI gives physical form to digital information and computation, salvaging the bits from the bottom of the water, setting them afloat, and making them directly manipulable with human hands.

21.2 FROM GRAPHICAL USER INTERFACE TO TANGIBLE USER INTERFACE

People have developed sophisticated skills for sensing and manipulating their physical environments. However, most of these skills are not used in interaction with the digital world today. A TUI builds upon these skills, situating physically embodied digital information within physical space. Much of the TUI design challenge surrounds extending the affordances of physical objects to express and support engagement with new associations, behaviors, and properties of the digital domain (Ishii and Ullmer 1997; Ullmer and Ishii 2000; Baskinger and Gross 2010).

Interactions with digital information are now largely confined to graphical user interfaces (GUIs). We are surrounded by ubiquitous GUI devices including personal computers, handheld computers, and smart phones. Graphical interfaces have been in existence in research form since the 1950s (Astrahan et al. 1957; Sutherland 1964; Thacker et al. 1979), first appearing commercially in the Xerox 8010 Star System (Smith 1982). With the commercial success of the Apple Macintosh and Microsoft Windows, the GUI has become the standard paradigm for human–computer interaction (HCI) today.

GUIs represent information (bits) with pixels on bitmapped displays. These graphical representations can be manipulated with generic remote controllers such as mice, touchpads, and keyboards. By decoupling representation (pixels) from control (input devices), GUIs provide the malleability to graphically mediate diverse digital information and operations. Utilizing these graphical representations and "see, point, and click" interaction, for many use contexts the GUI made significant usability improvements over its command user interface predecessor, which required the user to "remember and type" characters.

However, interaction with pixels on GUI screens is inconsistent with our interactions with the rest of the physical environment we inhabit. The GUI, bound to the screen, windows, mouse, and keyboard, is divorced from the ways interaction takes place in most physical contexts. Interacting with GUIs, we cannot take advantage of our dexterity and skills for physical manipulation, such as engagement with building blocks and shaping models out of clay.

TUIs aim to take advantage of these haptic interaction skills. The key idea of tangible interfaces is *giving physical form to digital information*. These physical forms serve both as representations and controls for their interwoven digital bindings and associations. TUIs make digital information directly manipulable with our hands, and perceptible through our foreground and peripheral senses.

TUIs serve as an alternative, and sometimes a complement to the current GUI paradigm, demonstrating a new path to materialize Mark Weiser's vision of Ubiquitous Computing (Weiser 1991). Weiser wrote eloquently of weaving digital technology into the fabric of physical environments, making computation invisible. Instead of melting pixels into assorted large and small screens of different devices, tangible interfaces seek an amalgam of thoughtfully designed visible materiality and cognitive transparency through diverse forms—soft and hard, robust and fragile, wearable and architectural, transient and enduring—situated throughout our varied physical habitats.

This chapter introduces the basic concept of TUIs, dimensions of tangibility, illustrative tangible genres and instances, and open design challenges and opportunities.

21.3 URP: A TANGIBLE EXAMPLE

As a first illustration of basic tangible concepts, we introduce Urp—the urban planning workbench (Underkoffler and Ishii 1999). Urp uses physical scale models of architectural buildings to configure and control an underlying urban simulation of shadow, light reflection, wind flow, and other properties (Photo 21.1). In addition to an ensemble of building models, Urp also provides a variety of interactive tools for querying and controlling parameters of the urban simulation. These tools include a clock to change the position of the sun, a material wand to change building surfaces between brick and glass (thus reflecting light), a wind tool to change wind direction, and an anemometer to measure wind speed.

Urp's physical building models cast digital shadows onto the workbench surface (using video projection). These correspond to solar shadows at a particular time of day. The time of day, entangled with the sun's position in the sky, can be controlled by turning the physical hands of a clock tool

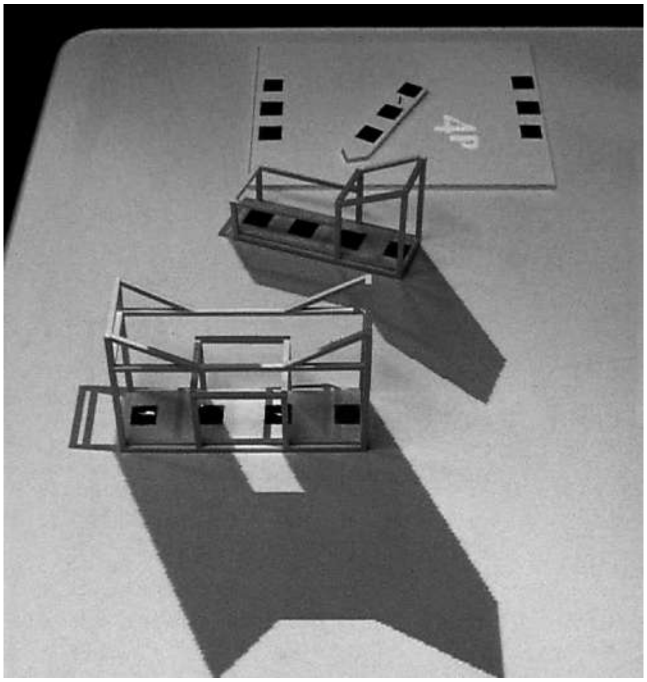

PHOTO 21.1 Urp and shadow simulation. Physical building models casting digital shadows, and clock tool to control time of day (position of the sun).

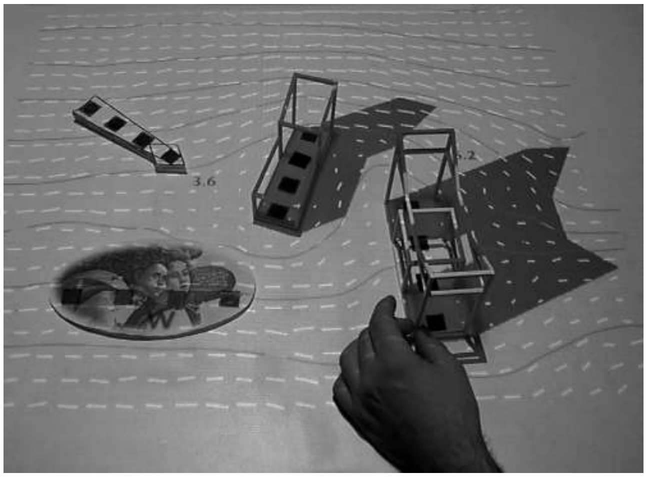

PHOTO 21.2 Urp and wind simulation. Wind flow simulation with wind tool and anemometer.

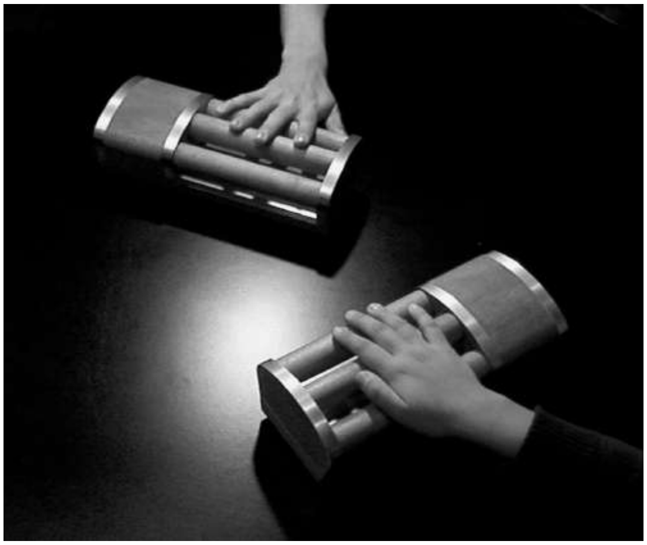

PHOTO 21.3 inTouch. inTouch is a prototype that explores tangible telepresence using touch over distance. Key idea is synchronizing distributed physical objects using force feedback technology.

(Photo 21.2). The building models can be repositioned and reoriented, with their graphically mediated solar shadows transforming according to their spatial and temporal configuration. Urban planners can identify and isolate intershadowing problems (shadows cast on adjacent buildings), and shape the play of urban light.

A material wand alters the surface properties of buildings. By touching the material wand to a building model, the surface material is transformed from brick to glass, and a simulated reflection of sunlight rebounds from the walls onto the worksurface (again through computationally mediated graphical projection). Moving the building allows urban designers to be aware of the relationship between building reflections and other infrastructure. For example, the reflection off the building at sundown might distract drivers on a nearby highway. The designer can experiment with altering the building's angles toward oncoming traffic, or moving the building further from the roadway. Tapping again with the material wand returns the material to brick; the reflected sunlight disappears, leaving only the projective solar shadow.

By placing the wind tool on the workbench, a windflow simulation is activated. This is based upon a real-time computational fluid dynamics simulation, with field lines graphically flowing around the buildings. Changing the wind tool's physical orientation correspondingly alters the orientation of the computational wind. Urban planners can identify potential wind problems, such as areas of high pressure that may result in challenging walking environments or hard-to-open doors (a real problem that partially disabled a building near our laboratory, until an iconic sculpture was commissioned to mold the wind). An anemometer tool allows monitoring of the wind speed (Photo 21.3). On placing the anemometer upon the workspace, the wind speed at that point is shown. Every few seconds, the corresponding numeric sails off along the flow lines, as with leafs upon the wind, to better visualize and quantify the evolving windflow. The interaction between the buildings and their environment allows urban planners to visualize and discuss intershadowing, wind, and placement problems.

In Urp, physical models of buildings are used as tangible representations of digital models of the buildings. To change the location and orientation of buildings, users grasp and manipulate the mediated physical model instead of pointing and dragging graphical representations on a screen with a mouse. The physical forms of Urp's buildings, and their configuration upon the workbench, represent and control the computational state of the urban simulation.

Although standard GUI devices such as keyboards, mice, and screens are also physical in form, the role of physical representation in TUI provides a key distinction. Urp's building models and tools are neither input nor output devices. Rather, these *tangibles* are manipulable representational physical embodiments of the simulation's key objects of interest. The building and tool tangibles are physical representations of both digital information (shadow dimensions and wind speed) and computational operations (windflow and shadowfall). Tangibles also serve as controls of the underlying computational simulation. Each specific physical embodiment supports a dual use in representing the digital model and allowing control of the digital representation.

In Section 21.4, a model of tangible interfaces is introduced, juxtaposed with a leading model for GUIs, to illustrate this mechanism.

21.4 BASIC MODEL OF TANGIBLE INTERFACES

Interfaces between people and digital information generally require two key components: input and output, or control and representation. *Controls* enable users to manipulate information, while *external representations* are perceived with the human senses. Figure 21.1 illustrates a simple such model of user interfaces consisting of control, representation, and information.

In the Smalltalk-80 programming language (Goldberg 1984; Burbeck 1992), the relationship between these components was proposed to follow a "model-view-controller" or "MVC" archetype. This has become a basic interaction model for GUIs.

Drawing from the MVC approach, we have developed an interaction model for both GUI and TUI. We carry over the "control" element from MVC, while dividing the "view" element into two subcomponents: tangible and intangible representations. We rename "model" to "digital information," toward generalizing this framework to illustrate differences between GUIs and TUIs.

In computer science, the term "representation" often relates to the programs and data structures serving as the computer's *internal* representation (or model) of information. In this article, the meaning of "representation" centers upon *external* representations—the external manifestations of information in fashions directly perceivable by human senses that include our visual, auditory, and tactile senses.

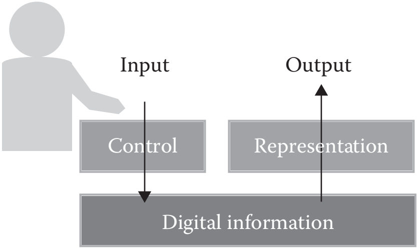

FIGURE 21.1 User interface. Interfaces between people and digital information requires two key components: 1) external *representations* (or view) that users can perceive, and 2) *controls* with which users can manipulate the representation.

21.4.1 Graphical User Interfaces

In 1981, the Xerox Star workstation set the stage for the first generation of GUIs (Smith 1982; Johnson et al. 1989), establishing the "desktop metaphor." This was initially modeled upon a partial simulation of an abstracted physical desktop, viewed upon a bitmapped screen. The Star workstation was the first commercial system to demonstrate the power of a mouse, windows, icons, property sheets, and modeless interaction. The Star also set several important HCI design principles, such as "seeing and pointing versus remembering and typing," and "what you see is what you get (WYSIWYG)." The Apple Macintosh brought this new style of HCI to the public's attention in 1984, creating a new trend in the personal computer industry. Now, the GUI is widespread, largely through the pervasiveness of Microsoft Windows and smart phones.

GUIs use windows, icons, and menus of pixels on bitmapped displays to mediate digital information. These are intangible representations. GUI pixels are traditionally rendered interactive through general "remote controllers" such as mice, touchpads and keyboards. In the pursuit of generality, GUIs typically introduce a deep separation between the digital (intangible) representation provided by the bitmapped display, and the controls provided by the mouse and keyboard.

Figure 21.2 illustrates the mainstream GUI paradigm in which generic input devices allow users to remotely interact with digital information. Using the metaphor of a seashore that separates a sea of bits from the land of atoms, digital information is illustrated at the bottom of the water, and mouse and screen are above sea level in the physical domain. Users interact with the remote control(s), and ultimately experience an intangible external representation of digital information (display pixels and sound).

21.4.2 Tangible User Interfaces

Tangible interfaces follow a different path than GUIs, using tangible representations of information that also serve as mechanisms for directly controlling digital information. Following articles including (Cohen, Withgott, and Piernot

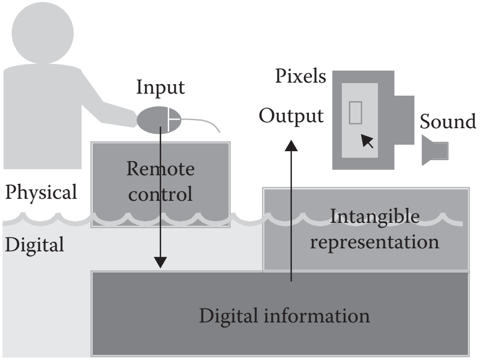

FIGURE 21.2 Graphical user interface. GUI represents information with intangible pixels on bitmapped displays and sound. General-purpose input devices allow users to control these representations.

1999; Singer et al. 1999; Ullmer and Ishii 2000), we will often refer to tangible representations as "tangibles." By representing information in both tangible and intangible forms, users can more directly control the underlying digital representation using their hands and bodies.

21.5 TANGIBLE REPRESENTATION AS CONTROL

Figure 21.3 illustrates the idea of tangible representation as control. Tangibles help bridge the boundary between the physical and digital worlds. Tangibles are computationally coupled to the control of the underlying digital information and computational models. Urp illustrates many examples of such couplings, including the binding of graphical geometries (digital data) to physical building models, and computational simulations (operations) to the physical wind tool. Instead of using a mouse to change the location and angle for graphical representations of a building model by pointing, selecting handles, and keying in control parameters, Urp users can grasp and move the building model to change both location and angle.

21.6 INTANGIBLE REPRESENTATION

While tangibles are coupled to digital information, they generally have limited direct ability to physically represent changes in their associated digital state. In comparison with malleable "bits," "atoms" are relatively inflexible. Unlike pixels on screens, today it remains comparatively difficult to change the form, position, or a property (e.g., color, size) of physical objects in real-time. (This may likely change in coming decades. Indeed, we will introduce several examples which already transcend these historical limitations.)

To complement this limitation of "atoms," TUIs also utilize malleable representations such as video projections and sounds, accompanying tangibles in their same physical space to give dynamic expressions of underlying digital information and computation. In Urp, the graphically mediated digital shadows and reflections that accompany physical building models are such an example.

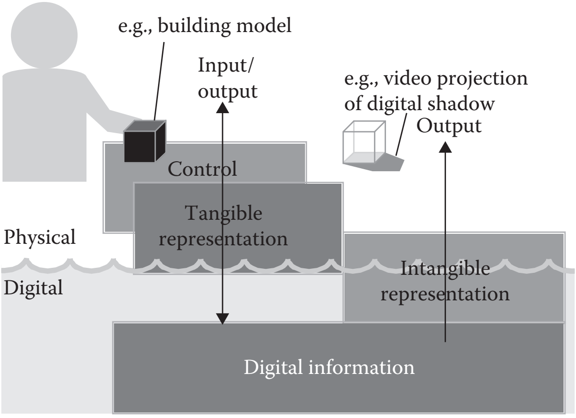

FIGURE 21.3 Tangible user interface. By giving tangible (physical) representation to digital information, TUI makes information directly graspable and manipulable with haptic feedback. Synchronous intangible representations (e.g. video projection) may complement tangible representations.

The success of a TUI often relies on a balance and strong perceptual coupling between tangible and intangible representations. In many successful TUIs, it is critical that both tangible and intangible representations are perceptually coupled to achieve a seamless interface that actively mediates interaction with the underlying digital information, and appropriately blurs the boundary between physical and digital. Coincidence of input and output spaces and real-time response are important elements toward accomplishing this goal.

Note: Some TUIs use actuation of tangibles as the central mean of computational feedback. Examples include inTouch (Brave, Ishii, and Dahley 1998), curlybot (Frei et al. 2000), and topobo (Raffle, Parkes, and Ishii 2004). This type of actuated TUI does not depend on "intangible" representation, as active feedback through the tangible representation serves as the main display channel.

21.7 KEY PROPERTIES OF TANGIBLE INTERFACES

While Figure 21.2 illustrates GUIs' clear distinction between graphical representation and remote controls, Figure 21.3 highlights TUIs' integration of physical representation and control. This model provides a tool for examining the following important properties and design requirements of tangible interfaces (Ullmer and Ishii 2000).

21.7.1 Computational Coupling of Tangibles to Digital Information

The central characteristic of tangible interfaces is the coupling of tangibles to underlying digital information and computational models. As corollaries, associated design challenges include (1) how to select or design legible, compelling tangibles that well-evoke their digital associations; and (2) how to best map tangibles and their manipulation to digital computation and feedback in a meaningful and comprehensible manner.

As illustrated by Urp, a range of digital couplings and interpretations are possible. Urp examples included coupling data to the building models, operations to the wind tool, and property modifiers to the material wand.

The embodiment and mapping of tangibles are influenced by application, audience, and the envisioned usage context. We will describe examples in which embodiments of varying specificity are used. In some applications, relatively abstract physical forms (such as round pucks) are used as generic controllers. These are typically reusable across varying bindings, allowing control over a variety of parameters through their rotation, depression, etc. (Patten et al. 2001). When a puck is used as a dial to control a simulation parameter, graphical feedback provides complementary information (e.g., the scale of the dial). In other cases, static bindings to physically representational tangibles can be a compelling alternative.

21.7.2 Tangible Embodiment of Mechanisms for Interactive Control

In addition to their representational aspect, tangibles serve as interactive physical controls. Tangibles may be physically inert, moving only as directly manipulated by a user's hands. Tangibles may also be physically actuated, whether through motors (e.g., inTouch, Curlybot), magnets (Pangaro et al. 2002), or other actuation methodologies (Biegelsen et al. 2000; Reznik and Canny 2001; Benhammous 2002).

Tangibles may be unconstrained and manipulated in free space with six degrees of freedom. They may also be weakly constrained through manipulation on a planar surface, or tightly constrained, as in the movement of abacus beads with one degree of freedom.

To make interaction simple and easy to learn, TUI designers need to utilize the physical constraints of the chosen physical embodiment. Because choices in physical embodiment interaction choices, designer should design interactions so that actions supported by tangibles are based on well-understood actions afforded by the artifact. For example, if a bottle-like form is chosen, opening the bottle by removing a cork or cap is a well-understood mechanism (Ishii, Mazalek, and Lee 2001). This understanding of culturally common manipulation techniques helps disambiguate the users' interpretation of how to interact with the object. Of course, these understandings vary widely between diverse cultures, presenting both opportunities and challenges.

21.7.3 Perceptual Coupling of Tangibles to Intangible Mediations

Tangible interfaces rely on a balance between tangible and intangible representations. Although embodied tangible elements play a central, defining role, TUIs' intangible representations play key supporting roles. A TUI's intangible representations—today, most often graphics and audio—often mediate much of the dynamic information provided by underlying computational processes.

Real-time feedback of intangible representations corresponding to tangible manipulations is critical toward supporting strong perceptual coupling. Coincidence of input and output spaces (spatial continuity of tangible and intangible representations) is also important to enhance perceptual couplings. For example, in Urp, the building tangibles are always accompanied by digital shadows (intangible representation) with minimal temporal or spatial gaps. This reinforces the illusion that the shadows are cast from the building models (rather than by the video projector).

21.8 DIMENSIONS OF TANGIBILITY

Building on the above properties, there are many dimensions surrounding the study and application of tangible interfaces. We next consider several of these, building upon frameworks and proposals by the broader research community. To be clear, these are not exhaustive, and is not as neatly classifiable as various categoricals amidst the hard sciences. We will then elaborate on several specific genres and examples of tangible interfaces in Section 21.9.

21.8.1 Conceptual

We have discussed tangible interfaces from the perspective of giving physical embodiments to digital information. A number of frameworks for tangible interfaces have been advanced. These have been recently considered at length in Mazalek and van den Hoven (2009) and Shaer and Hornecker (2009).

The term "tangible interaction" is a broader concept, of which tangible interfaces can be considered a particular approach. This perspective includes materiality, bodily interaction, and the embedding of systems in real spaces and contexts (Anderson et al. 2000; Djajadiningrat et al. 2002; Dourish 2002; Underkoffler and Ishii 1999; Hornecker and Buur 2006; Shaer and Hornecker 2009). Within this context, tangibility has often been approached from body (rather than information) centered perspectives (Dourish 2002; Klemmer, Hartmann, and Takayama 2006), with tangibles providing "resources for action" (Fernaeus, Tholander, and Jonsson 2008). Others have developed frameworks for tangibility surrounding the use of metaphors (Fishkin 2004; Hurtienne and Israel 2007), often drawing from embodiment and embodied action.

Another approach concerns the relationship between tangible interfaces and other physically situated forms of interaction (e.g., augmented, virtual, and mixed reality). One such perspective is reality-based interaction, which considers a fusion of physical-world properties and behaviors with bodily, environmental, and social awareness (Jacob et al. 2008). Tangible augmented reality is a specific example of crossover interaction techniques (Lee et al. 2004). In general, we see many opportunities for further understanding how tangible interfaces meet, engage, and hybridize with other styles of interaction.

21.8.2 Representational

As we earlier discussed, tangible interfaces are deeply concerned with the topic of representation. We have discussed earlier opportunities and tensions between tangible and intangible (e.g., graphical) representational forms. Representations in the physical world include a balance between shape and form (Djajadiningrat et al. 2004; Baskinger and Gross 2010), as well as static visual representations (Perlman 1976; Mackay and Pagani 1994; Perlman 1976; Ullmer et al. 2010). This could be seen as a tension and balance between body and skin. Tangibles can be general or specific in form and function and can use found/everyday/"readymade" objects (Goldsmith 1983; Mynatt 2000; Cheng et al. 2010) or purpose-designed forms (Frazer 1994; Gorbet et al. 1999; Djajadiningrat et al. 2004; Moggridge 2007; Baskinger and Gross 2010). Additional dimensions of representation (including related philosophical topics such as semiotics) are considered in Ullmer and Ishii (2000), Dourish (2002), Djajadiningrat et al. (2004), Hornecker and Buur (2006), and Shaer and Hornecker (2009).

21.8.3 Structural

Tangibles are influenced by a number of structural dimensions, influencing how they are shaped, constrained, and engage with each other and the world. The physical forms of tangibles may be rigid/solid, articulated, or malleable/plastic (e.g., as with clay, or more granularly as with sand). They may be used in the context of surfaces, edges, or spaces. Common surface examples include horizontal or vertical interactive surfaces, often illuminated graphically and sensed with computer vision or electromagnetic techniques (radio frequency identification). Wellner's DigitalDesk provided an influential early example and vision for interactive tabletops (Wellner 1993); we elaborate on this in Section 21.10.1. Ishii, Kobayashi, and Arita (1994) envisioned all the surfaces of architectural space—including walls, ceilings, windows, doors, and desktops—as active surfaces for engagement with remote partners and digital mediations.

Edges can serve to offer mechanical constraint; examples include linear racks and receptacles (Ullmer, Ishii, and Glas 1998; Cohen, Withgott, and Piernot 1999; Singer et al. 1999), rotary receptacles (MacLean, Snibbe, and Levin 2000; Ullmer, Ishii, and Jacob 2003), and material constraints such as strings and bands (Patten, Griffith, and Ishii 2000; Patten and Ishii 2007). In addition to their mechanical role as constraints, edges can partition architectural space, in the process establishing boundary regions—doorframes, hand rails, wainscoting, posts, columns, and culturally specific examples like the Japanese "genkan"—that can be awakened to computational mediation (Ullmer 2002).

There are also important structural implications in the ways that systems of tangibles are used together. In Ullmer and Ishii (2000), three such relationships were described: constructive, relational, and spatial (or positional). A fourth, associative, was also described, and has been developed further in van den Hoven and Eggen (2004), but is more semantic than structural in nature. We will discuss several of these in Section 21.9; they are also elaborated and extended in (Shaer et al. 2004; Shaer and Hornecker 2009).

21.8.4 Functional

Beyond the representational forms and structural relationships between tangibles lies the important question: what classes of functional roles can tangibles employ? Several generalizable conceptions of tangible functionality have been advanced. One approach is to consider physical instantiations of the GUI metaphor (Ishii and Ullmer 1997; Ullmer and Ishii 1997). Here, GUI windows, icons, menus, handles, and widgets can be physically instantiated as lens, phicon (physical icon), tray, handle, and instrument tangibles.

Another important approach advanced a model of containers, tokens, tools, and faucets (Holmquist, Redstr, and Ljungstrand 1999). Containers are tangibles that can be dynamically bound to instances or ensembles of digital information. The marbles of Bishop's well-known Marble Answering Machine (Crampton Smith 1995) that serve as containers for voice messages offer an early compelling example. As in other TUIs, Bishop used marble containers as a medium for moving information both within individual tangible products, and between systems of such products.

Holmquist et al. proposed "tokens" as a term for physically representational tangibles that are permanently bound to specific information bindings. The phicon term has also been used for this role (Ullmer and Ishii 1997), but without regard to whether the tangibles are abstract or representational in form, and dynamic or static in their physical–digital couplings. The "token" term has also been used more generically to refer to tangibles (Ullmer and Ishii 2000; Shaer et al. 2004); "totem" could be another alternative term (Lin 2007). Holmquist et al. consider tools as tangibles for binding to digital operations and faucets as access points for mediating the digital associations of tangibles (be they graphical, audible, haptic, olfactory, etc.).

Other researchers have discussed human language and parts of speech as inspirations for modeling the functionality of tangibles. Underkoffler and Ishii discuss nouns, verbs, attributes, and reconfigurable tools as tangible meanings within Urp (Underkoffler and Ishii 1999). Fishkin also describes noun and verb roles, both metaphorically and functionally (Fishkin 2004).

In another variation, Koleva et al. describe six different categories of tangibles: tools (specialized and general purpose), identifiers, proxies, projections, and illusions-of-same-object (Koleva et al. 2003). Edge and Blackwell make important contributions from the perspective of cognitive dimensions (Blackwell 2003; Edge and Blackwell 2006), grounding their analyses on tangible programming languages.

Development of functional models seems important for the future of tangible interfaces, both toward enabling rich behaviors within individual systems, and fostering interoperability between diverse systems (Ullmer et al. 2008; Ullmer et al. 2010). The above provide a number of promising points of departure; in parallel, we see this as an area where further progress is necessary.

21.8.5 Social

In the context of physical spaces and human relationships, it is known that distance matters (Olson and Olson 2000). Working in adjoining rooms, floors, buildings, or continents has quite different implications for human communications and collaborations (Kraut, Galegher, and Egido 1988). These observations have implications for entanglements between tangible interfaces and human social interactions. As cohabitants within physical space, tangible interfaces have a substantially different relationship with people than their screen-based kin. This relationship varies depending on physical locality, on whether proximal humans are alone or in groups, whether group interaction is collocated or distributed, and on cultural context (Hall 1969; Lawson 2001), among other social implications. Both as individuals and groups, people associate socially informed meanings with things (Csikszentmihaly and Rochberg-Halton

1981; Zigelbaum and Csikszentmihalyi 2009). In collocated groups, physical artifacts are important conversational mediators and facilitators (Hutchins 1995).

Building upon these and related observations, tangibles have been found to enable collocated collaborations that have been difficult to mediate with graphical interface alternatives (Streitz et al. 1999; Ben-Joseph et al. 2001; Eden, Scharff, and Hornecker 2002; Jacob et al. 2002; Hornecker and Buur 2006; Malone et al. 2009). Similar observations and opportunities have also been observed for tangibles mediating distributed collaboration (Brave, Ishii, and Dahley 1998) in both professional (Ishii, Kobayashi, and Arita 1994; Kuzuoka and Greenberg 1999; Moran et al. 1999; Singer et al. 1999; Everitt et al. 2003) and domestic contexts (Dunne and Raby 1994; Strong and Gaver 1996; Dodge 1997; Hindus et al. 2001; Chang et al. 2002). Tangible applications for distributed collaboration include intersections with genres of social media that have recently proved highly popular in mainstream culture (Kuzuoka and Greenberg 1999; Singer et al. 1999; Donath and Boyd 2004; Mackay and Beaudouin-Lafon 2005; Etter and Roecker 2007; Kalanithi and Michael Bove 2008).

21.9 GENRES OF TANGIBLE USER INTERFACE APPLICATIONS

TUIs have been used within a wide variety of application domains. This section gives an overview of seven genres for promising TUI applications. For a more exhaustive survey of TUIs in historical context, we encourage readers to refer to Ullmer and Ishii (2000) and Shaer and Hornecker (2009).

21.9.1 Constructive Assemblies

One of several structural approaches, the constructive assembly approach draws inspiration from LEGO and building blocks, centering upon the assemblage and interconnection of modular physical elements. This subdomain is typically concerned with the mechanical interconnection and kinetic relationships between systems of tangibles.

The constructive assembly approach was pioneered by Aish and Frazer in the late 1970s and early 1980s. Aish developed BBS for thermal performance analysis (Aish 1979; Aish and Noakes 1979). Frazer developed a series of intelligent modeling kits such as “Universal Constructor” (Frazer, Frazer, and Frazer 1980; Frazer 1994) for modeling and simulation. Additional examples include Geometry-Defining Processors (Anagnostou et al. 1989), AlgoBlock (Suzuki and Kato 1993), Triangles (Gorbet, Orth, and Ishii 1998), Blocks (Anderson et al. 2000), ActiveCube (Kitamura, Itoh, and Kishino 2001), and System Blocks (Zuckerman and Resnick 2004). Topobo (Raffle, Parkes, and Ishii 2004) inherited properties from both “constructive assemble” and “tangibles with kinetic memory” (Section 21.9.6).

21.9.2 Tokens and Constraints

“Tokens and constraints” is another structural approach, often concerned with tangibles linked to abstract digital information and manipulated using mechanical constraints (Ullmer, Ishii, and Jacob 2005). In this context, tokens are discrete, spatially reconfigurable tangibles that represent digital information or operations. Constraints are confining regions within which tokens can be placed. Constraints are mapped to digital operations or properties that are applied to tokens placed within their confines. Constraints are often embodied as physical structures that mechanically channel how tokens can be manipulated, often limiting their movement to a single physical dimension.

The Marble Answering Machine (Crampton Smith 1995) is a classic example that influenced many following research efforts. MediaBlocks (Ullmer, Ishii, and Glas 1998), LogJam (Cohen, Withgott, and Piernot 1999), DataTiles (Rekimoto, Ullmer, and Oba 2001), and tangible query interfaces (Ullmer, Ishii, and Jacob 2003) are other examples of this genre.

21.9.3 Interactive Surfaces

Interactive surfaces are likely the most popular structural approach for tangible interfaces. Both horizontal interactive surfaces, sometimes called tabletop TUIs or tangible workbenches, and vertical interactive surfaces/walls are common variations. Collaborative design, simulation, and performance, typically keying on the spatial/positional configurations of tangibles, have been explored by numerous researchers. In a typical augmented workbench, discrete tangible objects are manipulated, with their movements sensed by the workbench. Visual feedback is provided on the workbench surface, with coincident input/output space updated in real-time.

Digital Desk (Wellner 1993) is a pioneering work in this genre. Other examples include Bricks (Fitzmaurice, Ishii, and Buxton 1995b), metaDESK (Ullmer and Ishii 1997), InterSim (Arias, Eden, and Fischer 1997), Illuminating Light (Underkoffler and Ishii 1998), Urp (Underkoffler and Ishii 1999), Build-It (Rauterberg et al. 1998), Sensetable (Patten et al. 2001), AudioPad (Patten, Recht, and Ishii 2002), IP Network Design Workbench (IPNWDWB) (Kobayashi et al. 2003), Reactable (Jorda et al. 2007), and Lumino (Baudisch, Becker, and Rudeck 2010). Among wall-oriented systems, the ClearBoard was an early work (Ishii, Kobayashi, and Arita 1994), with LegoWall (Fitzmaurice 1996), Collaborage (Moran et al. 1999), Designer’s Outpost (Klemmer et al. 2001), and SenseBoard (Jacob et al. 2002) as additional well-known examples.

21.9.4 Continuous/Plastic Tangible User Interfaces

One limitation of early TUIs was an inability to change the forms of tangible representations during interaction. Users engaged predefined sets of fixed-form objects, changing the spatial relationship between them but not the forms of tangibles themselves. As an alternative, some TUI systems utilize continuous tangible materials such as clay and sand. Examples include Illuminating Clay (Piper, Ratti, and Ishii 2002), SandScape (Ishii et al. 2004), Phoxel-Space project (Ratti et al. 2004), and Digital Clay (Reed 2009).

21.9.5 Tangible Telepresence

Another tangibles genre concerns the mapping of haptic input to haptic representations over a distance. Also called "tangible telepresence," an underlying mechanism is the synchronization of distributed objects and the gestural simulation of "presence" artifacts, such as movement or vibration. These can allow remote participants to convey haptic manipulations of distributed physical objects. One outcome is giving remote users the sense of ghostly presence, as if an invisible person was manipulating a shared object. inTouch (Brave and Dahley 1997), HandJive (Fogg et al. 1998), and ComTouch (Chang et al. 2002) are illustrative examples.

21.9.6 Tangibles with Kinetic Memory

The use of kinesthetic gestures and movement is another promising application genre. For example, educational toys promoting constructionist learning concepts have been explored using actuation technology, taking advantage of tangible interface's input/output coincidence. Gestures in physical space can illuminate symmetric mathematical relationships in nature, and kinetic motions can be used to teach children concepts ranging from programming and differential geometry to storytelling. Curlybot (Frei et al. 2000) and topobo (Raffle, Parkes, and Ishii 2004) are examples of toys that distill ideas relating to gesture, form, dynamic movement, physics, and storytelling.

21.9.7 Augmented Everyday Objects

Augmentation of familiar everyday objects is an important approach for tangible interfaces to lower the design and conceptual floor, and make it easier to access and engage with basic tangible concepts. Early context from DuChamp's readymades is described in Goldsmith (1983) and Holmquist, Schmidt, and Ullmer (2004). Tangible interface examples include the Paper Audio Notebook (Stifelman 1996), musicBottles (Ishii et al. 1999), HandScape (Lee et al. 2000), Webstickers (Ljungstrand, Redström and Holmquist 2000), Everyday Media (Mynatt 2000), LumiTouch (Chang et al. 2001), Designers' Outpost (Klemmer et al. 2002), I/O Brush (Ryokai, Marti, and Ishii 2004), and iCon (Cheng et al. 2010). As evidenced by DuChamp (Goldsmith 1983), this genre seems particularly open to interpretation by artists and designers, toward questioning and engaging how everyday physical artifacts evolve with technology.

21.9.8 Ambient Media

In our early stages of tangibles research, we explored ways of improving the quality of interaction between people and digital information. We used two approaches for extending interaction techniques to the physical world:

- Allowing users to "grasp and manipulate" foreground information by coupling bits with physical objects
- Enabling users to be aware of background information at the periphery using ambient media in an augmented space

At that time (the mid-1990s), HCI research had focused primarily on foreground activity on the screen, neglecting the rest of the user's computing environment (Buxton 1995). However, people subconsciously receive ambient information from their peripheral senses without attending to these explicitly. If something unusual is noticed, it is awakened to our attention, and we can decide whether to bring it to the foreground. For example, people are subconsciously aware of the weather outside their window. If the user were to hear thunder or a sudden rush of wind, they can sense from their peripheral attention that a storm is on its way. If they wished, they could then look outside, attending to details, or continue working without distraction.

Ambient media describes a class of interfaces that is designed to smooth the transition of the user's focus of attention between background and foreground. For example, Natalie Jeremijenko's Live Wire (at Xerox PARC, 1995) was a spinning wire that moved to indicate network traffic. Designing such simple, legible representations for ambient media using tangible objects is a key part of the challenge of Tangible Bits (Ishii and Ullmer 1997).

The ambientROOM was a project that explored the ideas of ambient media, based upon a special room equipped with embedded sensors and ambient displays (Ishii et al. 1998). This work was a preliminary investigation into background/peripheral interfaces, and led to the design of standalone ambient fixtures such as Pinwheels and Walter Lamp that make users aware of "digital wind" and "bits of rain" at their peripheral senses (Dahley, Wisneski, and Ishii 1998).

Strictly speaking, ambient media lives at the edges of the TUI design space, as in many cases there are no direct interactions. Nonetheless, ambient media can serve as background information displays complementing tangible/graspable media that users manipulate in their foreground. The TUI approach to ambient media is concerned with design of simple mappings that give easy-to-understand form to information from cyberspace, representing related changes in subtle ways.

This concept of "ambient media" is now widely studied in the HCI community as a way to turn architectural/physical spaces into ambient, calm information environments (Wisneski et al. 1998; Redstrom, Skog, and Hallnas 2000; Holmquist and Skog 2003; Mankoff et al. 2003; Pousman and Stasko 2006). Another design space is low-attention interfaces for interpersonal communication through ambient media (Chang et al. 2001). This area has also been the subject of several commercialized products, such as Ambient Devices' Ambient Orb and Weather Beacon (http://www.ambientdevices.com/), and GlowCaps from Vitality (http://www.vitality.net/).

21.10 TANGIBLE USER INTERFACE INSTANCES

Next, several specific examples of tangible interfaces are presented both to illustrate the potential application domains described in Section 21.9 and to highlight unique features of TUIs. Since the mid-1970s, hundreds of tangible interfaces have been realized from scores of groups on every continent. Although not fully representative of broader community efforts, we describe a set primarily from the Tangible Media group's work of the past 15 years. We have chosen a subset that is illustrative of broader design spaces, as examples where our interpretations can go beyond the original published content. For a more broadly representative set of examples, we refer the reader to Ullmer and Ishii (2000), Mazalek and van den Hoven (2009), Shaer and Hornecker (2009), and Baskinger and Gross (2010). As illustrative examples beyond those described elsewhere in this chapter, we commend the reader to Reactable (Jorda et al. 2007; Jorda 2008), ISH (Hummels and Helm 2004), the Slot Machine (Perlman 1976; McNerney 2004), MONIAC (1952), Passive Props (Hinckley et al. 1994), Environment Audio (Oba 1990; Ullmer 2002), DataTiles (Rekimoto, Ullmer, and Oba 2001), Meatbook (Levisohn et al. 2007), CabBoots (Frey 2007), TinkerSheets (Zufferey et al. 2009), Lumen (Poupyrev, Nashida, and Okabe 2007), GeoTUI (Couture, Riviere, and Reuter 2008), Lilypad (Buechley et al. 2008), Siftables (Merrill, Kalanithi, and Maes 2007), BeatBearing (Bennett 2010), and SMSlingshot (Fischer et al. 2010).

21.10.1 DigitalDesk: A Pioneer of Tabletop Tangible Interfaces

DigitalDesk (Wellner 1993) was a pioneering system and vision that demonstrated ways to integrate physical and digital document processing on a table. Wellner brought functionality we typically associate with GUIs onto the physical desktop. He used a camera and a microphone to detect finger interaction on a graphical interface displayed on a desk with a video projector. Wellner used this desk for tasks such as graphic design and spreadsheet computations involving printed physical paper. This system also used and envisioned several kinds of physical props.

DigitalDesk illustrates compelling reasons for considering computer interfaces based on horizontal interactive surfaces. With many worksurfaces in our environment already existing as planar horizontal surfaces, integrating computation into these surfaces may provide opportunities for new types of relationships between cyberspace and physical objects. This juxtaposition may also help create computer systems that are more relevant to problem domains with established tabletop-based work practices. The DigitalDesk inspired many tabletop tangible interfaces including the Luminous Room (Underkoffler, Ullmer, and Ishii 1999), Urp (Underkoffler and Ishii 1999), and Sensetable (Patten et al. 2001).

21.10.2 Sensetable and AudioPad: A Tabletop TUI for Real-Time Music Performance

Sensetable (Patten et al. 2001) is a system that wirelessly tracks the positions of multiple objects on a flat display surface. Sensetable serves as a common platform for a variety of tabletop TUI applications such as AudioPad and the IPNWDWB.

AudioPad (Patten, Recht, and Ishii 2002) is a composition and performance instrument for electronic music. It tracks the positions of tangibles on a tabletop surface, and uses physical interactions with these to performatively engage with electronic music. AudioPad allows performers to pull sounds from a large repertoire of samples; juxtapose archived recordings against warm synthetic melodies; cut between drum loops to create new beats; and apply digital processing, all in parallel on the same physical table. AudioPad both allows for spontaneous reinterpretation of musical compositions, and creates a visual and tactile dialog between itself, the performer, and the audience.

AudioPad is based on the Sensetable platform. This uses a 2D array of antenna elements to track the positions of tagged tangibles. Each tangible represents either a musical track or a microphone (Photo 21.4). Software translates the identity and position of these tangibles into music and graphical feedback.

Experience with AudioPad in a series of live performances suggests that tabletop interaction with musically and graphically mediated tangibles can be a powerful and satisfying medium for musical expression. The seamless integration of input and output spaces allows the performer to focus on making music, rather than using the interface. The spatially multiplexed inputs of TUI also provide a compelling means for multiple musicians to collaboratively perform (Photo 21.5).

21.10.3 IP Network Design Workbench: An Event-Driven Simulation on Sensetable

The IPNWDWB is a collaborative project between NTT Comware and the Tangible Media Group. The IPNWDWB supports collaborative network design and simulation by groups of experts and customers (Kobayashi et al. 2003). This system is also based on the Sensetable platform, which wirelessly detects the location and orientation of physical pucks. The simulation engine is based on an event-driven simulation model. Using Sensetable, users can directly model and manipulate network topologies, control node and link simulation parameters, and simultaneously see simulation results projected onto the table in real-time (Photo 21.5).

The goal of IPNWDWB is to make simulation tools more accessible for nonexperts, so they can join the network design process and interact with experts more easily than when using traditional GUI computers. This system was commercialized and has been used for collaborative network design with customers to ensure their understanding of the performance and cost of network enhancements—for example, concerning

PHOTO 21.4 AudioPad running on Sensetable platform. Audiopad is a composition and performance environment for electronic music. Tangibles are tracked on an interactive tabletop system; their evolving physical/digital state is transformed into music.

PHOTO 21.5 IP Network Design Workbench running on Sensitable platform. The IP Network Design Workbench supports collaborative network design and simulation by multiple experts and customers on the Sensetable platform using an event-driven simulation engine.

increases in network traffic caused by Voice over IP and/or streaming video. The large horizontal work surface and tangible interaction invites participants to touch and manipulate pucks simultaneously, helping the decision-making process to become more democratic and convincing.

Comparing IPNWDWB with Urp, we see a substantial difference in the nature of applications. In Urp, the principle tangibles were physical scale models of buildings, which humans have used for 1000 years in the design of cities. It is natural to apply TUIs to such domains where physical models have been used and surrounding work practices established long before the birth of digital computers.

In contrast, IP Network Design is based on event-driven simulation models that are quite abstract, new, and largely dependent on computers. IPNWDB is important in its demonstration that tangible interfaces can empower the design process even for abstract application domains that do not have straightforward mappings from abstract concepts to physical objects. A wide range of modeling and simulation techniques, such as system dynamics and event-driven simulation, use 2D graph representation. We learned that many such applications can be supported by Sensetable-like TUI platforms in collaborative design sessions. For example, simultaneously changing parameters, transferring control between different people or different hands, and distributing the adjustment of simulations dynamically are interactions enabled by TUI.

21.10.4 Actuated Workbench: Closing the Loop between Sensing and Computational Actuation

The tabletop tangible interfaces we have discussed share a common weakness. While input occurs through the physical manipulation of tangibles, output is displayed only through sound or graphical projection on and around the objects. As a result, the tangibles can feel like loosely coupled handles to digital information, rather than physical manifestations of the information itself.

In addition, users must sometimes compensate for inconsistencies when links between digital data and tangibles are broken. Such broken links can arise when a change occurs in the computer model that is not reflected in a physical change of its associated object. With the computer system unable to move the tangibles, it cannot physically undo user input (e.g., restore the physical state of tangibles), correct physical inconsistencies in tangible layouts, or physically guide the user in the manipulation of tangibles. As long as this is so, the physical interaction between human and computer remains one-sided.

To address this problem, the Actuated Workbench was designed to provide a hardware and software infrastructure allowing tangibles to be moved on an interactive surface in two dimensions under computational control (Pangaro et al. 2002). The Actuated Workbench uses an array of magnets to move one or multiple objects upon a table. It is intended for use with existing tabletop tangible interfaces, providing an additional feedback loop for computer output and helping to resolve inconsistencies.

Actuation enables a variety of new functions and applications. For example, a search and retrieve function could respond to a user query by (say) moving matching items to another place on the tabletop, or wiggling them to seek the user's attention. Going a step further, a set of tangibles could, under computational control, be physically sorted and arranged on the table according to user-specified parameters. This could help the user organize a large number of data items, sets, or databases (each equally appropriate for tangible embodiment) before manually interacting with them. As a user makes changes to data through physical interaction, he or she may wish to undo some changes. A physical undo could move tangibles back to their positions before the last change. It could also show the user the exact sequence of movements he or she had performed. In this sense, both "undo" and "rewind" commands are possible.

One advantage of tabletop TUIs is the ease with which multiple users can make simultaneous changes to the system. Users can observe each other's changes, with any user reaching out and physically changing the shared layout. The situation is altered when users collaborate remotely. Here, a mechanism for physical actuation of tangibles becomes valuable for synchronizing tangibles upon physically separated workbenches (Photo 21.6). Without such a mechanism, real-time physical synchronization of the tables would not be possible, and inconsistencies could arise between the graphical projection and the tangible's physical state.

In addition to facilitating synchronization, the Actuated Workbench can recreate remote users' gestures with objects on the table, adding considerably to the "ghostly presence" sought in remote collaboration interfaces (Brave, Ishii, and Dahley 1998). This approach is in resonance with broader trends in embodied telepresence (Paulos and Canny 1998; Jouppi et al. 2004).

As an example application, Actuated Workbench was found to be helpful in teaching students about physics by demonstrating attraction and repulsion of charged particles (represented by pucks on the table). As students moved tangibles about the table, the system could make them pull together or push apart, illustrating the forces between the objects. A major next-generation system built upon the workbench platform, Pico, added both actuated and passive mechanical constraints, and realized a cell phone tower placement domain application (Patten and Ishii 2007) (see Photo 21.6).

21.10.5 SandScape: A Continuous Tangible User Interface for Landscape Design

SandScape (Ishii et al. 2004) is a tangible interface for designing and understanding landscapes through the combination of physical sand and a variety of computational simulations. Users view these simulations projected on the surface of a sand model representing terrain. Users can choose from

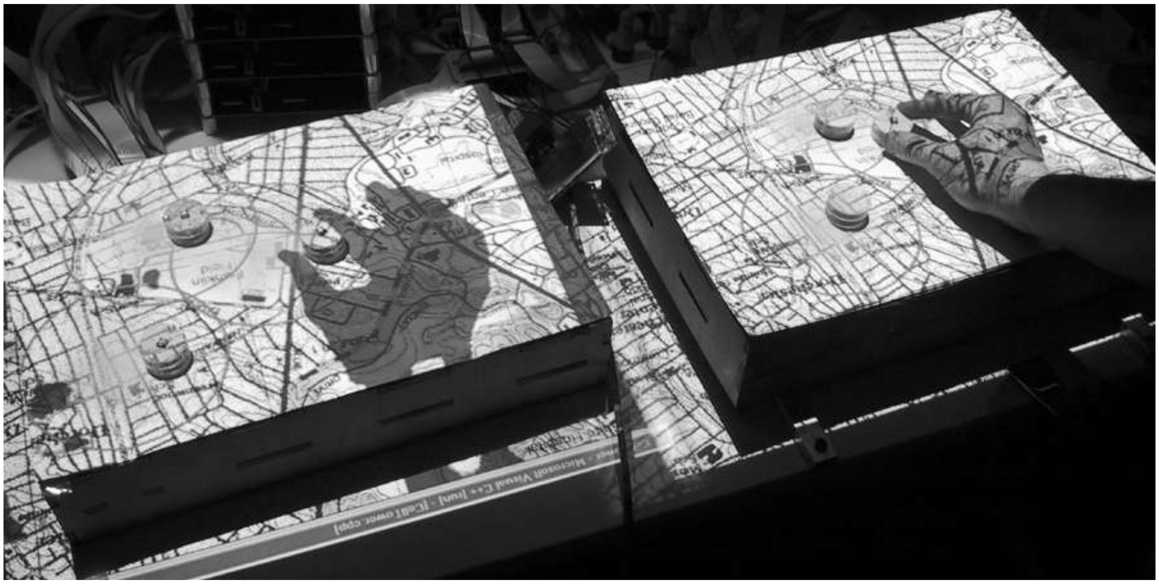

PHOTO 21.6 Actuated Workbench used for distributed collaboration. A mechanism for physical actuation of the pucks becomes critical for synchronizing multiple physically separated workbench stations.

a variety of different simulations that highlight the height, slope, contours, shadows, drainage, or aspect of the landscape model (Photo 21.7).

Users can alter the form of the landscape model by manipulating sand, seeing the resultant effects of computational analysis generated and projected on the sand's surface in real-time. The project illustrates how TUIs can leverage our ability to understand and manipulate physical forms, while still harnessing the power of computational simulation to help our understanding of model systems.

Our SandScape configuration was based on a box containing millimeter-diameter glass beads, lit from beneath with an array of 600 high-power infrared light-emitting diodes (LEDs). Four IR mirrors were placed around the LED array to generate a more even radiance distribution. A monochrome IR camera was mounted 2 meters above the surface of the beads, capturing the intensity of light passing through the volume. The intensity of transmitted light is a function of the depth of the beads; a look-up table was used to convert surface radiance values into surface elevation values. The system was calibrated to work with a specific bead size and type. SandScape is less accurate than its predecessor, Illuminating Clay, which used laser range finder to capture the geometry of a clay model; but at the time, the infrared approach was roughly one-hundredth the cost of the laser scanner (Piper, Ratti, and Ishii 2002).

SandScape and Illuminating Clay illustrate some of the potential advantages of combining physical and digital representations for landscape modeling and analysis. The physical clay and sand models convey spatial relationships that can be intuitively and directly manipulated by hand. Users can also insert any found physical objects directly under the camera. This approach allows users to quickly create and understand highly complex topographies that would be difficult and time-consuming to produce with conventional CAD tools. We believe this "continuous/plastic TUI" approach makes better use of our natural abilities to discover solutions through the manipulation of physical objects and materials.

In parallel, projected graphics give users real-time feedback. While tracked physical models interfaced with computers were not in themselves novel, we believe that SandScape and Illuminating Clay offered a new contribution by using the model's continuous surface geometry itself as the input/output mechanism. In this way, we hoped to give projective intangible information the same tangible immediacy as the clay/sand material itself, allowing quantitative data to support an intuitive understanding of the landscape.

Landscape architecture, as well as urban and architectural design, requires the collaboration of multiple specialists. These include earth engineers, water engineers, agrarian managers, land economists, transport engineers, and beyond. In the current design process, collaboration happens at different stages, sometimes without much direct interaction. SandScape and Illuminating Clay provide a common platform for collaboration centered on the table workspace. Numerous representations and analyses can be combined in a single design environment, potentially offering greater cohesion between different specialists and streamlining the design process.

21.10.6 MusicBottles: A Transparent Interface of Augmented Glass Bottles

MusicBottles introduced a tangible interface where physical bottles serve as containers and controls for digital information (Photo 21.8). The system consists of a specially designed table and systems of corked bottles that "contain" the voices of contributing instruments. For example, a classical variation (containing Edouard Lalo's Piano Trio in C Minor,

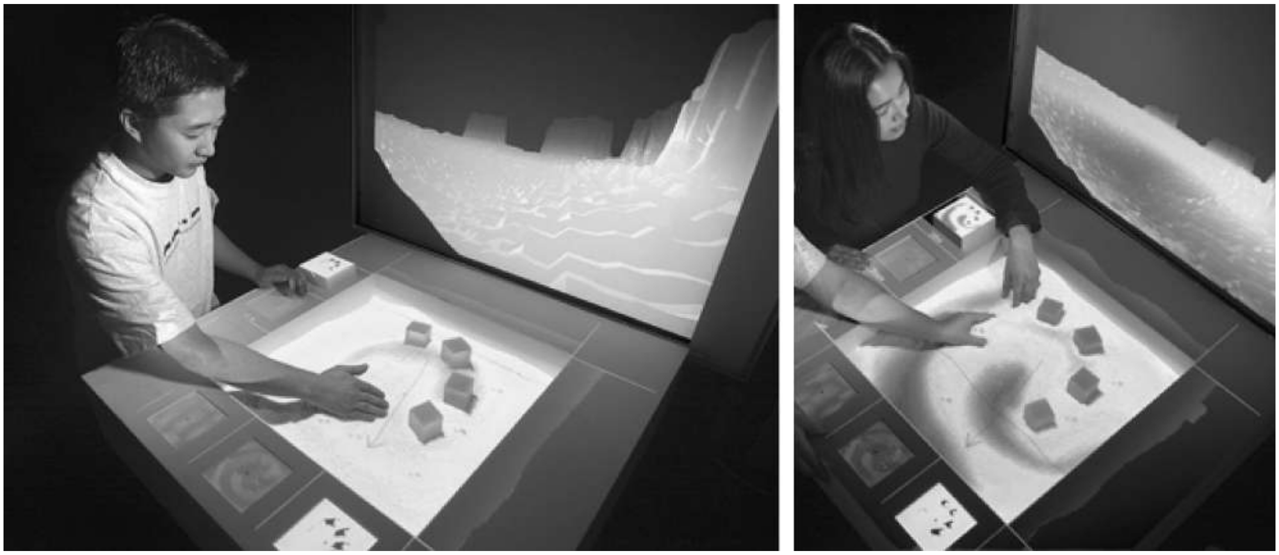

PHOTO 21.7 Using SandScape, users can alter the form of a landscape model by manipulating sand. The effects of computational analysis are generated and projected upon the sand's surface in realtime.

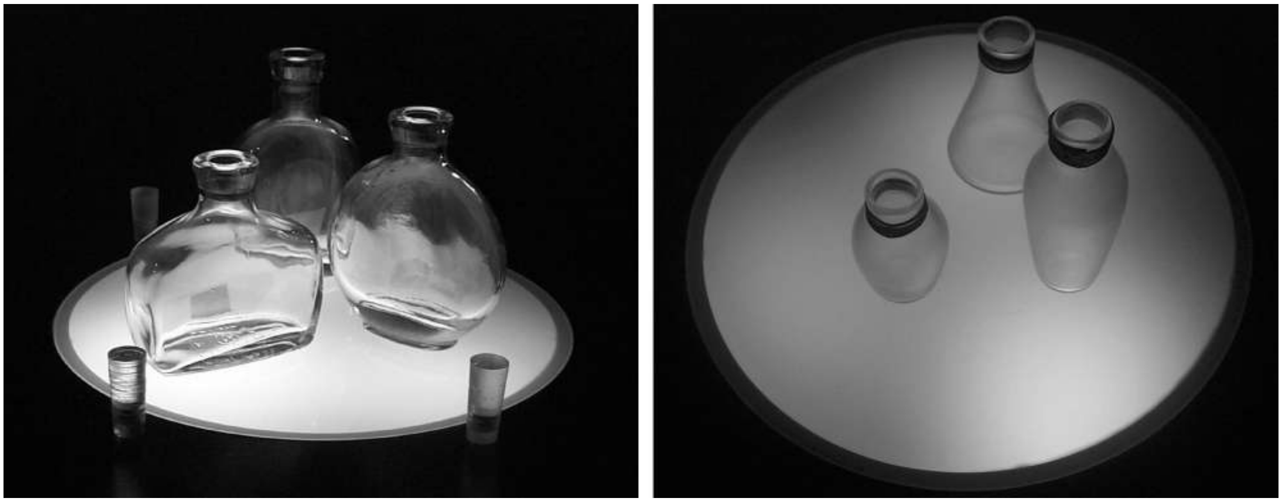

PHOTO 21.8 musicBottles. musicBottles is a tangible interface in which bottles exist as containers and controls for digital information. The system includes a specially designed table and (here) three corked bottles that "contain" the sounds of classical, jazz, and techno music. The interface allows users to structure the experience of the musical composition by physically manipulating the different sound tracks.

Op. 7) contained three bottles—violin, cello, and piano; bottle sets for jazz, electronic music, weather, and various spoken voice ensembles—were also realized. Custom electromagnetic tags embedded in the bottles and their stoppers enable each to be individually identified.

When a bottle is placed onto the stage of the instrumented table, the system identifies the bottle, and illuminates the stage to indicate the bottle has been recognized. The opening and closing of bottles is also detected; as the stopper is removed, the corresponding instrument becomes audible. A pattern of colored light is rear-projected onto the table's translucent surface to reflect changes in each instrument's pitch and volume. The interface allows users to structure the experience of the musical composition through physically manipulating the contributing voices.

Humans have used glass bottles for thousands of years. Through extending the affordances and metaphors of physical bottles within our interwoven physical and digital world, the bottles project explored new dimensions of interface transparency (Ishii 2004).

A wide variety of contents, including music, weather reports, poems, and stories were designed to investigate the concept (Ishii et al. 1999). The arrangement of many hand-blown musicBottles upon the purpose-designed table; the feel of the glass on opening; the music; and the light from the LED lamps, illuminating the sometimes diffuse, cracked, and colored glass together create a highly evocative aesthetic experience—one not found from the click of a mouse.

Potential applications are not limited to music. One might imagine perfume bottles filled with poetry, or wine bottles that decant stories (Mazalek, Wood, and Ishii 2001). More practical applications might include medicine chests of bottles that tell the user how and when to take them, and let the hospital know when they do. (This scenario has begun to be realized with Vitality's GlowCaps.) As an intimate part of our daily lives, augmented glass bottles offer a compelling instance and vision for simple, cognitively transparent tangible interfaces.

21.10.7 InTouch: Tangible Telepresence through Distributed Synchronized Physical Objects

InTouch explored new forms of interpersonal communication over distance through touch by preserving the physical analog movement of synchronized distributed rollers (Brave and Dahley 1997; Brave, Ishii, and Dahley 1998). Force feedback was used to create the illusion that people, separated by distance, are interacting with a shared physical object. The "shared" object provides a haptic link between geographically distributed users, opening a channel for physical expression over distance.

InTouch is a paired tangible, with each built around three rollers (Photo 21.3). Each roller is synchronized to the corresponding roller on the distant peer mechanism; when one roller is moved, the corresponding distant roller also moves. If the movement of one roller is held, the roller transmits that resistance to the other roller. The rollers are in a sense connected by a stiff computational spring. Two users separated by distance can then play, moving or tapping the rollers or more passively feel the other person's manipulation of the object. The presence of the other person is represented tangibly through physical interaction with the inTouch device.

Force feedback is commonly used to allow a user to "touch" virtual objects in the computer screen through a single point. Instead, inTouch applies this technology to realize a link for interpersonal haptic communication. InTouch allows people to feel as if they are connected through touching the rollers, to another person. Instead of touching inanimate objects, each person is touching a dynamic, shared physical object.

Some of the important features of inTouch from an HCI perspective include the following:

1. No boundary between "input" and "output" (input/output coincidence: the wooden rollers are force displays as well as input devices)
2. The principal instruments of human input and output are the hands, not the eyes/ears (with touch being the primary modality)
3. Information can be sent and received simultaneously through one's hands

The telephony and telepresence communities have framed their ultimate goal as reproducing human voice and imagery as realistically as possible, toward creating the illusion of "being there." In the spirit of "beyond being there" (Hollan and Stornetta 1992), inTouch takes the opposite approach, making users aware of the remote partner without rendering them in bodily terms, creating what we call a tangible or ghostly presence. By seeing and feeling tangibles physically moving with human nuance, we imagine the influence of ghostly bodies. This concept of ghostly presence provides us an alternate perspective—a minority report, as it were—on potential futures for telepresence.

21.10.8 Curlybot: A Toy to Record and Play

Curlybot is a toy that can record and replay physical motion (Photo 21.9). As one plays with the device, it remembers how it has been moved, and can replay this movement with all the intricacies of the original gesture. Every pause and acceleration, even shaking in the user's hand, is recorded. Curlybot then repeats this gesture indefinitely, creating beautiful and expressive patterns. Children can use curlybot to gain a strong intuition for advanced mathematical and computational concepts (e.g., differential geometry) through play in a context fully apart from traditional HCI (Frei et al. 2000).

The actuation technology developed for real-time communication in inTouch was used in curlybot for gestural recording and playback. Two motors equipped with an optical encoder enable free rotation, in addition to forward and backward movement.

PHOTO 21.9 Curlybot. Curlybot is a toy that records and plays back physical motion. Curlybot remembers how it has been moved by human users, and can replay this movement with all the intricacies of the original gesture. Every pause and acceleration – even shaking in users' hands – is recorded and repeatedly relived, allowing simple gestures to expand into complex geometric patterns.

When the user presses curlybot's lone button, a proximal LED is illuminated, indicating recording is in progress. The user then moves curlybot about; meanwhile, an encoder records this embodied gesture. Pushing the button a second time terminates recording; the LED passes from red to green, indicating playback is in progress. The internal microprocessor compares the current position with stored positions, and guides the motors toward retracing the steps within curlybot's memory.

This project contributes both to interface design and education. As a tangible interface, like inTouch, curlybot blurs the boundary between input and output. Curlybot is the indivisible sum of both an input device which record gestures, and a self-actuating display that re-enacts them. By allowing the user to teach curlybot gestures with her hand, then bodily re-enacting these gestures in physical space, curlybot enables a strong connection between body and mind—one going beyond any facsimile expressible on a computer screen.

From an educational standpoint, curlybot allows very young children to explore "advanced" mathematical and computational concepts. Curlybot supports new ways of thinking about geometric shape and pattern. Children can use curlybot to explore basic ideas behind computational procedures, such as how complexity can result from simple primitives. This is similar to outcomes possible with the Logo programming language, but does not require children to read or write, thus making powerful ideas experientially accessible to younger children. Curlybot also draws strongly on children's intuition about their own physical actions in the world toward the ends of learning—what Seymour Papert calls "body syntonic learning" (Papert 1980). Finally, the direct input and beautifully expressive patterns that result from curlybot's Mnemosynetic dance keep children playing and engaged.

21.10.9 Topobo: Three-Dimensional Constructive Assembly with Kinetic Memory

Topobo, from the terms "topology" and "robotics," is a three-dimensional (3D) constructive assembly system with kinetic memory (Raffle, Parkes, and Ishii 2004). Like curlybot, topobo has the ability to record and replay physical motion. By snapping together a combination of passive (static) and active (motorized) components, Topobo users can quickly assemble dynamic, biomorphic forms (e.g., resembling animals and skeletons). Topobo allows users to animate these forms by recording movement—for example, pushing, pulling, and twisting—and later observe the system cyclically replay these motions. This kinetic memory aspect is inherited from curlybot, while its constructive geometric language derives from the commercial toy Zoob.

As an example, a dog can be constructed, then taught to gesture and walk by twisting its body and legs. The dog will repeat these movements, walking indefinitely forward (as space allows). Similar to the ways people learn about static structures through passive building blocks, users can learn about dynamic structures through play with topobo. Topobo embeds computation within a dynamic building system, allowing gestural manipulation to become a kind of primitive programming language (Photo 21.10).

Topobo was inspired by current trends in computational media design, and by artists and empiricists using visual explorations and models of natural phenomena to more deeply appreciate patterns found within the natural world. In this spirit, Topobo allows people to use experimentation, play, and self-expression to discover and explore relationships between natural forms and dynamic motion.

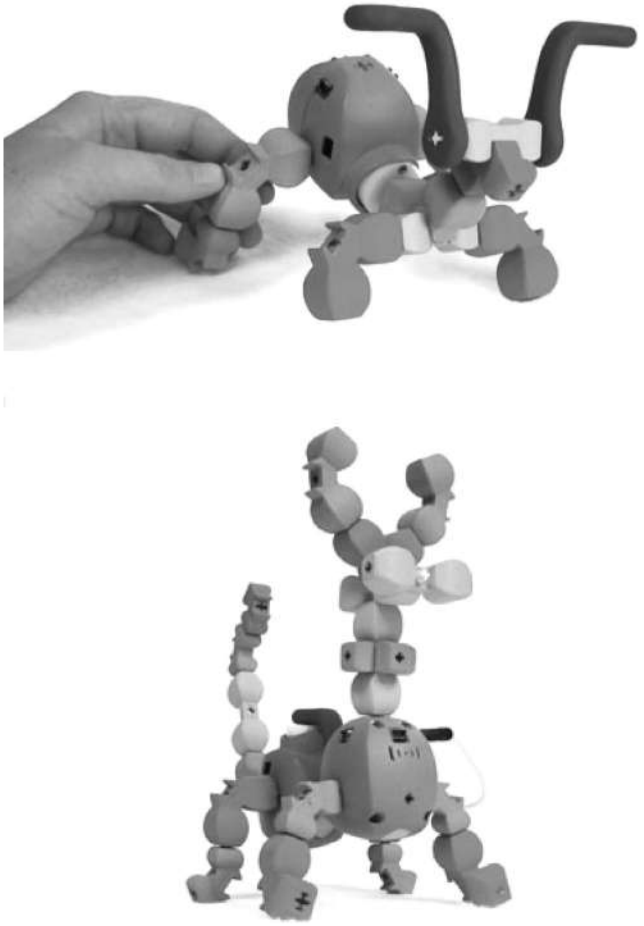

PHOTO 21.10 Topobo. Topobo is a 3D constructive assembly system with kinetic memory: the ability to record and play back physical motion. Topobo is distinguished by its coincident physical input and output behaviors.

21.10.10 MediaBlocks: A Token and Constraint-Based System

The mediaBlocks system is a tangible interface for manipulating lists of online digital media such as video clips and images (Ullmer, Ishii, and Glas 1998). Whereas Urp provides a spatial interface for leveraging object arrangements consistent with real-world building configurations, the mediaBlocks system provides a relational interface for manipulating more abstract digital information.

MediaBlocks are small, digitally tagged blocks, dynamically bound to elements or lists of online media. MediaBlocks support two major modes of use. First, they function as containers for physically embodying network-based (cloud) media, and for moving it between different media devices (e.g., conference room cameras, digital whiteboards, wall displays, and printers). In a sense, this role combines a tangible container with physically situated copy and paste.

Second, mediaBlocks can be used as physical containers and controls on a media sequencing device (Photo 21.11). Partially modeled after the tile racks of the board game Scrabble^{TM} a "sequence rack" allows the media contents

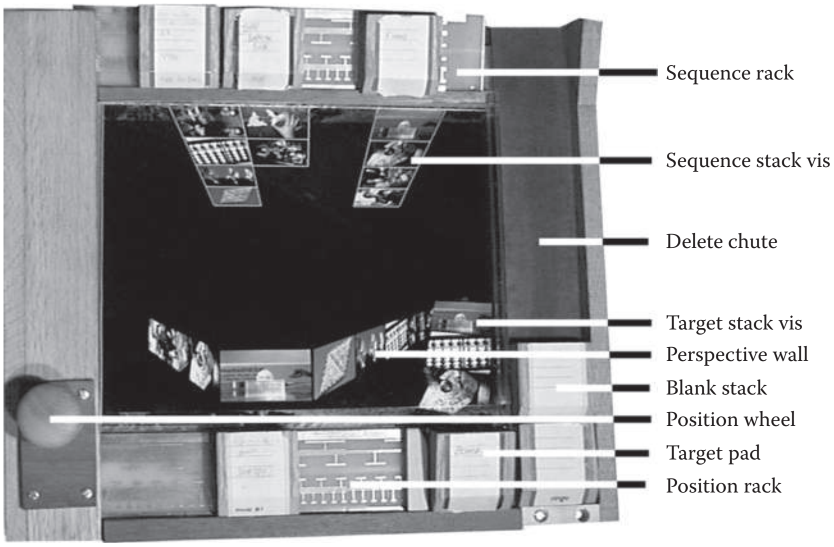

PHOTO 21.11 MediaBlocks: media sequencing device. The mediaBlocks system is a tangible interface for manipulating lists of online digital media (e.g., video clips and images). MediaBlocks act as both containers and controls, with behaviors determined by physical constraints within artifacts like this media sequencing device.

of multiple adjacent mediaBlocks to be copied into a new mediaBlock container. Similarly, a "position rack" maps the physical position of a block to an indexing operation upon its contents. When mediaBlocks are positioned on the left edge of the position rack, the first media element of the block is selected. Intermediate physical positions on the rack provide access to later elements in the associated media list of the block. Like its Marble Answering Machine, TuneTown, and LogJam predecessors (Crampton Smith 1995; Cohen, Withgott, and Piernot 1999; Singer et al. 1999), and descendants like Tagged Handles and Tangible Query Interfaces (MacLean, Snibbe, and Levin 2000; Ullmer, Ishii, and Jacob 2003), mediaBlocks illustrates how systems of physical tokens and constraints can embody and support manipulation of abstract digital information and operations.

21.10.11 Pinwheels: Ambient Interfaces to Digital Information

Pinwheels is an example of ambient media. They demonstrate a new approach to interfacing people with online digital information through subtle changes in sound and movement, perceptible in the background of awareness. Pinwheels spin in a "wind of bits," representing an invisible flow of digital information such as network traffic, embodied as physical movement within architectural spaces (Photo 21.12).

Nature is filled with subtle, beautiful, expressive ambient media that engage each of our senses. The sounds of rain and feelings of warm wind on our cheeks help us understand and enjoy the weather even as we engage in other activities. Similarly, we are aware of the activity of neighbors through passing sounds and shadows at the periphery of our attention. Cues like an open door or lights in an office help us subconsciously understand the activities of other people, and communicate our own activity and availability.

Current personal computing interfaces largely ignore these rich ambient spaces, and squeeze vast amounts of digital information into small rectangular screens. We seek to broaden the concept of "display," making use of the entire physical environment as an interface. Using ambient media, information can be manifested as subtle changes in form, movement, sound, color, smell, temperature, or light. We call such systems ambient displays.

PHOTO 21.12 Pinwheels. Pinwheels is an example of ambient information display. The flow of digital information is presented at the periphery of human perception.

Pinwheels evolved from the idea of using airflow as ambient media. However, we found the flow of air itself was both difficult to control, and challenging to interpret as a conveyance of information. As an alternative, we envisioned that a visual/physical representation of airflow based on spinning pinwheels could be both legible and poetic. Pinwheels spin in the "bit wind" with different speeds and dynamics based upon their evolving information source. For example, an atmospheric scientist might map patterns of solar wind into patterns of pinwheel spinning within a room.

We envisioned ambient displays as being sited at many locations in architectural space, and suited to the display of the following:

1. Human presence (awareness of physically and/or temporally remote human activities and status)
2. Atmospheric and astronomical phenomena
3. General states of large and complex systems (e.g., diverse physical and digital infrastructure)

There are many design challenges surrounding ambient displays. One is the mapping of information to physical motion and other ambient media. A designer of ambient displays must transform digital data into a meaningful pattern of physical motion that successfully communicates the source information. The threshold between foreground and background is another key issue. Ambient displays are expected to go largely unnoticed until some change in the display or of users' attention brings it into the attentional foreground. How to best keep the level of display at the threshold of attention remains an open design issue.

21.11 CONTRIBUTIONS OF TANGIBLE USER INTERFACES

Tangible interfaces have several important advantages over traditional graphical interfaces within certain contexts, as well as attendant limitations. This section summarizes and discusses some of these.

21.11.1 Double Interaction Loop—Immediate Tactile Feedback

One important advantage of TUI is that users receive passive haptic feedback from tangibles as they are grasped and manipulated. This allows users to complete actions kinesthetically without waiting for digital (primarily visual) feedback.

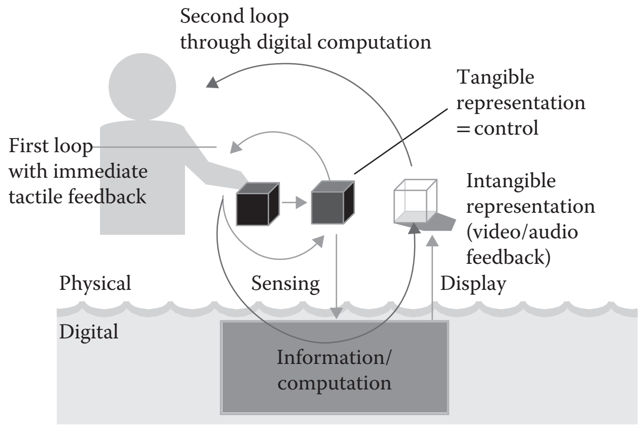

FIGURE 21.4 TUI's Double Feedback Loops. TUI provides two feedback loops: 1) immediate tactile feedback, and 2) feedback through digital processing (with possible delay).

Typically there are two feedback loops in TUI, as shown in Figure 21.4:

1. The passive haptic feedback loop provides users with immediate confirmation that they have grasped and moved the object. This loop exists within a physical domain and does not require computational sensing or processing. Thus, there is no computational delay. The user can begin manipulating tangibles as desired without needing to wait for the second feedback loop: mediated (typically visual) confirmation from the interface. In contrast, when one uses a mouse with a GUI, he or she must wait for visual feedback (the second loop) to complete an action.
2. The second circle is a digital feedback loop that requires sensing tangibles as moved by users, computing responses to the sensed data, and displaying the results as visual (and auditory) feedback. Thus, this second loop takes longer than the first.

Many frustrations from using current computers come from the delay of digital feedback, as well as weak confirmations of computational actions. We believe the double loops of TUI provide users a path toward easing these frustrations.

Note: Actuation technology, as illustrated by the Actuated Workbench, will contribute to add another loop. Figure 21.5 illustrates the third loop introduced into the TUI model by computer-controlled actuation and sensing. The third loop allows the computer to give feedback on the status of the digital information as the model changes or responds to internal computation.

21.11.2 Persistence of Tangibles

As physical artifacts, tangibles are persistent. Tangibles also maintain physical state, with their physical configurations typically tightly coupled to the digital state of the systems they represent. A distinction between in-band and out-of-band interactions is also an important consideration (Ullmer, Ishii, and Jacob 2005).

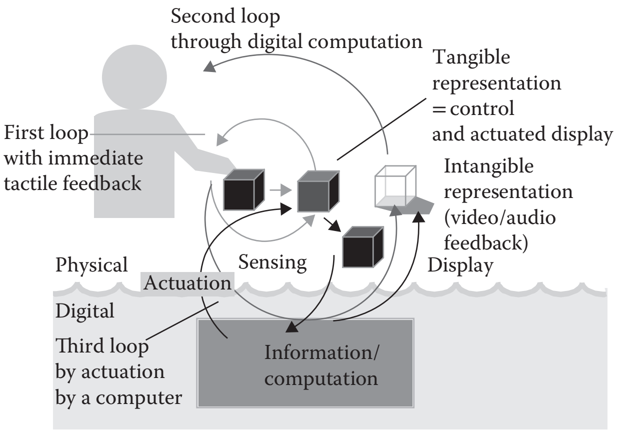

FIGURE 21.5 TUI with actuation (actuated workbench). Computational actuation provides another loop for computer to control position of objects (tangible representations) on the workbench.

Tangibles' physical state embodies key aspects of the underlying computation's digital state. For example, the identity, position, and orientation of Urp's tangibles upon the workbench serve central roles in representing and controlling the state of the underling digital simulation. Even if the mediating computers, cameras, and projectors of Urp are turned off mid-interaction many aspects of the system's state remain concretely expressed by its physical configuration. In contrast, the physical form of the mouse holds little representational significance, as GUIs represent information almost entirely in visual form.

21.11.3 Coincidence of Input and Output Spaces

Another important feature and design principle of TUI is coincidence of input and output spaces. This supports the provision of seamless information representations spanning both tangible (physical) and intangible (digital) domains.

GUIs prototypically utilize the mouse and keyboard as generic "remote" controllers (input), with the screen serving as the primary output medium. Thus, a spatial discontinuity separates these two spaces. (Some evolution has begun with increasing popularity of touch interaction with smartphones, tablets, et al.) There is also multimodal inconsistency, as touch is the main input while vision is the primary output.

TUIs work to coincide input and output spaces (with some exceptions) to realize a seamless coupling of physical and digital worlds (Ishii and Ullmer 1997). Urp has provided one strong example (Underkoffler and Ishii 1999). Illuminating Clay (Piper, Ratti, and Ishii 2002) and SandScape (Ishii et al. 2004) provide two other examples of input/output coincidence using continuous flexible materials (sand). Curlybot and topobo also demonstrate this concept, using actuated tangibles simultaneously as input and output.

21.11.4 Special Purpose versus General Purpose

From an interaction perspective, GUIs are deeply general-purpose interfaces that mediate varied applications visually using dynamic pixels and generic remote controllers. In comparison, TUIs are relatively specific interfaces tailored to certain types of applications in order to increase the directness and intuitiveness of interaction, facilitate multi-user interaction, and support expanded modalities for maintaining awareness.

In Urp, a notable design decision is its use of tangibles with very application-specific physical forms (e.g., partially abstracted building models and clock representations) as fundamental elements of the interface. These give users important visual and tactile information about the conceptual and computational entities they represent. Some tangibles may invert prior artifact behaviors. For example, in Urp, instead of the clock hands moving to indicate the passage of time, the user manipulates the clock to change time of day for shadow studies (Photo 21.1). Similarly, she can change the orientation of the weather vane to control the direction of the wind (Photo 21.2).

Of course, this special-purposeness of TUIs can become a disadvantage if users wish to apply them to widely diverse applications, as tangibles tailored to certain application may not be reusable in others. By making the form of objects more abstract (e.g., a round puck), one loses the legibility of tangible representation. Here, the tangibles may transform into generic handles, rather than a physically legible representation of underlying digital information. Which design choice is preferred varies between systems, users, and contexts, and remains both art and science in equal measure. Altogether, a balance between specific/concrete versus generic/abstract forms, sometimes in the form of core versus domain tangibles (Ullmer et al. 2008; Ullmer et al. 2010), seems an important component of good design.

21.11.5 Space-Multiplexed Input

Another feature and contribution of tangible interfaces concerns space-multiplexed input (Fitzmaurice, Ishii, and Buxton 1995a). Each tangible representation serves as a controller occupying its own space. This encourages two handed and multiuser interaction with underlying computational models. In this way, TUIs are often particularly suitable for collocated collaboration, allowing concurrent manipulation of information by multiple users.

In contrast, GUIs traditionally have provided time-multiplexed input, allowing users to use one generic device to control different computational functions at different points in time. For instance, the mouse is used for menu selection, scrolling windows, pointing and clicking buttons in a time-sequential manner.

TUI can support not only collocated collaboration, but also remote collaboration. Here, actuation can become important for synchronizing the physical states of tangibles over distance (Pangaro et al. 2002). Combining the Urp scenario with the Actuated Workbench, it is possible to have multiple distributed Urp tables in different locations, linked and synchronized over the Internet. One Urp can be in Tokyo and another in Boston, with the building tangibles and their shadows synchronized as the distributed planning team collaborate through the system. This synchronization allows both teams to discuss and effect changes in real-time, providing a common reference for otherwise ethereal qualities such as wind, time, and shadows.

21.12 DESIGN CHALLENGES AND OPPORTUNITIES

Tangible interfaces are today the subject of much activity—both in academic research labs, niche contexts such as museums and classrooms, and broader domestic and commercial use. In parallel, many important design issues are still at best partially understood. We identify and discuss several of these, partly toward fostering continuing academic study and commercial engagement.

- What should be tangible, and what should be intangible?

  Not all elements of computational systems can, or should, be physically embodied. Choosing which system elements should be tangible is a critical and still challenging decision. One heuristic is to physically embody the "key objects of interest" (Ullmer 2002; Hornecker and Buur 2006). Tangibility decisions also relate to many aspects of application context. Are eyes, ears, or hands typically engaged by other aspects of the system or surrounding context (Cohen and Oviatt 1995)? Is mobility important? Does the application typically engage one or multiple users? If multiple, are they collocated or distributed, peers or differentiated?

- Does a given physical artifact have a digital binding?

  Not all physical artifacts are, or should be, bound to digital associations. Today, most physical artifacts have no digital associations. How should users distinguish tangibles from "ordinary objects?" Sometimes, physical and temporal context can provide sufficient cues. For example, the box of a stored board game helps segregate playing elements from "other stuff"; similar approaches can be used for TUIs. Specialized physical or visual design, potentially including special human and/or machine-parseable symbols or conventions, can help in this differentiation (Ullmer et al. 2010). In other cases, mediation or engagement with the artifact may be required.

- What is a tangible's digital binding (both in the absence and presence of mediation and interaction)?

  Tangible interfaces use widely varying modes of representation. Some use one or a few relatively generic tangibles, leaving most representation to computational mediation. Some incorporate static text and other visual content; others use evocative physical forms with little or no "skin" differentiation. Some incorporate dynamic visual displays (e.g., LEDs or bistable displays like e-ink) and/or actuators.

These varying representational forms may be sufficient for novice or expert users to unambiguously identify a tangible's bindings—or not. "In-band" engagement (e.g., with a mediating surface or glasses) may be required, as may "out-of-band" activities—consulting a supporting GUI, manual, or expert user. In time, codified "human interface guidelines" (as championed by Apple and other companies) may help users evolve specific expectations. Trust is also at stake. Users are often unaware of important activities web pages and mobile phones are taking on behalf of them (or others). Similar challenges likely lie ahead for tangibles.

- How might tangibles best coexist and engage with other genres of HCI?

It is unlikely that tangible interfaces will "obsolete" graphical interfaces, speech interfaces, or other interaction modalities. We have argued that tangible interfaces are a strong fit for a variety of application contexts. Still, it is unlikely that (say) the full spectrum of GUI office productivity applications would evolve into tangible form. Also, hybrid interfaces are a distinct possibility. For example, while some interfaces are "purely" graphical or textual, hybrid combinations of graphical and textual interaction techniques are common. Analogies may likely unfold for tangible and graphical interaction, as well as between TUIs and other post-WIMP techniques (Jacob et al. 2008)—for example, tangible augmented reality (Lee et al. 2004). This presents both needs and opportunities for physical and graphical approaches that bridge multiple paradigms.

Another opportunity relates to the progressive realization of Weiser's ubiquitous computing vision. It is now routine for users to wear and carry several "computers" (e.g., laptop, slate, handheld, glasses, and garments), amidst many others deployed on desks, walls, ceilings, and floors. With wireless networking near-ubiquitous in some regions, data interchange is clearly technically possible. However, paradigms for compelling coordination of these complex ecologies, joined by tangibles and other interactives, arguably remain in infancy. With their native physicality, tangibles hold a potentially privileged role in helping mediate these physical/digital ecosystems. Helping manage scarce attention is one important component; comediating collaborative work is another.

- In a world where tangibles are common, how are they likely to be made?

New graphical interfaces can spring fully realized upon screens at the speed of electrons and photons. Tangibles experience a more labored gestation and delivery. Paper printing, electronic device fabrication, and handcrafts each lend valuable perspective on possible futures.

At least four locales for paper printing are now common. Much paper is bulk-printed in distant lands, delivered in days or weeks. Stores in the same city or neighborhood can offer similar services in hours, typically trading cost for service and customization. Many homes and offices now have multiple printers per room, bringing renditions in minutes or seconds. Bistable paper displays can trim delivery to milliseconds.

A similar story likely suggests one path in the future of tangibles. Diverse 2D, 3D, and higher-dimensional printers and cutters—some allowing printed artifacts to "walk out" by their own volition (Gershenfeld 2005)—are becoming common at each of these physical locales. Tangibles today and tomorrow are finding origin in each of these settings, each bringing different trade-offs.

The fabrication of electronic devices and handcrafts provide different perspectives. Today, most electronic devices are mass-produced far from their point of consumption, driven by high fixed costs and low wages. Handcrafts are created both at global and local origins—in both cases, again typically earning meager returns for the laborer. These different production pathways also have consequential implications for sustainability (Blevis 2007; Kloepffer 2008; DiSalvo, Sengers, and Brynjarsdottir 2010; Geyer and Doctori Blass 2010) and the design and engineering approaches by which tangible interfaces are realized (Greenberg and Fitchett 2001; Beigl and Gellersen 2003; Villar and Gellersen 2007; Buechley et al. 2008; Sankaran et al. 2009).

The mass production and paper printing models are likely to suggest the most common paths for fabricating tangibles. However, in a time where myriad communities and whole continents struggle desperately toward finding a future, the physicality, material craft, and potential cultural specificity of tangibles potentially offer real and promising prospects.

21.13 CONCLUSION

Ishii met a highly successful computational device called the "abacus" when he was 2 years old (Photo 21.13). He could enjoy the touch and feel of the "digits" physically represented as arrays of beads. This simple abacus was not merely a digital computational device. Because of its physical affordances, the abacus also became a musical instrument, imaginary toy

PHOTO 21.13 Abacus. The beads, rods, and frame of abacus serve as physical representations of both information (numbers) and computation (arithmetic operations). They serve as directly manipulable physical controls to compute on numbers. The abacus can be seen as a model of tangible interfaces.

train, and a back scratcher. He was captivated by the sound and tactile interaction with this simple artifact.

His childhood abacus also became a medium of awareness. When his mother kept household accounts, he was aware of her activities by the sound of her abacus, knowing he could not ask to play while her abacus made its music.

This abacus suggests to us a new direction of HCI that we call TUI. The abacus makes no distinction between "input" and "output." Rather, the beads, rods, and frame serve as physical representations of numerical information and computational mechanism. They also serve as directly manipulable physical controls to computationally engage with numbers.

Also, the simple, transparent mechanical structure of the abacus (absent any digital black boxes) provides rich physical affordances (Norman 1999). Even children can understand many potentials of this artifact without reading a manual.

Tangible interfaces pursue these features further into the digital domain by giving physical form to digital information and computation, using physical artifacts both as representations and controls for computational media. The TUI design challenge concerns seamless extension of the physical affordances of artifacts into the digital domain.

This chapter has introduced basic concepts and example applications to address key properties and design challenges of tangible interfaces. The TUI approach still remains in its infancy, and extensive research is required to identify the "killer applications," scalable methods for their realization, and a set of strong design principles.

Tangible interface research naturally and fruitfully intersects with the paths of industrial/product design, as well as environmental design, architecture, and interior architecture (Kurtich and Eakin 1993; Kernaghan 2011). TUIs have made an impact on the media arts/interactive arts community. The authors hope tangible interfaces will continue promoting these interdisciplinary design research movements within and beyond the HCI community, bringing strong design culture and a media arts perspective both to the scientific/academic communities, and across the far broader, diversely populated ecologies of our beautiful, challenged planet.

Mark Weiser's seminal article on Ubiquitous Computing (Weiser 1991) began with the paragraph:

> The most profound technologies are those that disappear. They weave themselves into the fabric of everyday life until they are indistinguishable from it.

We believe tangible interfaces are one of the promising paths toward Weiser's vision.

ACKNOWLEDGMENTS

The authors thank many of the former and current Tangible Media Group (TMG) students and colleagues in the MIT Media Lab for their contributions to tangible interface research. Special thanks are due to Dr. John Underkoffler, Dr. Kimiko Ryokai, Dr. James Patten, Dr. Angela Chang, Dr. Hayes Raffle, Dr. Amanda Parkes, Dr. Oren Zuckerman, Dr. Alexandra Mazalek, Matthew Gorbet, Paul Yarin, Jamie Zigelbaum, and many others. Thanks are also due to Things That Think and Digital Life Consortia at the Media Lab for support of our research. Ullmer thanks the students and postdoctoral researchers of LSU's Tangible Visualization group, the faculty and staff of LSU CCT and the Department of Computer Science, and the NSF MRI and Creative-IT programs for support. Ishii thanks Professor Bill Buxton and Dr. George Fitzmaurice for collaboration on the Bricks project in 1994 at University of Toronto (Fitzmaurice, Ishii, and Buxton 1995b) which laid the foundation of TUI, and Professor Mitchel Resnick for his vision of Digital Manipulatives (Resnick et al. 1998), which influenced our design of educational TUI applications.

22 Achieving Psychological Simplicity

Measures and Methods to Reduce Cognitive Complexity

John C. Thomas and John T. Richards

CONTENTS

22.1 INTRODUCTION: SCOPE AND STRUCTURE OF THIS CHAPTER

In this chapter, we explain why psychological complexity is (or should be) of interest to the designers of human–computer systems. We then distinguish between intrinsic complexity and undue complexity. We presume that undue complexity is generally (but not universally) counterproductive in that it leads to more errors, frustration, and greater task completion times. Generally, these are all things to be avoided in a work-oriented context. In a more aesthetic, recreational, or pleasure-oriented context, however, increased psychological complexity can often be desirable. We then examine the sources of undue complexity. We hypothesize that undue complexity can arise in the following three ways: (1) intentionally, (2) through incompetence, or (3) most commonly, as an unintended side effect of normal socialization processes.

We then differentiate complexity from many related concepts such as uncertainty, obscurity, and difficulty. We review various approaches to measuring complexity. We suggest where and how complexity may be introduced during the overall development of human–computer systems and several approaches that may help minimize undue complexity including making better use of the human capacity for performing "Theory of Mind" tasks. Finally, we speculate on some possible future developments in the field of psychological complexity and briefly discuss a number of case studies in which various approaches have been tried to reduce complexity.

22.1.1 Why Study Psychological Complexity?

Although mathematicians have treated complexity as a topic for a long time, more recently this interest has spread into many fields (see e.g., Holland [1995]; Bar-Yam [1997, 2000]). The attempts to understand fields as diverse as economics, ecology, biology, and machine learning, among others, relate to similar mathematical treatments, often under the general rubric of "Complex Adaptive Systems." Although there are still many unsolved problems in this field, one might raise the issue of why there needs to be a separate inquiry into the nature of psychological complexity. There are two basic reasons why psychological complexity deserves a separate treatment. First, what may be thought of as objectively complex, may or may not be psychologically complex. Indeed, an exploration of these differences forms a major part of this chapter. Second, when we consider complexity in the more specific context of human–computer interaction (HCI), it is useful to differentiate *intrinsic* complexity from *undue* or gratuitous complexity. Some tasks are inherently complex. We may help people perform these tasks via work aids, education, documentation, rule-based systems, or the clever design of work groups, but some considerable intrinsic complexity may remain. In contrast, although regrettable, it still seems to be a fact of life that many systems, applications, and artifacts are unnecessarily complex. Poor design, for instance, burdens users with complexity above and beyond what is required by the nature of the task. We will, in this chapter, explore sources of this "undue" complexity as well as ways to prevent or mitigate it. Although this chapter will reference some of the relevant literature on the more general topics of "complexity" and "psychological complexity," the focus of this chapter is on how we can use these concepts to improve HCI, in most cases by reducing undue complexity.

In terms of the underlying cause, there seem to be three main reasons for undue complexity. First, undue complexity sneaks into systems even though people consciously try to prevent it. This can happen for numerous reasons which we will explore in greater detail below, for example, lack of appropriate methodology. Second, seemingly undue complexity can be injected into systems *intentionally*. For instance, systems commonly enforce rules governing both password structure and password lifetime. These are often perceived as an annoyance by end users but are intentional policy decisions aimed at improving overall system security. A third and more subtle reason for undue complexity relates to ordinary social processes. As a group of people work together or live together, they develop and evolve ways of referring to things that become convenient short hands for the "in-group" but become increasingly obscure or difficult for the "out-group." In the extreme, this results in different accents and dialects and eventually distinctly different natural languages, customs, and assumptions. Disparate groups of people end up, not simply using different terms, but thinking about the world differently (Abley 2005). This process is typically, though not exclusively, unconscious. This type of socialization begins early; experiments indicate that children as young as several weeks old are already *less capable* than they were at birth of making auditory distinctions within the phonemic categories deemed equivalent by their linguistic community. In one experiment, as children living in an English-speaking environment aged from 6 to 12 months, their percentage of discriminations of a non-English distinction decreased from 80% correct to 10% (Werker and

Tees 1984). Categorical speech perception is only one fairly dramatic form of a process that is happening all the time and at many levels in normal social interaction.

22.1.2 Nature of Psychological Complexity as a Variable

Why are people interested in psychological complexity? Basically, the intuition is that it is an important intervening variable that simplifies analysis and prediction. On the one hand, there are a number of factors, explored in detail in this chapter, that impact psychological complexity and on the other hand, there are a number of dependent variables which psychological complexity influences.

One might yet question the utility of "complexity" as a unifying variable. Although Card, Moran, and Newell (1983) talk about "complex behavior" (and the principle of "Rationality" to help explain how to build models of complex behaviors from simple ones), they do not treat "complexity" as a variable, per se. Despite this, under a wide variety of conditions, accurate predictions of complex human behavior are possible (see also, e.g., John [1990] and Gray et al. [1990]). Modeling at this level of detail requires a substantial amount of work although CogTool (Harris, John, and Brezin 2010), which will be discussed in more detail in Section 22.7.5, greatly reduces this workload. The hope for "complexity" is that one might develop predictive measures of complexity that could be applied fairly easily without special expertise that would still be highly predictive of human behavior. In the ideal case, for instance, a development team might calculate the complexity of several alternative design ideas for a human–computer system and make at least some of the many necessary design decisions without the need for assessing each one with costly behavioral observations.

We expect intuitively that increased psychological complexity is positively correlated with increased errors, increased time to complete a task, and decreased productivity, as well as increased frustration in a "results-oriented" work environment. (Even in such work contexts, there may be exceptions; e.g., when lengthy vigilance at an overly simple task may actually produce more errors than a somewhat more complex one). Nonetheless, the overall presumption, both in the public mind and in the scientific literature is that unnecessary complexity is to be generally avoided on the grounds of reducing errors and improving productivity. The cost of complexity can be considerable. For example, according to a recent study by den Ouden (2006), half of the consumer products returned as "malfunctioning" are actually functioning as designed; they are just too complex for the customer to use. A well-meaning attempt to "improve" a homeland security system resulted in more errors, longer decision times, and a decreased probability that people would even use the system (Coskun and Grabowski 2005). Although details vary, Figure 22.1 shows the general relationship of complexity to performance and frustration.

However, the relationship of psychological complexity to more ludic (pleasure-oriented) and a aesthetic variables is more complex. In general, the prevailing wisdom is that a moderate amount of complexity is esthetically pleasing (see Figure 22.2). Stimuli, responses, mappings between stimuli and responses, or contexts that are *either* too complex *or* too simple are not as interesting, pleasurable, or engaging as those that are moderately so. This seems to be a fairly robust phenomenon applying to infants as well as adult humans and to various species. Of course, it is still the case that what constitutes moderate complexity for an individual depends on previous knowledge as well as personality predilections for more or less complexity. In any case, psychological complexity is potentially a powerful intervening variable that, on the one hand, promises to collapse the impact of numerous separate independent variables into one (i.e. "complexity") and, on the other hand, to expand the implications of complexity onto a number of dependent variables. In the case of performance-related variables, the relationship is thought to be monotonic; in the case of subjective variables, the relationship is thought generally to be an inverted U-function although it may vary according to the sense and the individual.

In the last few decades, most HCI work has examined work contexts in which productivity, in the broadest sense, has been a primary focus. As computing technology has become more intertwined with home life and entertainment, the importance of also using psychological complexity as a predictor of pleasure and preference is increasing. This implies that HCI practitioners must take care not to presume that *minimal* complexity is necessarily the *best level* of complexity.

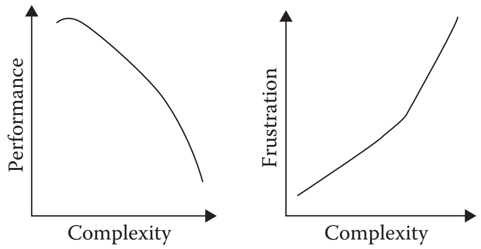

FIGURE 22.1 The general relationship between complexity and performance and complexity and frustration.

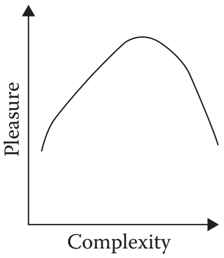

FIGURE 22.2 The typical relationship between complexity of a stimulus and the associated aesthetic pleasure in ludic situations.

In the domains of art and architecture, some attempts have been made to quantify what makes for "interesting" or "aesthetically pleasing" patterns. For example, Christopher Alexander's work on *The Nature of Order* (2002) includes an examination of and ordering of visual binary patterns, and Klinger and Salingaros (2000) suggest a metric for measuring the visual complexity of simple arrays. Kidd, Piantadosi, and Aslin (2010) show that infants prefer moderate complexity. Other recent approaches attempt to relate preferences to fractal numbers (Taylor et al. 2005). Other investigators have tried to predict musical complexity based on objective factors (see e.g., Pressing [1999]; Shmulevich and Povel [2000]; Shmulevich et al. [2001]).

In more work-oriented contexts, psychological complexity is clearly related to other intervening variables such as stress (Figure 22.3), difficulty (Figure 22.4), and workload (Figure 22.5). However, there are distinctions among these. Stress depends not just on the complexity of the problem situation itself but also on external factors such as the payoff matrix and internal factors such as neuroticism. For instance, a specific puzzle might be thought to have a certain level of complexity. However, the amount of stress that one experiences in attempting to solve it would depend on the perceived rewards, punishments, and time pressure as well as the individual's internalized habits for viewing how various outcomes relate to overall life goals; for example, proclivities for "awfulizing" (Ellis 2001) tend to increase stress far more than what might be "objectively" justified.

The more complex the task, the more difficult we would expect it to be; other things being equal. However, difficulty can also accrue to a task for a number of other reasons including environmental stressors such as extreme heat or cold, vibration, noise, or the necessity of applying large forces.

Workload is a term more commonly applied to an individual or a team *across* tasks. So, one can imagine an individual with a large number of tasks, each of which is fairly simple, but whose job includes many interruptions and context switches from one "simple" task to another. In such a case, the workload may be fairly high even though any particular task may be fairly simple. It is sometimes useful to make a similar distinction within a task. Programming, for instance, often involves some mix of creative tasks that deal with the essential problem and a number of administrative overhead tasks that must be accomplished as well. In our work on reducing complexity for high-performance computing, we are attempting to quantify the impact that reducing the administrative overhead may have, not only in directly reducing overall time, but also in terms of allowing the programmer to concentrate more effectively on the creative aspects of the task.

There is another sense in which the term "psychological complexity" is sometimes used. Social critics may use the term to refer not to a single task or system but to the totality of life experiences. Modern life in the information age is sometimes deemed to be too complex *in its totality.* This increased complexity may apply to politics, personal relationships, child-rearing, transportation, health care, food choices, and so on extending potentially to every aspect of modern life. Even providing for our entertainment needs has become a complex endeavor (Grinter and Edwards 2005). In addition to the notion that each separate aspect of life is becoming more complex, people often find themselves multitasking and task switching (e.g., Gonzalez and Mark 2005). Although this is a potentially interesting avenue to explore in its own right, it is basically beyond the scope of this chapter, which instead will focus on psychological complexity as it applies to individual systems or tasks that have information technology aspects.

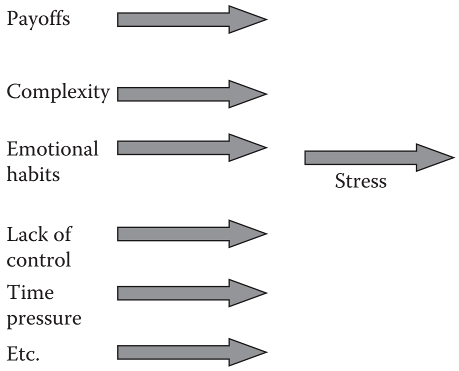

FIGURE 22.3 A number of variables, including complexity, can increase stress.

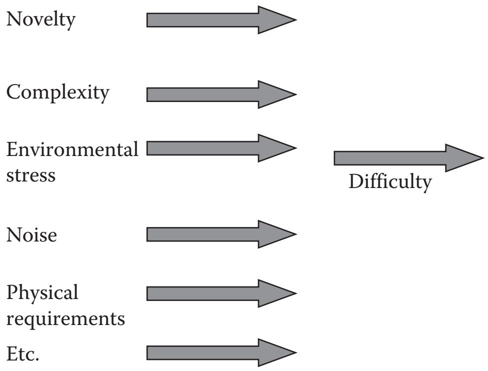

FIGURE 22.4 A number of variables, including complexity, can add to task difficulty.

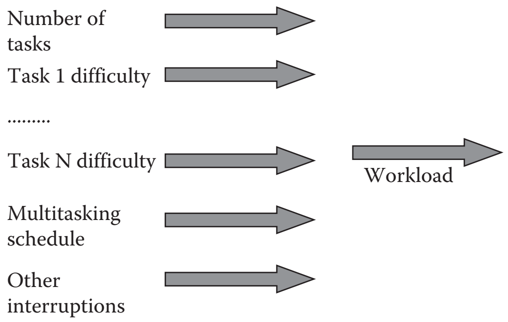

FIGURE 22.5 Overall workload is influenced by the difficulty of various tasks, the number of tasks, the scheduling of the tasks, and other factors.

Early attempts to measure task difficulty with objective metrics include Attneave's (1957) figure complexity. There have been attempts to provide measures for the "meaningfulness" of trigram "nonsense" stimuli, responses, and the mapping between the stimulus and response in the verbal learning literature. Others have attempted to extend this work to real words; English words have been rated for frequency of occurrence (Kucera and Francis 1967; Brown 1984), concreteness (Paivio, Yuille, and Madigan 1968), and so on. In one case, for example, (Rubin 1980), *fifty-one* dimensions of words were measured. Such measures do provide predictability in a wide range of laboratory tasks. For instance, the log of word frequency is closely related to decreased latency in a simple naming task where subjects are shown pictures and asked to name the pictured object as quickly as possible (Thomas, Waugh, and Fozard 1977). However, such empirical relationships as these are problematic in terms of applicability to HCI. For one thing, when measures are taken on real words in English, many dimensions tend to be correlated. Work by Carroll and White (1973), using a linear regression model, showed that *age of acquisition* is actually a more powerful predictor than frequency of occurrence (though the two are highly correlated). Neural net models of learning also demonstrate this effect (Smith, Cottrell, and Anderson 2001). How might one apply such findings to HCI? For example, given a choice between two otherwise equally appropriate words, it is generally better to use the word that is more frequent in the language, or even better, one that is learned early in life. The relevance of this heuristic to the design of instructions, web pages, error messages, and so on, however, is very limited because in real design situations, we seldom have a choice between two "otherwise equally appropriate words." More frequent words also often have the property of being more ambiguous, both semantically and syntactically (e.g., "can," "run") than longer, less frequent words. Words learned early in life often have little relevance to most tasks that adult users engage in. Generally, knowledge of the particular users, their vocabulary, task demands, conventions, contexts, and so on dominates more general properties of the language in suggesting the best wording.

22.2 COMPLEXITY AND RELATED CONCEPTS

In this section, we attempt to further define psychological complexity by distinguishing it from a number of similar concepts.

22.2.1 Relationship of Complexity and Ease of Use

Intuitively, it would seem that "ease of use" and "simplicity" constitute closely related concepts. However, they do differ in several ways. First, "ease of use" implies an empirical orientation. There are a number of interesting issues involved in measuring "ease of use" such as choosing the set(s) of reference users, representative tasks, and in choosing the dependent variables to be measured (time to complete, errors, quality of result, etc.). "Ease of use" can, in principle, be measured objectively in terms of human behavior. Complexity, on the other hand, does not have the same degree of conceptual consensus. There are approaches that focus on the formal, intrinsic properties of a system or stimulus (e.g., Halstead's *Software Physics* [1977]; Christopher Alexander's recent work on *The Nature of Order* [2002]). Other approaches focus on the reactions of a human being to the system or stimulus. These can include passive measures such as pupil dilation, staring time, or heart rate deceleration. They can also include more subjective judgments or attempts to measure various aspects of task-oriented behavior, for example, the number of steps in a process or the number of variables that must be remembered (e.g., Brown and Hellerstein 2004; Brown, Keller, and Hellerstein 2005).

Nonetheless, other things being equal, one would expect something that is less complex to be easier to use. However, other things are typically *not* equal. "Ease of use" often depends heavily on people's expectations that may result from cultural conventions, often varying widely with time and place. Today, a new application that uses the typical graphical user interface (GUI) widgets such as pull-down menus may be fairly easy to use for experienced users, primarily because people have a fair amount of positive transfer from earlier, similar experiences. A unique and unfamiliar but "less complex" interface may not prove as easy to use.

In addition, a design that maximizes visual simplicity through symmetry and minimalism may actually increase the difficulty of use. For example, a shower arrangement with one, clearly marked handle for hot water and another for cold water, combined with a two-position lever for shower and bath is more complex visually than a single, unlabeled knob with several degrees of freedom. At least initially, however, the former will be easier to use. Similarly, a "normal" bottle opener is not particularly elegant or simple in shape. However, its asymmetries, as well as its commonality, make it easy for people (in our culture) to use. An alternative bottle opener (see Figure 22.6) consists of a metal cone with a thin protruding knob. This device is physically "simpler," but harder to use, at least initially.

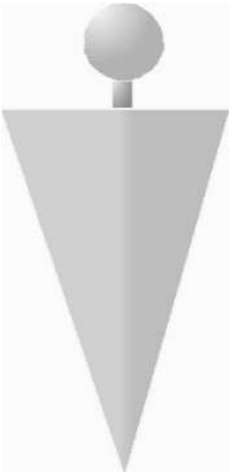

FIGURE 22.6 A "simple" but highly nonintuitive bottle opener.

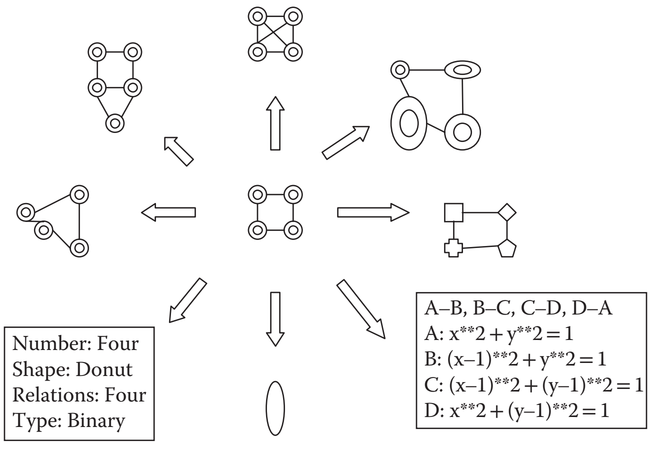
22.2.2 Relationship of Simplicity and Complexity

Intuitively, simplicity and complexity seem to be opposites. Indeed, they are listed as opposites in Roget's Thesaurus (2005). However, there is an interesting asymmetry hidden in their opposition. It is as though absolute "simplicity" is the center point of an *n*-dimensional sphere while, absolute "complexity" is the surface. In other words, there are many "ways" of moving away from simplicity toward complexity. Figure 22.7 illustrates just a few of the many ways that a system can become more complicated. For simplicity, we illustrate a two-dimensional rather than *n*-dimensional space.

This is more than an idle philosophical observation. In the real-world iterative cycle of design and behavioral observation, it is relatively difficult to move "inward" toward greater simplicity while improving ease of use. It is relatively easy to move along the circumference of a notional circle, resolving some types of complexity while simultaneously introducing others and therefore not increasing either overall simplicity or ease of use. For example, in designing a word processing system, you might find that people are having difficulty finding desired items in long pull-down menus. You decide to make each menu "simpler" by changing the pull-down options depending on whether one clicks or clicks with the shift key depressed. This makes each menu simpler but introduces another kind of complexity. Much of the "art" and the importance of experience in HCI can be conceived of as being able to move "in" from the surface rather than "around" the surface. See the work by Lewis (2007) for a related discussion with respect to simplicity and accessibility.

22.2.3 Relationship of Complexity and Uncertainty

Increased complexity is associated with increased uncertainty, *ceteris paribus.* Complexity is a term that can reasonably be applied to stimuli, responses, or to the mapping between them. The concept of uncertainty, however, seems to apply only to mapping. One can have uncertainty about what a stimulus is, or uncertainty about what response to make, but fundamentally, it has to do with what action is appropriate, given the current circumstances.



Number: Four
Shape: Donut
Relations: Four
Type: Binary

A–B, B–C, C–D, D–A
A: x**2 + y**2 = 1
B: (x–1)**2 + y**2 = 1
C: (x–1)**2 + (y–1)**2 = 1
D: x**2 + (y–1)**2 = 1

FIGURE 22.7 A "simple" system can be complicated in many different ways. (Here are just a few.)

Complexity, as mentioned earlier, can be thought of either as something objectively measurable or as something subjective. The term "uncertainty" also has an objective meaning. If one turns over a randomly chosen card from an ordinary deck, there is more objective uncertainty about the outcome than if one flips a coin. The term uncertainty may also be applied in a purely subjective way. In this subjective sense, a given person may be "completely certain" that a randomly chosen card will be the Ace of Spades (because of nothing more than a compelling intuition) and completely uncertain about the outcome of a coin toss. The concept of subjective uncertainty has even further shades of application. One may watch the movie *Apollo 13* on numerous occasions. At one level, the outcome is already predefined and completely known. There is neither objective nor subjective uncertainty. Yet, within the inner context of watching the story play out, the viewers "allow themselves" (each time!) to feel the subjective uncertainty of outcome.

Subjective uncertainty in HCI can apply at numerous levels. For example, to make touch typing a felicitous interaction, one subjectively presumes that each keystroke will be correctly transmitted to the computer and that what appears on the screen is an accurate mapping of what is actually being stored inside the computer. Objective certainty about the states of electromechanical systems probably never reaches 100%. However, as a *strategy* for partitioning effort, it is often useful to ignore very small error probabilities in subjective judgments. The first time that one of the authors (JT) typed a sentence with an initial "the" and had it automatically transformed into a "The" by the word processing software, this "certainty" changed. The author began to wonder "what else" the application might be doing. Later, a much worse problem surfaced in the form of an automatic update to styles. In response to something typed on page 1, something might change appearance on page 100. Subjective uncertainty also bears some resemblance to the concept of "trust." One might have 1000 interactions with someone, each of which provides evidence of "trustworthiness," yet even a *single* interaction that shows a person to be untrustworthy may color a relationship for years to come. Similarly, if an interaction between user and the computer system violates an assumed behavioral norm by doing something completely unexpected, the level of subjective uncertainty created may be much greater than warranted in any "objective sense." Moreover, if the user's experience includes such a violation, the *scope* of subjective uncertainty may be difficult to predict. One user may simply generalize uncertainty to a specific function; another may come to "distrust" a specific application (have a high degree of uncertainty), whereas a third may come to "distrust" computers, *in general.*

22.2.4 Relationship of Complexity to Number

One would expect that if systems A and B are equivalent in other respects, but system A is more extensive than system B in terms of the number of items, that system A is more complex than system B. However, the degree to which an increase in number produces an increase in complexity depends greatly on the structure of the systems. Suppose that systems A and B consist of 5 and 10 buttons, respectively, combined with an "OK" light. The user has to use trial and error to discover the correct button to push to cause the OK light to light. On average, it will take 2.5 trials to press the right button for system A and 5 trials to press the right button for system B. Here, doubling the number of choices doubles the average number of trials. On the other hand, imagine that the user must find a sequence of 5 button pushes for system A and 10 button pushes for system B. When the user hits each correct button, the OK light comes on. On average, it will take the user $2.5 + 2 + 1.5 + 1 + 1 = 8$ attempts to execute the right sequence for system A and $4.\ 5 + 4 + 3.5 + 3 + 2.\ 5 + 2 + 1.5 + 1 + 1 = 22$ attempts to find the right sequence for system B. Here, a doubling in the number of buttons results in nearly three times the mean number of trials. For a final case, imagine that the OK light comes on only after *all* buttons are pushed in the correct sequence. There are 5! possible sequences for system A, and the user will find the correct sequence on average in 5!/2 trials or 60 trials. There are 10! possible sequences for system B, and the user will find the correct sequence, on average in 1,814,400 trials. Here, a doubling in number has led to an increase in trials by a factor of 30,240. In practical terms, system A, though cumbersome, could be solved by hand in a few minutes. System B would probably extend beyond anyone's patience. A quantitative difference in complexity actually would result in the qualitative difference between something doable and something not doable. These examples illustrate that the impact of number on complexity greatly depends on the nature of the system. In particular, "hidden states" are almost always a "bad thing" in terms of complexity, but just how bad they become rises quickly with increasing number.

Another example has to do with working memory and relates to George Miller's (1956) famous paper, "The magic number 7 plus or minus 2." Although the "size" of working memory varies somewhat depending on the number of dimensions and the type of material, it is not large. A system that allows a person to operate within that span can be nearly error free, while a system that forces a person to operate beyond that span will be extremely error prone. A fairly modest increase in memory load can thus result in a very large increase in time and errors (see Figure 22.8). This is one reason we feel, for instance, that a modest increase in support for the administrative overhead of programming may result in a larger increase in overall productivity.

22.2.5 Relationship of Complexity to Nonlinearity

One of the defining characteristics of complex adaptive systems is that they exhibit nonlinearity. From the perspective of survival, this nonlinearity is a good thing. From the perspective of someone trying to interact with a computer system, nonlinearity can be a major source of difficulty in understanding, predicting, and controlling the behavior of the system. For example, one of us (JT) once had to debug a PDP-8 program that was intended to collect reaction time data. There was only a single bit wrong in the entire program (which probably had roughly 5000 bits total). In a linear system, you would expect that a 0.02% error would result in a small behavioral problem; for example, the reaction time would be off by a constant 0.02%. Of course, nothing of the kind happened. The program did not collect reaction times at all. Instead, it eventually caused the interpreter to crash. The "bit" that was wrongly set was the "indirect bit" so that instead of storing the reaction time, the program used the reaction time as an address to store the contents of a register. Furthermore, since every time the author tried to test the program, the reaction time varied slightly, the precise behavioral path of the program was different every single time. This example is not at all unusual but illustrates the property that computer systems are typically highly nonlinear in their behavior. Generally, higher layers of software are designed to make the system, as seen by the user, as being more nearly linear (and therefore, more predictable). However, even in commonplace high-level applications, many nonlinear aspects typically remain.

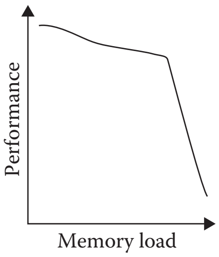


FIGURE 22.8 How memory load can have a minor effect on performance, up to a point, after which increasing memory load still more yields a sharp drop in performance.

22.2.6 Relationship of Complexity to Distribution

Halstead (1977) claimed that complexity C is equal to a constant k times the sum of the number of unique operators U times the natural log of the total number of operators u plus the number of unique operands O multiplied by the natural log of the total number of operands o.

$$C = k(U + \text{In}\, u + O + \text{In}\, o) \tag{22.1}$$

This is not an unreasonable approximation. We have already seen how number can increase complexity. However, we could also consider how these operators (or operands) distributed throughout a program. We speculate that

1. AAAAAAAABBBBBBBCCCCCCCC

is easier to comprehend, use, edit, and so on than

2. AABBCAABCBBCCAABCAACCCB

It has been known for some time that repeated operations are typically faster than alternating ones (e.g., Fozard, Thomas, and Waugh 1976). There can be exceptions to this general rule based on rhythm, fatigue, or satiation, especially for extremely simple tasks. However, for complex tasks, we generally expect a distribution such as 1 above to be much easier than 2. For example, in the Stroop task, one can be asked either to name the colors of ink (while ignoring the word) or to read the names of colors (while ignoring the color of ink). Alternating between the two every line is much slower than doing either task *en masse* (e.g., Philips et al. 2002). In the Brown, Keller, and Hellerstein (2005) model, this source of complexity is modeled as context shifts.

22.2.7 Relationship of Complexity to Nature of Elements

Given the same number and structure of elements, two systems that are formally isomorphic may be quite different in terms of psychological complexity based on differences in human biology, learning, or both. For example, it seems clear that the human visual system is especially well tuned to handle the complexity of human faces. For example, Johnson and Morton (1991) present evidence that babies as young as 3 hours after birth can recognize human faces. Chernoff (1973) suggests that this ability may be used to represent underlying complexity in a way that is easier for humans to deal with. In the auditory domain, it is clear that the difficulty of dealing with (recalling, rearranging, etc.) a string of phonemes that follow the phonological rules of one's native language is much less than dealing with an equal length string that violates those rules.

22.2.8 Relationship of Complexity to Naming Scheme

Consider two programs that manifest identical structures. The program asks the user to input an integer from 1 to 100. For each integer, the program then displays a corresponding unique horoscope. Structurally, this is a very simple program. However, imagine that in one version, the user's input number is called, "User's Input Number" and in another it is called "NXBNM." Further, suppose the horoscopes in the first program are labeled, "Horoscope1, Horoscope2, Horoscope3, etc." for each corresponding integer. In the second program, they are each labeled with a random two-letter string such as "HA," "IB," "JK," and so on. It is hopefully clear that these two programs, though formally identical would be vastly different in how easy they would be to understand, modify, and debug.

Although the above example is somewhat contrived, developing a consistent and intuitive naming scheme is a real world problem. Often, when a programmer (or any other kind of designer) begins to name things, they do not have a complete understanding of the space of things they will have to name. For instance, when JT began working on a recent project, he named a file folder "ELFL" for "Electronic Learning Flow Language." As the project grew, one folder was much too generic for all the nuances that emerged. Furthermore, the focus of the project changed and noone even talked about "Electronic Learning Flow Language" anymore. Furnas et al. (1984) found that, not only are two different people likely to come up with different names for things; even the same person over time is unlikely to spontaneously come up with the same name. They suggest tables of synonyms to help alleviate this problem. Real computer systems are often rife with names that are difficult to comprehend or to recall precisely. The use of common search engines by millions of people helps solve this problem.

22.2.9 Relationship of Complexity to Obscurity

Consider the following two sequences of binary digits:

A: 0000 0001 0010 0011 0100 0101 0110 0111 1000
B: 1000 0101 0100 0001 0111 0110 0011 0010 0000

These two sequences each contain the same number of binary digits and the same number of groupings. The first sequence is essentially a counting sequence from zero to eight. This is a fairly obvious sequence *if* one knows how to count in binary. The second sequence would presumably be much harder to memorize for most people. However, it also represents the numbers zero to eight; however, they are arranged in alphabetical order according to the English names. Once one realizes this rule, memorizing or reconstructing the second sequence becomes much easier. There is a sense in which the first sequence strikes us as a natural ordering because it is based on what we can see right before us. Numbers are likely to be highly associated with counting, after all. The rule that orders the second sequence strikes us as more obscure however since it depends on some other representation (the English names of the numbers) that is not naturally and strongly associated with the numbers qua numbers. This notion of "obscurity" is closely associated with the contrary concept of "affordance" (Norman 1988). Basically, if the perceptible properties of an object or system immediately make it clear what it can do and how to do it, we can say that the object or system has good affordances. Of course, whether something appears obscure or not depends heavily on the user's previous experience, both cultural and personal, and may include inborn factors as well. In Figure 22.7, the "equations" version of the simple diagram in the middle illustrates obscurity.

22.2.10 Relationship of Complexity to Structural Framework

One of the interesting aspects of perceived complexity is that when it comes to human beings, sometimes "more" is "less." For example, most English readers are capable of distinguishing "WORD" from "CORD" at a briefer presentation time than they can distinguish "W" from "C." (Reicher 1969; Hildebrandt et al. 1995). Learning a set of paired associates, presented along with mnemonic visual images, is much easier than learning the set of paired associates alone (Thomas and Ruben 1973). Subjects presented with a set of sentences and a context-setting theme or picture have a much easier time learning and remembering a story than those who do not have the picture (Bransford and Johnson 1973). Recalling a story that fits with our cultural patterns is much easier than recalling one which does not (Bartlett 1932). In all the above cases, it appears that the advantage of the structural framework is because it relates new items to something that already exists in memory.

In other cases, however, the advantage of structure seems to have more to do with the underlying nature of the nervous system. For example, in attempts to develop useful and novel representations of speech signals to improve synthesis, one technique developed by Pickover (1985) mapped an autocorrelation function into polar coordinates scaled to fit within a 30° angle. The resulting dot patterns proved singularly difficult to interpret in any useful way. However, when the pattern was reflected to include a mirror image and the resulting 60° angle repeated six times around a central point to produce a snowflake-like pattern (see Figure 22.9), the representation easily differentiated various vowel sounds as well as some subtleties like anticipatory nasalization, which were virtually invisible in the traditional sonogram. Of interest in this context is the fact that the useful representation contained no more information than did the useless one. Arguably, one could say the "speech-flake" pattern was more complex. However, the "complexity" apparently allowed visual symmetry detectors to come into play and produced far more distinguishable and memorable patterns. These symmetrized dot patterns have since been applied to numerous other domains as diverse as cardiac signals, mechanical stress, and even the crunchiness of cereals!

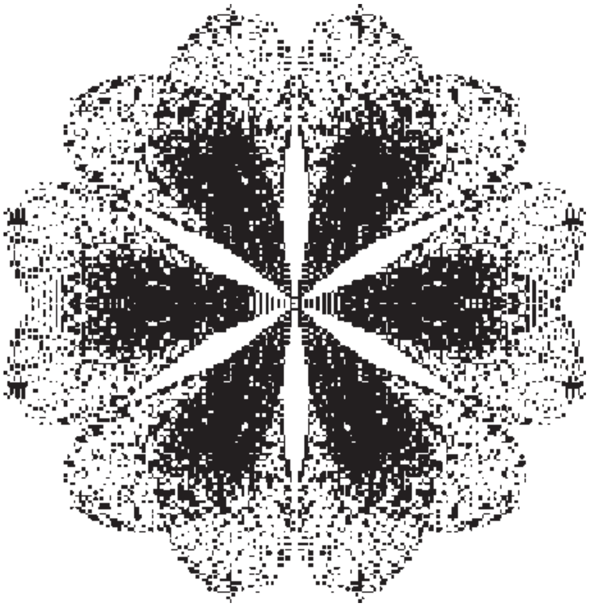

FIGURE 22.9 A symmetrized dot pattern.

22.2.11 Complexity of System versus Task Complexity

It is easy to fall into the trap of conflating the complexity of an interactive computer system with the complexity of the task that one is attempting to perform while using that system. In fact, many studies in the HCI literature compare two or more versions of systems by having subjects perform a small number of tasks in the two systems. Often these tasks are treated as fixed factors when they are actually a small sample (probably not randomly chosen) of all possible tasks. In principle, it is very difficult to generalize about the superiority of one system over another on the basis of performance on a few specific tasks. One cannot really know that a different set of tasks may not have completely obliterated or even reversed any observed trend.

As a general heuristic, one might suppose that the complexity of the system should reflect the complexity of the necessary tasks to be supported. That is, if the user only needs to perform very simple tasks, it may be enough to provide a simple system. However, if the user needs to perform very complex tasks, then a more complex tool may be required. In general, there may be some truth to this heuristic, but it must be applied with care. One caveat is that the function associated with this increased system complexity must actually be useful and allow the user to focus attention on the task at hand. Otherwise, additional complexity in a system may actually be *more disruptive* when the task is complex than when it is simple. For example, consider the tasks of writing a two-page trip report and writing a full-length novel. Writing the novel (we assume) is a much more complex task. It may be that the various functions, fonts, formatting, and options in a complex word processor are unnecessary and even more distracting for someone trying to keep in mind a complex set of subplots and characters than for someone writing a short trip report.

Another important distinction is between the underlying complexity of a system and the complexity that is surfaced to the user. A huge amount of research and technological sophistication may be involved in the development of an automatic transmission but from the driver's perspective, the transmission is simple. From the perspective of the user, modern search engines provide a simple, commonplace interface. Most end users have no notion of the complexity of the underlying processes. In fact, even *developers* apparently do not always see the necessary complexity behind providing common user interface functionality such as "undo." Apparently, the provision of architectural patterns can aid in ensuring the necessary insights (John et al. 2009).

Probably, the ideal case is to provide a layered interface in which the system reveals only the complexity needed for the task at hand. Early examples of this approach include the concept of "training wheels" (Carroll and Carrithers 1984). The interfaces for another related set of projects, the Speech Filing System, the Audio Distribution System, and the Olympic Message System (Gould and Boies 1984), also provided layered interfaces. However, in many real systems, it often happens that the user inadvertently "falls through" the user interface into a deeper layer or *must* do so to accomplish their real task. In addition, undue complexity in the underlying system can *indirectly* hurt the user experience by making code harder to test, debug, document, and maintain. Therefore, we consider undue complexity as something to be generally avoided both internally and in terms of what is to be made visible to the end user.

22.2.12 Complexity of System versus Contextual Complexity

A person may be using a system, which is fairly simple; for example, a bicycle, and their task may be fairly simple: riding in a fairly straight line without falling or crashing. However, riding that bicycle in a straight line on a dedicated and fairly empty bike path through a park might be quite different from riding on a busy city street. It is somewhat of a judgment call to draw a line between "task" and "context." In this example, one might just as well say that the two tasks are different. However, collapsing all such variations into the task complexity is probably counterproductive because the types of actions that can be taken and the power to take those actions are typically quite different in the case of simplifying the task versus simplifying the context.

Contextual complexity could increase overall complexity by providing secondary tasks, or by bombarding the person with extraneous stimuli. Contextual complexity might also produce internal distracting material. Imagine two students using a word processor to complete a take-home essay exam. One of them is also worried about the outcome of some diagnostic medical tests. Or, consider two executives who are using presentation software to construct a sales pitch. But one of them is operating in an organizational context that makes it necessary to pass the presentation through four layers of management, each with very different ideas about what makes a good sales presentation. It seems much more natural to consider such differences to be differences in contextual complexity rather than task complexity. We might expect the design of the presentation software to help the user deal with the task complexity in this example, but not the contextual complexity.

22.2.13 Complexity, Feedback, and Interactivity

Finally, the extent to which we can easily understand, control, and predict the behavior of a system has much to do, not only with how complex it is but how readily we can interact with it and receive timely and unambiguous feedback. For example, the "dynamic query" system (Ahlberg, Williamson, and Shneiderman 1992) does not decrease the complexity of the underlying data that one is attempting to understand, nor does it decrease the complexity of the interface by which one browses that data. In fact, the interface is actually more complex than a static browsing interface might be. However, what it *does* allow is fast, continuous, unambiguous feedback. Conversely, it is well known that delayed auditory feedback (or delayed visual feedback possible with television circuits) is highly disruptive to performance. In some settings, feedback on performance can still present complexity in the form of credit assignment. If you lose a game of chess, it is unambiguous that you lost, but determining what caused you to lose is difficult. This is not just a "human" problem; the "credit assignment" issue is crucial to any complex adaptive system (Holland 1995). In golf, putting can be a very difficult skill to improve. The main reason is that it is difficult to determine which of many possible factors is responsible for success or failure in putting in a real game situation. For example, if you miss a putt to the left, it might mean that you misread the slope of the green; misread the grain of the green; hit the ball off center of the putter; hit the ball with a curved arc swing; hit the ball with a blade not normal to the path and all combinations of these factors. In the domain of HCI (and elsewhere), this lack of unambiguous feedback about which subset of actions is causing which difficulties has sometimes been referred to as "tangled problems" (e.g., Carroll and Mack [1984]). In the domain of golf, Dave Pelz, an MIT physicist and ex-astronaut, has invented a series of devices to give the learner unambiguous and differentiated feedback about these various possible sources of error (Pelz 2000). Studying these devices might be a valuable exercise for system designers hoping to provide a similar untangling for users.

22.3 FOUR SOURCES OF DIFFICULTY FOR HUMAN–COMPUTER INTERACTION

One goal related to psychological complexity is to provide a system that will allow nonprogrammers to do what is essentially programming; that is, allow them to get a computer system to do what they want it to, not just in terms of choosing from preexisting options but to allow them to have more open-ended productive control. A whole succession of projects at Carnegie Mellon University (see, e.g., Myers, McDaniel, and Kosbie [1993]), the LOGO and related projects at MIT (e.g., Papert 1993); most recently, Scratch (Resnick et al. 2009) and the long series of projects by Alan Kay and others leading most recently to Squeak and Etoys have attempted to reach this goal. Much of the focus of these projects was based on trying either to simplify the syntax and semantics of communicating with the computer or allowing it to take place in a manner more nearly like the way people communicate with each other. It is certainly true that the detailed and often obscure syntax of "ordinary" computer languages can provide a barrier to use. Weinberg (1971) pointed out, for example, that FORTRAN then had one set of rules for what constituted a valid arithmetic expression when used in an assignment statement and another, more restrictive set of rules for what constituted a valid arithmetic expression in an array index. Typically, programming languages are full of these kinds of details and no doubt, they do provide unnecessary complexity for someone who does not spend a large amount of time using such a language. However, it is important to note that such details are only one of four potential sources of difficulty people may have in communicating their desires to a real computing system. For concreteness, consider a scenario in which a chess grandmaster without programming experience desires to write a computer program that plays excellent chess.

22.3.1 Understanding the Syntax and Semantics of Communicating with the Computer

As stated, the chess grandmaster will probably have to learn the somewhat arbitrary syntax and semantics of a programming language. Although there is still promise in techniques aimed at programming by example and natural language communication, at this point, such systems are insufficient for writing something as complex as a chess program.

22.3.2 Making Tacit Knowledge Explicit

Assuming that the expert can master the rules of some programming language and its associated development environment, there are other difficulties. One of these is that the chess expert, like experts in many fields, is unlikely to be consciously aware of all the knowledge that he or she brings to bear on the game of chess. Although some of this knowledge is somewhat explicit; for example, "develop the center," "protect your king," "look for double attacks," much more of it exists in the form of patterns that have developed over the course of many experiences (DeGroot 1978; Simon and Barenfeld 1969; Simon and Gilmartin 1973). Making this tacit or implicit knowledge explicit, for fields of any depth and breadth, will probably prove a far more difficult and time-consuming task than learning the details of a specific programming language. The methods and techniques of knowledge programming and expert systems may be of some help here along with storytelling (Thomas 1999; Thomas, Erickson, and Kellogg 2001). Typically, one may elicit additional tacit knowledge (i.e., transform it from tacit to explicit) by encouraging the expert to recall specific instances, asking them to generalize, and then asking for counterexamples. It can also be useful to involve pairs or small groups in exchanging stories about their experiences.

22.3.3 Making the Computation Efficient and Effective

Another set of issues revolves around the efficiency of what is going on "under the covers." Although computers are becoming ever more powerful and cheaper, it is still easy for nonexperts to write programs that are so inefficient as to be unworkable. A chess program that theoretically makes good moves but takes years for each move is unworkable and unusable. In fact, a naive approach to writing a chess program is simply to do an exhaustive search to all finishes and work backwards. It may or may not be obvious to someone untrained in mathematics or computer science that such an approach would be completely unworkable.

Although the chess case may be extreme, far less extreme cases can still be quite problematic. If one is writing an interactive program, timing issues are important and how to achieve good timing may require a great deal of expertise and knowledge. If systems involve multiple people and or computers, it is quite easy to introduce inconsistencies, deadlocks, thrashing, and so on even if a "nonprogrammer" can master syntax and make implicit knowledge explicit. For a deeper examination of the relationship of usability and choices in the underlying architecture, see the work by Bass and John (2003).

22.3.4 Making the System Understandable and Maintainable

In the ongoing stream of behavior, we make what seem to be "obvious" choices, such as where to put the car keys. If, a day later, we are prone to forget this "obvious" choice, imagine how much more difficult it can be to understand and recall the numerous decisions that must be made in designing and implementing a computer system. A nonprofessional programmer may have very little knowledge of documentation, help systems, updates, security, compatibility issues, the process for reporting and fixing bugs, and so on. As a consequence, even if the first three hurdles are overcome and a workable program is produced, its life may be very short indeed.

To summarize, the goal of having nonprogrammers directly instruct computers in a generative way has often focused on designing a very simple and consistent syntax for a programming language. In Sections 22.3.1 through 22.3.4, we indicated that such a focus only addresses the first of four major stumbling blocks end users face: to wit, learning a complex syntax.

Although the possibility of programming by nonprogrammers is intriguing and probably quite a bit more difficult than it at first appears, there is a slight variant that is becoming more commonplace. There are instances where a community of practice includes some individuals who, although perhaps not professional programmers, are quite proficient at finding and modifying code to fulfill certain functions. In some cases, they may be using programming-like functions in an application program such as a spreadsheet. In other cases, they may actually be using full-fledged programming languages. By modifying existing code incrementally, these semi-expert users are often able to address all four of the issues mentioned above. An interesting early example of such a community was "Moose Crossing" (Bruckman 1997), which provided a shared environment for kids to teach each other object-oriented programming in a special simplified language. Nonetheless, there remain many applications and systems that users interact with that are developed by professional programmers working in software companies. An examination of the way in which products are developed, in turn, can provide some insight into various places where undue complexity may be injected into systems (and therefore, how they might be prevented).

22.3.5 Conceptualizing Human–Computer Interaction as a "Theory of Mind" Task

To perform correctly on the so called Theory of Mind task (Premack and Woodruff 1978) requires that the subject be able to "put themselves in the place" of another. In a prototypical task, a treat might be hidden under a pillow in view of the subject A and another person B. The second person B leaves the room and, in full view of A but not B, the treat is moved to another location, say, on a shelf. Now you ask A, "When B returns, where will they look for the treat?" A very young child will say "on the shelf" because he or she knows that that is where the treat is. Most children over five will say "under the pillow" because they understand that it is behavior consistent with the state of knowledge of person B. Adults with autism spectrum disorders may have considerable difficulty with this type of task. However, most adults seem to have the *capacity* to put themselves in another's shoes, at least when it comes to physical knowledge. It is more problematic when it comes to understanding that someone may behave differently because of differences in culture or language. For example, one of us (JT) working on a multinational team suggested that one of the team members might want to record the pronunciation of their name in a corporate directory for the benefit of other team members. He replied, "Oh, there's no need because my name is quite simple—Johnston." He did not seem to realize that such a name might *not* be simple for someone whose native tongue was not English. In a workshop on cross-cultural issues in HCI at CHI 92, we used a card game in which people at different tables were initially given slightly different sets of rules. All went well until people began switching tables, at which point different sets of rules came into conflict. What is interesting about this exercise is that people initially attributed other people's behavior to incompetence or greed and only much later did the possibility that they were operating under different sets of rules surface. This was in a workshop whose explicit theme was cross-cultural issues! In a similar manner, one can imagine that it may be difficult for developers to imagine that end users would not have the same kinds of concerns and goals that they do.

So here we have an interesting paradox. On the one hand, the ability of people to "put themselves in another's shoes" greatly simplifies what would otherwise be an overwhelmingly complex world of possibilities. We must often rely on the heuristic, "What would I do in this situation?" In driving, for example, or playing a decent game of chess, tennis, or baseball, we rely constantly on a model of what others would do, which begins with a model of what we would do in their situation. There appears to be a physiological basis for this (Gallagher 2008). However, a highly competent tennis player will develop a model of an opponent, which is different from their self-model. The other player might be faster, or slower, or have a better backhand. Similarly, a competent development team will have mechanisms to realize that their end users are not "just like them." A full treatment of this topic is well beyond the scope of this chapter, but we speculate that providing tools to help facilitate both developing and using the human capacities for "Theory of Mind" tasks may offer a significant improvement in terms of lessening gratuitous complexity.

22.4 SOURCES OF COMPLEXITY IN THE DEVELOPMENT PROCESS

22.4.1 Radical Iteration in the Field

Although this topic is dealt with in more detail elsewhere in this handbook as well as in the article by Greene et al. (2003), it is worth at least a brief mention here that radical iteration in the field can generally help avoid, prevent, and address *all* the sources of complexity that we are about to enumerate. By working as closely as possible with the potential users of a system doing their real work in their real context, one can avoid unnecessary complexity that might otherwise be injected during problem finding, problem formulation, design, development, deployment, and maintenance.

22.4.2 Problem Finding

Most of our typical education focuses on solving problems that other people have already found and formulated. Great leverage can arise from finding and formulating problems. Conversely, unnecessary complexity in a system can be injected from the very beginning by "finding" a problem that is not really a problem (for the users). A computer scientist, for instance, might discover that users intuitively choose a sequence of tasks to complete that is not quite as efficient as the theoretically optimal sequence. The users choose routes that are "good enough" and "satisficing" (Simon 1962). However, the computer scientist (or accountant) might see the inefficiency as a "problem" that needs to be "solved." The result may be a system that requires users to key in a long list of tasks to be done, resources to be used, the data required by the tasks, and so on. The system that "solves" the (imaginary) problem could easily take far longer than the labor supposedly saved. Of course, there is the even more insidious problem that in order to model the efficiency of a process in the first place, certain simplifying assumptions must be made and these simplifications may well lead to a solution that is *less* nearly optimal in the real world than the original behavior. For example, in a large telecommunications company, a "route optimization" program was developed to dictate schedules to repair people. The program failed because it did not take into account many specific details that the repair people knew about the times and schedules and constraints of others with whom they had to coordinate.

Inadequate observation or starting with untested assumptions about what problems exist may also prevent people from even noticing easily solvable problems. On one factory tour in the early 1980s, one of the authors (JT) was shown someone whose job was to precisely align two silver needles. The person was sitting in a very awkward position and behind the silver needles was a silver background. It was explained to the author later that since the error rate was so high, they were working on a project to use machine vision to replace this position. The author pointed out that they might first try providing the person with ergonomic seating and a different background against which to align the needles. Automation proved unnecessary.

22.4.3 Problem Formulation and Requirements

One popular anecdote that illustrates the importance of proper problem formulation recounts a modern high-rise office building in which the office workers kept complaining about the slowness of the elevators. Computer programmers were called in, and they reprogrammed algorithms. The complaints increased. Engineers put in heavier duty cables and motors so that the elevators could move faster. Complaints remained as strong as ever and several important multifloor tenants threatened to move out. In desperation, the building owner was considering sacrificing some of the floor space and adding additional elevator shafts at what would obviously be a high price. Someone suggested putting mirrors on all the floors near the elevators and the complaints ceased. In this case, people initially assumed that the problem to be solved was that the elevators ran too slowly and focused on various ways to increase the speed. Eventually, someone came along who realized that the real problem was that people were *unhappy* about the elevator speed. Mirrors apparently gave them something to do and the time waiting did not seem so onerous.

In many real-world cases, this step is made more complex because typically there are a number of stakeholders, each of whom may have very different perceptions of the problem(s) to be solved. A sociotechnical pattern “Who Speaks for Wolf?” (Thomas, Danis, and Lee 2002) based on a Native American story transcribed by Paula Underwood (1993) suggests both the importance of finding all the relevant perspectives and stakeholders early in development and various techniques to try to accomplish that. Briefly, one of the members of a tribe was called “Wolf” because he made a life study of wolves. Once, while Wolf and a few other braves were on an extended hunting expedition, the tribe held council and decided they needed to move. A location was chosen and the tribe moved; however, a few months later, it became obvious that the tribe had moved into the midst of the spring breeding ground of the wolves. They had to decide whether to move again, post guards, or destroy the wolves. They finally decided to move again, but asked themselves, “What did we learn from this and how can we avoid this kind of error in the future?” Someone pointed out that if Wolf had been present at the first council, he would have advised against the location. From then on, they decided that whenever they made a major decision, they would ask themselves, “Who speaks for Wolf?” to see whether there were missing stakeholders or perspectives that needed to be taken into account. Many projects could profit from such a process.

It is typically well understood that the earlier in the process of development an error is caught, the less expensive it is. An error in problem formulation can be extremely long lived and expensive because it sets the context for measuring success. A product or system may be developed which appears to be successful at every step because the wrong thing is being measured so that ultimate failure goes unnoticed until too late. A “classic” example is the replacement of “Coca-Cola” with “New Coke.” According to Gladwell (2005), executives at the Coca-Cola Company were worried because they were losing some market share to Pepsi, and blind taste tests indicated that Pepsi was more often preferred. As a result, a sweeter version of Coke that tasted more like Pepsi was developed and put on the market as a replacement for Coke. The reaction was surprising, immediate, passionate, and nearly disastrous for Coke. People wanted the “old” Coke back! The entire story probably involves brand loyalty, memory, and cognitive dissonance, but one fundamental problem was that the Coca-Cola executives were assuming that the goal was to develop a new product that was sweeter so that it would be preferred in taste tests over Pepsi. And, they succeeded—at solving the wrong problem. What tastes best when you take a decontextualized sip is not necessarily what you prefer (for a variety of reasons, not all directly related to taste) day after day, month after month. In contrast to the “taste” test, the “case” test shows what people actually buy over a long period of time and of course, it is the latter measure which is actually important to profitability. In this case, the use of too *simple* a measure resulted in the wrong problem being solved. This is probably a common situation. Another example of this type occurred when the manufacturer for a new terminal for telephone operators did usability and productivity tests on operators using the terminal but failed to take into account the phone company *customer* who was also on the line and whose behavior actually turned out to be on the critical path most of the time. The entire design, development, testing, and so on were predicated on optimizing a system that consisted of the computer and the operator when the system that really mattered was the operator, the computer, and the *customer*. Again, an *initial* (over)-simplification resulted in a much more complex total solution than a more inclusive (and somewhat more complex) initial formulation would have produced. In this case, cognitive modeling (Gray, John, and Atwood 1993) subsequently confirmed by empirical tests helped avoid significant unnecessary expense and lead to redesign efforts.

Undue complexity can also be introduced by formulating the problem in overly complex terms. The idea of (and failure of) detailed centralized economic planning may be the quintessential example.

In summary, undue complexity can be introduced by beginning with the *wrong* problem formulation. Even if a better formulation is discovered later, unless the development team is willing to throw out everything and start over, remnants of the original formulation will tend to persist into design, development, deployment, testing, and so on, making both the resulting system and its associated elements (sales and marketing materials, documentation, education packages, problem determination aids, etc.) more complex than they need have been.

22.4.4 Design

In an attempt to break down a complex problem into manageable sub-problems, development teams, quite reasonably, divide into sub-teams to deal with various subsystems. Unfortunately, this can result in inconsistencies in basic functionality as well as in the user interface. For example, in one word processor, under certain conditions, the user would be faced with a message that said, in essence, "You cannot delete that file because it does not exist." However, an attempt to create another file by the same name resulted in a message that said, in essence, "You cannot create that file because it already exists." It seems clear that no commonly agreed upon definition of what it meant for a file to "exist" held sway through the whole of the development team.

At a more superficial level, one approach to reduce unnecessary discrepancies in the way that the user interface functions is to provide a "style guide" so that diverse developers or business partners working on various aspects or functions of an application suite will tend to provide a similar "look and feel." There is much to be said for this approach provided that it is applied with perspective and intelligence. In the worst case, development teams may blindly follow what was meant as a guideline and interpret it as an iron-clad rule. For instance, one of us (JT) became involved in the development of an application for the service representatives for a large telecommunications company. The corporate development team insisted that we "must" follow some "guidelines" that claimed users should choose an object before choosing an action. For users who must move between multiple applications, there is a relative advantage of having consistency among applications. In this specific context, however, the users did not use multiple applications, and it was clear that the way that they naturally thought of and interacted with the task, choosing an action first was far more intuitive, quicker, and less error prone than choosing an object first. Nonetheless, the management of the development team believed that the guidelines provided were "received truth" and therefore must be followed. (Incidentally, the project, which ultimately employed hundreds of programmers, never completed.)

22.4.5 Development

Perhaps the greatest contributor to undue complexity is that the development team (and to a lesser extent, management, associated marketing and sales, documentation specialists, etc.) becomes so familiar with a system that almost everything about it becomes "obvious" and "easy" regardless of how it might be perceived by an end user. Once one sees a hidden figure (such as a pig in the clouds), it is nearly impossible *not* to see it. Over the lifecycle of a product, tens, hundreds, or even thousands of little conventions and assumptions become second nature to those associated with the development.

The main cure for this malady is to continually test the scenarios of use, the designs, paper mock-ups, screenshots, prototypes, and beta versions with naive users, that is, folks who are representative of potential users but *not* part of the design team. If, for any reason, this is not feasible (e.g., security, the users do not yet exist) other techniques can provide some amelioration. For instance, heuristic evaluation (Nielsen and Landauer 1993) is likely to catch a fair proportion of actual problems. This is best done with HCI experts who are already familiar with both the technology and the application area. Typically, five to eight experts provide the most value. A variation on this technique involves having people successively take on different personae while interacting with a system, and this may increase the number of errors found in the same period (DeSurvire and Thomas 1993).

22.4.6 Testing

All too often, testing schedules become compressed. Partly as a result of time pressure and partly as a result of the fact that the development team has become accustomed to the high-level and low-level design, the error codes (or error messages) are often cryptic and designed for the productivity and convenience of the testing team or even left over from initial development. Unfortunately, in many cases, these error messages persist into the product experienced by the end user. Testers are often testing functions in a very well-specified context so that an error message is quite interpretable to them. However, to an end user, these same error messages are completely incomprehensible, and often the output comes from "dropping down" several layers in the software stack. Thus, an end user attempting to hit a button in a high-level application may see an error message which not only does not specify what corrective action to take; it mentions software elements that the end user did not even know existed.

Another issue with testing, of course, is that testers who work in the development organization may only test "reasonable" combinations of function. One of us (JT) designed the user experience for a "Dynamic Learning Environment" (Farrell et al. 2004; Thomas and Farrell 2006). In testing the code, he tried altering the URL returned by the system to find what he was looking for. The developers all knew that "you couldn't do this" and it caused the system to crash—but it is an often-used strategy. For instance, if you know that www.umich.edu/~person1 is the URL of person 1 and you are trying to find the website of their colleague at Michigan, person 2, you might reasonably suspect that their URL might be www.umich.edu/~person2 and indeed this often works. Happily, he was able to convince the developers to prevent this ploy from crashing the system. More generally, it is important to have potential *users* test the system as well as those steeped in the cultural assumptions of IT generally and a particular company or product specifically.

22.4.7 Deployment

Today, many applications include "Wizards" to help unzip, install, and even use a product. Often, the distribution of applications is via websites, and therefore finding the right application, finding the right version of the application, finding out whether one has all the prerequisites and necessary patches, and then deciding which features and options to turn on or off can prove as complex, or even more complex, than actually using the application. Often, the instructions and interfaces associated with deployment suffer obscurities from the same root cause as those introduced by the development team—being overly familiar with the application or system. For example, in recently attempting to download an upgrade to a system, the instructions cautioned the user to be sure to use one specific URL and not another. This URL, however, did not refer to the actual URL for finding the desired download. The required URL lay three layers down a menu structure in a *different application*. To the folks who deployed this update, the *context* in which this specific URL was to be used was so obvious as to not bother making that context explicit. A related problem occurs when paper documentation refers the user to look at a specific URL for important details. This generally works at the time the documentation is first released, but later, linking to that URL produces a "not found" error, and the user is referred to a very large generic website where the needed information, if it still exists at all, will be very troublesome to find.

22.4.8 Service

With the spread of an ever cheaper, higher bandwidth telecommunications infrastructure, service has experienced the dual trends of centralization of function and service being geographically distant from the users they are trying to support. Although centralization offers some benefits in economy of scale and knowledge sharing, having service personnel geographically distant can mean a decrease in shared context between service people and users they support. For example, local telephone operators used to be able to answer questions such as, "I need the number for that gas station across from the theater down town." Such questions are currently unanswerable from distant, centralized locations. In some cases, service personnel and users/customers may even have different native languages and come from different cultures. There is a possibility that some of this shared context may soon be reinstated, for example, from geographical information systems and from systems that allow service people to view screens and actions remotely. It may be that a shared view of the real visual world is unnecessary; a shared representation of the salient features, assuming they can be identified, may be enough (O'Neill et al. 2005).

From a user's perspective, undue complexity is often injected into the process of joint problem solving with service personnel because the service personnel are often organized according to the underlying system that they are trying to support rather than the symptom experienced by a user. An end user may, for instance, attempt to print something on a new printer and get an error message indicating that the print job failed. The user calls the "help desk" and the top level menu asks whether they are having a problem with connectivity, the operating system, or an application program, any of which may be the appropriate answer.

An apparently successful innovation in online help is the "Answer Garden" (Ackerman and Malone 1990), which allows expert users, over time with minimal disruption to "grow" a more and more detailed tree of FAQ's. Other trends making the end user's job of getting help simpler include the use of search engines as well as wiki's and blogs to support communities of practice and communities of interest.

22.4.9 Maintenance

Consider the maintenance of an automobile circa 1950. Although such machines were complex, the parts were all large enough to be visible and when a part broke, it could be replaced by a similar part. Such repairs might be simple or they might be complex in that replacing a part might require moving other parts to reach the part to be replaced. Modern software systems (and such systems are becoming ubiquitously embedded in all other technologies) introduce a set of new and often complex maintenance issues. Before installing a new upgraded version of one piece of software, for instance, it is often necessary to check for several prerequisite pieces of software. Each of these may in turn require still other prerequisites. Even if you already have one of the prerequisites installed; say, version XXX of program Y, you may also need to install a fair number of patches to XXX. In some cases, you need to uninstall software, taking care throughout to reboot as needed to clear out persistent memory. Indeed, even if this entire tree is followed, it may still be the case that installing some new piece of software causes something else that used to work, not to work any longer. Although the use of "wizards" has made maintenance much simpler in many cases, if something does fail, diagnosing and fixing the failure may require delving into several layers of software beneath the GUI that is supposed to provide the "simple" interface for the end user.

22.5 WAYS TO MEASURE COMPLEXITY

22.5.1 A Priori Mathematical Models

We have already mentioned an attempt to measure the complexity of programs by Halstead (1977). Other measures have been proposed; probably the best-known are those by McCabe (1976), McCabe and Butler (1989), and Jones (1996). These metrics aim to capture the inherent psychological complexity of the program and not just the behavior that the program surfaces to the end user. We might think to find useful analogues here to measures for the complexity of the user's interaction with a program as well. Unfortunately, the measures do not currently deal with several major factors of psychological complexity. First, the models do not deal with the complexity of the visual (or other sensory) stimuli presented to the user. Second, the models do not deal with the complexity of the response required of the user. Third, the models do not take into account the many complicating factors mentioned above that impact the correspondence between what is required of the user's behavior and what the user already knows.

One of the first attempts to quantitatively predict ease of use a priori tried to measure the complexity of the internal structure necessary to generate behavior (Reisner 1984). A similar approach has been used to try to predict learning time (Bovair, Kieras, and Polson 1990). Basically, both approaches consider the complexity of the underlying rule systems. Reisner's claim is that, other things being equal, it takes longer to execute a more complex rule set. Bovair, Kieras, and Polson claim that it takes longer to learn a more complex rule set and to execute it once learned. Both of these claims seem justified, though only with the caution of *ceteris paribus.* See Rautenberg (1996) for a meta-analysis of quantification attempts of user interfaces and Ivory and Hearst (2001) for a broader review of attempts to automate all or part of the process of usability evaluation.

22.5.2 Linear Regression

Psychological tests have often been constructed by taking a very large number of diverse items and then seeing which ones correlate with a desired criterion. Of course, one needs to revalidate these items with a new sample, but it is interesting that somewhat predictive tests have been constructed with this method for many domains. In fact, linear predictive models have been successfully applied to a large number of domains and are generally better than human experts (see, e.g., Dawes [1982]; Dawes, Faust, and Meehl [1989]). Walston and Felix (1977) used such a technique to predict the effort needed to complete a wide selection of software development projects. Interestingly, the most important factors had to do with the sociopolitical aspects of projects rather than the technical ones. A widely used, flexible method to predict various aspects of software development efforts is the Costructive Cost Model (COCOMO) (Boehm 1981, 2000). Although not strictly linear, the calculations are based on an empirical analysis of actual software development projects.

Perhaps such approaches can be profitably extended to psychological complexity as well. In fact, at least one attempt to measure the "goodness" (related at least in part to complexity) of websites used a similar approach (Ivory, Sinha, and Hearst 2001) and showed some evidence of success. However, in their study, somewhat different factors were predictive for different topic areas. Further, because conventions and underlying technology keep changing, it is likely that linear predictive equations might have to be updated on a frequent basis. In general, this is a potential limitation of linear predictive models. They can be quite accurate and quite robust but only provided the underlying conditions remain relatively constant. The absence of a theoretical underpinning can lead to predictions that can become inaccurate without warning.

22.5.3 Subjective Measures

An entirely different approach to measuring cognitive complexity is to use subjective measures; in effect, to ask people to rate or rank items in terms of cognitive complexity. In judgments of simple stimulus sequences, it appears that complexity and randomness are highly related (Falk and Konold 1997). An interesting and sophisticated attempt to provide a more differentiated subjective view of complexity applicable to real-world systems is that of "Cognitive Dimensions of Complexity" (Green 1989; Green and Petre 1996). This approach identifies 14 different dimensions of complexity. It can be used as a practical tool to focus the attention of developers successively on various areas of design that can lead to undue complexity. More recently, related work has focused on "mismatches" between the concepts inherent in the design of an artifact and the way users conceptualize (Connell, Blandford, and Green 2004). IBM's consumability measures aim at covering all aspects of the experience of different stakeholders and include both objective and subjective measures (Kessler and Sweitzer 2007; Calcaterra and Spangler, 2011).

22.5.4 Textual Analysis of Documentation

In general, we expect the complexity of a description of something to correlate highly with the complexity of that thing. Of course, it is possible to describe a simple thing with undue complexity, but in most circumstances, both extrinsic reward structures and the rules of conversation tend to push description to be sufficiently complex to describe something accurately but sufficiently simple to be understood. Therefore, one promising ersatz measure of the complexity of something, for example, a computer system or a procedure using that system, is to measure the complexity of the description. One commonly used measure is the "Flesch Formula" (Flesch 1948), which basically uses the average length of words in letters and the length of sentences in words in a document to provide as a score the educational reading level required to understand that document. Another metric is the "Gunning Fog" index (Gunning 1952), which seeks to measure the clarity of writing. A still more sophisticated automated approach is possible with the DICTION program (Hart 2001), which gives 31 primary and several derived dimensions to describe the rhetorical style of a document. One of the primary dimensions is labeled complexity and several of the others might also relate. Although this approach offers promise as a metric to be applied after the fact, caution must be applied to using it as an "in-process" metric. Otherwise, writers could use various tricks to make the description of an artifact appear "simple" while in reality making it incomprehensible. (In the absurd limiting case, one could provide a manual for a complex product that simply said, "Use it.") Clearly, documents must also be constrained to be *complete* in order for a fair and useful application of complexity metrics to descriptions.

22.5.5 Iterative Design and Testing

Clearly, much of the rest of this handbook expands on this topic. Although considerations of complexity may prove useful, at this point, there is no complete substitute for interacting with real users doing real work in their real context as a general method for designing, developing, and deploying truly useful and usable systems. Thinking about and measuring complexity may help in this process, however, especially in cases where real user testing is impractical.

22.6 POSSIBLE FUTURE APPROACHES

One can imagine that ever more sophisticated techniques for brain activity imaging and other physiological measures may someday render a reliable and easy-to-use objective index of psychological complexity. Somewhat more likely is the continued evolution of modeling approaches such as Soar (Laird, Newell, and Rosenbloom 1987) Executive Process Ineractive Control [EPIC] (Kieras and Meyer 1997) CogTool (John et al. 2004), Adaptive Control of Though-Rational [ACT-R] (Taatgen and Anderson 2008), and Information Foraging (Pirolli 2007). The follow-on programs might someday conceivably "automatically" calculate a set of complexity numbers for combinations of user, task, system, and context. In the nearer term, it seems likely that continued improvement of heuristic approaches that do require some human intervention will prove useful (e.g., "Dimensions of Cognitive Complexity" [Green 1989] and the Brown, Keller, and Hellerstein [2005] model) in helping to design better user experiences. The latter model assumes that an "expert path" is known and complexity depends on the number of actions, the memory load associated with retaining needed parameters, and the number of context shifts.

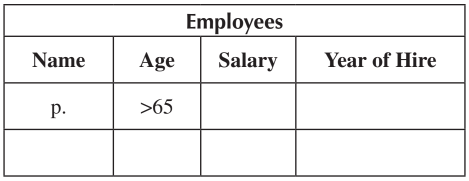
In our own work, we are attempting to extend this model to account more completely for points of uncertainty and the difficulties of decision making. In addition, we are building tools that enable complexity metrics to be produced as a side effect of normal development processes. In this way, developers may gain feedback that is both timelier and more differentiated with respect to their design decisions. In the short term, such metrics should provide useful feedback. As the tools come to be used over time, we expect the development teams to internalize the implications so that better initial design decisions are made.

22.7 COMPLEXITY REDUCTION IN PRACTICE: CASE STUDIES

Clearly, complexity is itself a complex topic. But it is clearly not intractable. Numerous examples of good design and development leading to suitable levels of complexity may be found. We conclude this chapter with five case studies from our own laboratory that illustrate how complexity may be considerably reduced in a real-world setting.

22.7.1 Case Study 1: Query By Example

Query By Example, invented by Moshe Zloof in the early 1970s, was an attempt to provide a query language easy enough for computer-naive novices to learn to use. Early studies indicated that nonprogramming high school and college students were fairly successful in translating English questions into the syntax of this formal query language (Thomas and Gould 1975). One probable reason for the relatively fast times and low error rates was that, in many cases, users only had to *select* the right place to write information rather than having to write all information "from scratch." Another likely reason was that, in Halstead's (1977) terms, Query By Example was quite "dense" (see Figure 22.10). That is, almost all of the symbols required for a given query were symbols that would be required in any conceivable query language. There was little overhead. In other words, the intrinsic complexity of any given query remained, but there was no "gratuitous" or undue complexity introduced by the system itself.



Employees			
Name	**Age**	**Salary**	**Year of Hire**
p.	>65		

"Print the names of everyone who is more then 65 years of age." Only the "p." and the ">65" is entered by the user.

FIGURE 22.10 A simple query in Query By Example.

In some cases, students continued to have some difficulties, but further studies showed that these difficulties did not spring from the query language per se, but from general difficulties with logic (Thomas 1976). For example, students had some difficulties with quantifiers (all vs. some), logical connectives (and, or, not) and with operational distinctions (sum, count, and count unique). These same difficulties occurred in the absence of any requirements of the query language. Additional difficulties were encountered when the structure of the data base did not match well with the structure of the question. So, for instance, if the database contained a column labeled "Year of Hire" a question asking for the names of people "hired after 1970" was fairly easy. A question asking for the names of people "who have worked for more than 35 years" however, was much more problematic.

In a follow-on study (Thomas 1983), students were not given English questions to translate but instead were shown a database structure and given problem statements. They were then to generate their *own* English questions relevant to the problem and then translate their own questions into Query By Example. These results were much less encouraging. Basically, these students had very little concept of what types of questions were reasonable to ask the computer. One problem given was, "Some of the younger faculty members feel that they are not paid enough relative to the older faculty. Write a question that you think might shed light on this issue." A typical question was, "Are the younger faculty paid enough?" In other words, many of the students expected the computer to simply "formulate and solve the problem" for them.

In the 1970s, novice computer users not only might have trouble writing a correct query; they might also write an incorrect query that would consume a huge amount of resource. For this reason, it was considered worthwhile to try to predict the chances that a query was correct before submitting it to the search engine. Based on the formal properties of the query alone (number of operators, etc.), we were able to predict 54% of the variance in query accuracy. If we added the time taken to write the query and the student's own confidence rating, we achieved an accuracy of 75%. Finally, if we added a term for whether the mapping between the English and query was straightforward, more than 90% of the variance was predictable. All these measures may be thought of as factors related to psychological complexity. Although the interface and language were developed and improved iteratively, our studies also showed that remaining user difficulties were due to intrinsic task complexity.

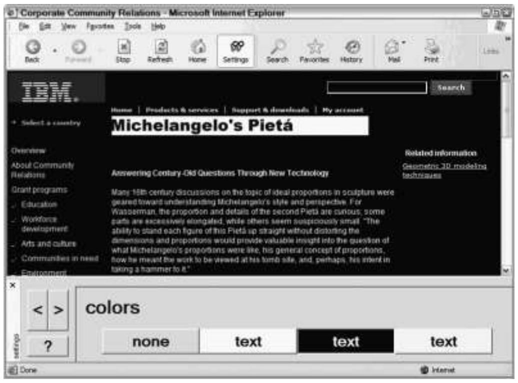
22.7.2 Case Study 2: Web Accessibility Technology

With the web growing in importance to both recreation and work, it became clear to us some time ago that barriers to web use needed to be lowered. It was no longer acceptable for people with visual and motor disabilities to be denied effective web access.

We began our explorations in this area by working directly with older adults, a population needing both web content modifications (text and image enlargement, navigational simplification, visual contrast modifications, etc.) and input adaptations (to filter out hand tremors, remove extraneous key presses and mouse clicks, etc.). Of course, modern browsers and operating systems provide a number of these modifications and adaptations but access to them is distributed throughout the system, inconsistently surfaced, and, often inaccessible to those most in need. Our challenge lay in finding a way to simultaneously reduce the complexity of so much functionality while adding still more accessibility features not otherwise available.

Our approach was iterative and user centered. Early on it became clear that our users did not want a "simplified" browser. Nor did they want to be restricted to a subset of the web. After multiple attempts (chronicled in the work by Richards and Hanson [2004]; Hanson and Richards [2005]), we converged on a design that added a set of very simple control panels to the bottom of an otherwise normal browser, each control panel being dedicated to one class of adaptation or transformation. See Figure 22.11 for one such panel in the context of the full browser.

The only change to the browser's normal interface is the addition of a single "Settings" button. Clicking on this button brings up the first of the series of control panels. Clicking on one of the buttons in a control panel applies an immediate change to the web content. If the change is desired, it is kept by doing nothing more with the panel. Otherwise, it is cancelled by clicking on a "None" or "Standard" button depending on the panel. The panels are organized in a conceptual ring. Clicking on the > button brings up the next panel. Clicking on the < button brings up the previous panel. Clicking on the help button brings up an interactive help page keyed to the current panel, which allows the user to easily explore the full range of modification the panel exposes.



Michelangelo's Pietá

Answering Century-Old Questions Through New Technology

Many 16th century discussions on the topic of ideal proportions in sculpture were geared toward understanding Michelangelo's style and perspective. For Wasserman, the proportion and details of the second Pietá are curious; some parts are excessively elongated, while others seem suspiciously small. "The ability to stand each figure of this Pietá up straight without distorting the dimensions and proportions would provide valuable insight into the question of what Michelangelo's proportions were like, his general concept of proportions, how he meant the work to be viewed at his tomb site, and, perhaps, his intent in taking a hammer to it."

FIGURE 22.11 The "colors" panel for web accessibility software.

A number of mechanisms lie beneath this simple surface. Some modifications are applied by altering browser settings stored in the systems global registry. Others are applied by automatically creating and installing a user style sheet. Others are applied by adjusting parameters in the underlying accessibility settings of the system. Others are applied by modifying the web page's in-memory Document Object Model. Still others are applied by means of always running agents examining input event streams. All of this complexity is hidden from the user.

For a concrete example of the resulting simplification, consider the case of changing the colors of web pages. This is a modification often found useful for people with visual disabilities and for people with various forms of dyslexia. To change just the text foreground and background colors on a popular browser requires 16 separate steps. To ensure that link, visited link, and hover colors are suitably contrasting requires 24 additional steps. In contrast, in our design, setting two of the most popular color combinations—black text on white backgrounds or white text on black backgrounds—requires only a single click on a button showing the desired color combination. Optimally contrasting link, visited link, and hover colors are automatically set as a side effect of this choice. For those needing a broader range of choice, another simple panel allows the direct setting of the foreground and background RGB values. Again, the link, visited link, and hover colors are set automatically.

This case study illustrates a number of approaches to reducing software complexity. First, iterative user-centered design allowed for the rapid exploration of a range of alternative interfaces. Second, the addition of a new interface layer allowed for the unification of a number of disparate mechanisms. Third, careful analysis of the needs of users allowed for some choices to be surfaced prominently and others to be removed. Fourth, the provision of immediate feedback allowed users to directly experience the effects of any choice, trying them alone or in combination until their overall web experience was optimal.

22.7.3 Case Study 3: Teaching Better Strategies

Users are often too *busy* with the task at hand to try to *optimize* their behavior. When they are using tools, the attention of the expert user is likely to be on the goal, and the progress toward the goal and not on the *processes* that they are using to achieve that goal. In addition, it may not be at all clear that their current behavior is significantly less than optimal. This is likely to be particularly true for knowledge workers today because many people work on individual and unique tasks in isolation. In the past, hunters, gatherers, farmers, and widget makers would often have quite similar tasks and quite objective means for determining their performance relative to their peers. In today's world, this remains true in some domains, for example, sports. It is quite common for people to compare their performance on comparable tasks such as the time to run a specific distance or the score on a particular golf course. However, suppose that an athlete never directly observed another one doing the same task nor had information about performance on identical tasks. A person might well run an 8-minute mile or shoot 110 for 18 holes and believe these to be quite adequate performances.

Even if a person does realize that their performance can and should be improved, it is still a complex *and different task* to determine *how* their strategy must change to enhance their performance. Indeed, it may not even be obvious that *strategy* as opposed to *execution* is a major block to better performance. The complexity of determining attribution is illustrated by the work already mentioned on what might *seem* to be a simple athletic skill, namely, putting. An early example of the impact of strategy on performance comes from studies done in our laboratory on problem solving (Carroll, Thomas, and Malhotra 1980). Left to be independent, subjects quite naturally represented a spatial problem in terms of a spatial layout and performed relatively well. Given an isomorphic problem stated in terms of scheduling, however, subjects did relatively poorly and did not use a spatial representation. When encouraged to do so, they were able to use such a representation and the performance differences disappeared. In other words, while the objective complexity of the task remained constant, the psychological complexity was mediated by the representational strategy chosen and people did not automatically choose a good strategy. Earlier work (Thomas 1974) showed that virtually noone approached a simple river-crossing problem in terms of a strategy guaranteed to work; viz., exhaustively exploring the rather small problem graph. Instead, subjects appeared to want to insist on continually making "progress" toward their goal when the solution requires what appears superficially to be moving away from the goal.

In the cases reported above, subjects were presented with novel experimental tasks. However, Bhavnani and John (2001) examined the behavior of domain experts (in architectural design) who had experience with a computer-aided design system and still found that they used nonoptimal strategies. Bhavnani, Reif, and John (2001) extended this work and found that students taught effective strategies and functionality (in an equal time period) performed better than students whose instruction focused only on functionality. In further related work, Bhavnani et al. (2006) found that it is possible to design tools to help guide users into using a more fruitful search strategy when searching for medical information.

Another example of strategy support comes from the domain of storytelling (Landry and Guzdial 2006). Although storytelling is a "natural" and effective way to handle complex events, communicate and build social capital, (Thomas 1999) almost no public school training is typically given on the effective strategies for narrative construction, at least in the United States. Landry and Guzdial recognized people's desire to tell stories and built a plug-in for Flickr to allow them to construct stories around personal photographs. However, some strategy support was necessary to help make these stories more effective.

The lessons to be learned from this and related research are threefold: (1) people do not necessarily hit on strategies to simplify their tasks, (2) better strategies can be taught, and (3) tools may help guide people into using better strategies.

22.7.4 Case Study 4: Coping with Ecological Complexity

An important new area of research in HCI is the application of HCI principles to helping deal with ecological issues. One aspect of this, that our laboratory has been particularly interested in, is the use of *human intelligence* in addressing ecological challenges. The ecological domain is intrinsically a very complex one and many attempts to improve sustainability are being made in terms of top-down optimizations. However, we believe that in many cases, this can be complemented by making use of citizen knowledge. Citizens are often very motivated to deal with local issues, and have detailed knowledge specific to time and place. With the ubiquity of computing technology and sensors, there are increased possibilities for inputting huge quantities of data relevant to a particular problem. An interesting example of the envisioned genre is the Cyclopath application (Panciera et al. 2010), which allows bicyclists in the Minneapolis area to view and input information about the bikeability of various routes.

A related thread of work examines the role of distributed intelligence in the handling of complexity of disasters (e.g., Vieweg et al. 2010; Palen and Liu 2007). When disasters strike, officials attempt to gather, organize, and disseminate data to reduce the human impact of these disasters. Unfortunately, for a number of reasons, studies of such incidents as the shootings at Virginia Tech, the Katrina Hurricane, and wildfires in California indicate that "official" information is often inaccurate or not timely. With the widespread use of mobile phones, people attempt to gather, organize, and disseminate timely and useful information themselves. This has the potential, on the one hand, of providing more locally useful and timely information but on the other hand of spreading unfounded rumors.

Work in our laboratory is underway on a similar topic, namely, to allow more open communication between a city command center and the citizenry. City command centers offer another example of complex work requiring the coordination of many sources of information as well as the expertise of many people. The work on the human factors of the command centers is excellent but historically does tend to treat such centers as self-contained entities. In the past, this was generally a valid simplifying assumption but in today's world, there are both significant opportunities and challenges from understanding the role that crowd-sourcing may play in such command centers. The lesson to be learned from this line of research is that one way of helping to deal with complex real-world situations is to design for input from a large number of people and provide natural ways to vet and organize that information.

22.7.5 Case Study 5: Productivity Tools for High-Performance Computing

As part of a long-term project, IBM is building a new generation of super-computers (http://www.research.ibm.com/hptools/). We would all like to see these computers evidence not only greater throughput but greater programmer productivity as well. Programming is typically a quintessentially complex task and much research has been conducted to attempt to model programmer productivity, to make "programming" accessible to nonprogrammers, and to provide tools to enhance programmer productivity. It seems clear that factors other than tools and task complexity can have a major impact on individual and team productivity (Brooks 1975; Walston and Felix 1977; DeMarco and Lister 1987). Nonetheless, it seems clear that various tools can also contribute substantially to reducing the *undue* complexity in this domain. This is particularly important in high-performance computing. Although programming itself is always complex, *parallel* programming typical of high-performance computing can be *particularly* complex.

IBM is attempting to enhance programmer productivity through the development of a suite of tools, through the encouragement of further open source tools built on Eclipse, and with a new programming language, X10 (http:x10-lang.org). Part of our group is measuring the productivity gains that such tools provide compared with people attempting to do similar tasks in 2002. Purely objective empirical comparisons are problematic, both because there are no detailed baseline data from 2002 and because there are as yet no experts in the tools, which are still under development.

One of several approaches we are using, therefore, is to *model* the complexity of the tasks required by the 2002 tools that were available and to compare that with models of the tasks required by the new tools. We assume that the parameters of the human information processor are unchanged and that in both cases, expert behavior eventually emerges, is taught, or developed through sharing within a community of practice. This is one example of the "time machine" aspect of cognitive modeling since it allows comparisons between something that did but no longer exists and something that does not yet exist! Our earlier modeling efforts were based on the model of Brown and Hellerstein (2004), whereas more recent efforts have been rendered in the keystroke level models first explicated in Card, Moran, and Newell (1983) but now much more conveniently done with the advent of CogTool (Bellamy et al. 2010; Richards et al. 2010). Further discussion of the history and usage of cognitive modeling tools can be found in Kieras (2012). In combination with empirical evaluations, retrospective analyses, and other methods, we believe we can reach a reasonable understanding of the savings in undue complexity due to the new suite of tools.

22.8 CONCLUSIONS

Not surprisingly, psychological complexity is itself a complex topic. It should be of interest to designers of HCI because they typically need to reduce undue complexity. There are occasional exceptions, for instance, in entertainment and learning applications where the designer may want to *increase* psychological complexity. In this chapter, we have distinguished complexity from many related but different concepts such as uncertainty. We have also explored how undue complexity may be introduced into the development process and suggested approaches to measure and reduce undue complexity. As the intrinsic complexity of the world seems to be increasing, the importance of reducing undue complexity will continue to increase.

23 Information Visualization

Stuart Card

CONTENTS

23.1 INTRODUCTION

The working mind is greatly leveraged by interaction with the world outside it. A conversation to share information, a grocery list to aid memory, a pocket calculator to compute square roots all effectively augment a cognitive ability otherwise severely constrained by what is in its limited knowledge, by limited attention, and by limitations on reasoning. But the most profound leverage on cognitive ability is the ability to invent new representations, procedures, or devices that augment cognition far beyond its unaided biological endowment—and bootstrap these into even more potent inventions.

This chapter is about one class of inventions for augmenting cognition, collectively called "information visualization." Other senses could be employed in this pursuit—audition, for example, or a multi-modal combination of senses—the broader topic is really *information perceptualization*; however, in this chapter, we restrict ourselves to visualization. Visualization employs the sense with the most information capacity; recent advances in graphically agile computers have opened opportunities to exploit this capacity, and many visualization techniques have now been developed. A few examples suggest the possibilities.

23.1.1 Example 1: Finding Videos with the FilmFinder

The use of information visualization for finding things is illustrated by the FilmFinder (Ahlberg and Shneiderman 1994a,b). Unlike typical movie-finder systems, the Film Finder is organized not around searching with keywords, but rather around rapid browsing and reacting to collections of films in the database. Figure 23.1 shows a scattergraph of 2000 movies, plotting rated quality of the movie as a function of year when it was released. Color differentiates type of movies—comedy from drama and the like. The display provides an overview, the entire universe of all the movies, and some general features of the collection. It is visually apparent, for example, that a good share of the movies in the collection were released after 1965, but also that there are movies going back as far as the 1920s. Now the viewer "drills down" into the collection by using the sliders in the interface to show only movies with Sean Connery that are between 1 and 4½

hours in length (Figure 23.2). As the sliders are moved, the display zooms in to show about 20 movies. It can be seen that these movies were made between 1960 and 1995, and all have a quality rating higher than 4. Since there is now room on the display, titles of the movies appear. Experimentation with the slider shows that restricting maximum length to 2 hours cuts out few interesting movies. The viewer chooses the highly rated movie, *Murder on the Orient Express* by double-clicking on its marker. Up pop details in a box (Figure 23.3) giving names of other actors in the movie and more information. The viewer is interested in whether two of these actors, Anthony Perkins and Ingrid Bergman, have appeared together in any other movies. The viewer selects their names in the box, and then requests another search (Figure 23.4). The result is a new display of two movies. In addition to the movie the viewer knew about, there is one other movie, a drama entitled *Goodbye, Again*, made around 1960. The viewer is curious about this movie and decides to watch it.

Information visualization has allowed a movie viewer in a matter of seconds to find a movie he or she could not have specified at the outset. To do this, the FilmFinder employed several techniques from information visualization: (a) an *overview* of the collection showing its structure; (b) *dynamic queries*, in which the visualization seems to change instantaneously with control manipulations; (c) *zooming in* by adding restrictions to the set of interest; (d) *details on demand*, in which the user can display temporarily details about an individual object, and (e) *retrieval by example*, in which selected attributes of an individual object are used to specify a new retrieval set.

FIGURE 23.5 TreeMap of daily stock prices. (Courtesy SmartMoney.com.)

23.1.2 Example 2: Monitoring Stocks with TreeMaps

Another example of information visualization is the TreeMap visualization on the SmartMoney.com website,* which is shown in Figure 23.5a. Using this visualization, an investor can monitor more than 500 stocks at once, with data updated every 15 minutes. Each colored rectangle in the figure is a company. The size of the rectangle is proportional to its market capitalization. Color of the rectangle shows movement in the stock price. Bright yellow corresponds to about a 6% increase in price, bright blue to about a 6% decrease in price. Each business sector is identified with a label like "Communications." Those items marked with a letter *N* have an associated news item.

In this example, the investor's task is to monitor the day's market and notice interesting developments. In Figure 23.5a, the investor has moved the mouse over one of the bright yellow

* This figure is produced by a program called SiteMap by Xia Lin and Associates. See http://faculty.cis.drexel.edu/sitemap/index.html.

rectangles, and a box identifying it as Erickson, with a +9.28% gain for the day, has popped up together with other information. Clicking on a box gives the investor a pop-up menu for selecting even more detail. The investor can either click to go to World Wide Web links on news or financials, or drill down, for example, to the sector (Figure 23.5b), or down further to individual companies in the software part of the technology sector (Figure 23.5c). The investor is now able to immediately note interesting relationships. The software industry is now larger than the hardware industry, for example, and despite a recent battering at the time of this figure, the Internet industry is also relatively large. Microsoft is larger than all the other companies in its industry combined. Selecting a menu item to look at year-to-date gains (Figure 23.6), the investor immediately notes interesting patterns: Microsoft stock shows substantial gains, whereas Oracle is down; Dell is up, but Compaq is down; Tiny Advanced Micro is up, whereas giant Intel is neutral. Having noticed these relationships, the investor drills down to put up charts or analysts' positions for companies whose gains in themselves, *or in relation to a competitor*, are interesting. For example, the investor is preparing a report on the computer industry for colleagues and notices how AMD is making gains against Intel, or how competition for the Internet is turning into a battle between Microsoft and AOL/Time Warner.

23.1.3 Example 3: Sensemaking with Permutation Matrices

As a final information visualization example, consider the case proposed by Bertin (1981) of a hotel manager who wants to analyze hotel occupancy data (Table 23.1) to increase her return. In order to search for meaningful patterns in her data, she represents it as a permutation matrix (Figure 23.7a). A permutation matrix is a graphic rendition of a cases x variables display. In Figure 23.7a, each cell of Table 23.1 is a small bar of a bar chart. The bars for cells below the mean are white; those above the bar are black. By permuting rows and columns, patterns emerge that lead to making sense of the data.

In Figure 23.7a, the set of months, which form the cases, are repeated to reveal periodic patterns across the end of the cycle. By visually comparing the pairs of rows, one can find rows that are similar. These are reordered and grouped (Figure 23.7b). By this means, it is discovered that there seem to be two patterns of yearly variation. One pattern in Figure 23.7b is semiannual, dividing the year into the cold months of October through April and the warm months of May through September. The other pattern breaks the year into four distinct regions. We have thus found the beginnings of a *schema*—that is, a framework in terms of which we can encode the raw data and describe it in a more compact language. Instead of talking about the events of the year in terms of individual months, we can now talk in terms of two series of periods, the semiannual one, and the four distinct periods. As we do so, there is a *residue* of information not included as part of our descriptive language. Sensemaking proceeds by the *omission and recoding of information into more compact form* (see Resnikoff 1989). This residue of information may be reduced by finding a better or more articulated schema, or it may be left as noise. Beyond finding the basic patterns in the data, the hotel manager wants to make sense of the data relative to a purpose: she wants to increase the occupancy of the hotel. Therefore, she has also permuted general indicators of activity in Figure 23.7b, such as % Occupancy and Length of Stay, to the top of the diagram and put the rows that correlate with these below them. This reveals that Conventions, Businessmen, and Agency Reservations, all of which generally have to do with convention business, are associated with higher occupancy. This insight comes from the match

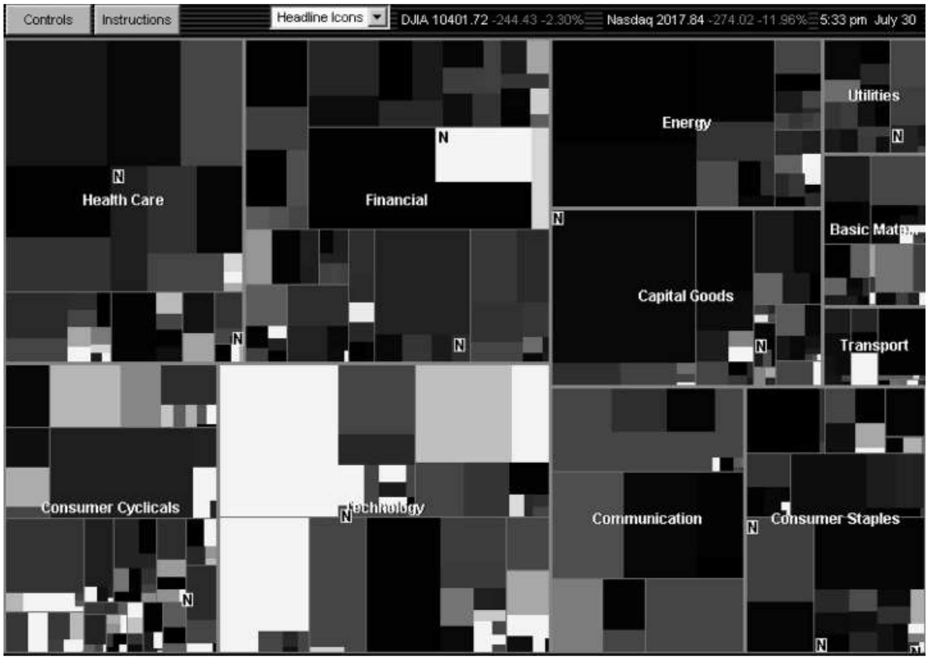

FIGURE 23.6 TreeMap of year-to-date stock prices. (Courtesy SmartMoney.com.)

in patterns *internal* to the visualization; it also comes from noting why these variables might correlate as a consequence of factors *external* to the visualization. She also discovers that marked differences exist between the winter and summer guests during the slow periods. In winter, there are more local guests, women, and age differences. In summer, there are more foreign tourists and less variation in age.

This visualization was useful for sensemaking on hotel occupancy data, but it is too complicated to communicate the high points. The hotel manager therefore creates a simplified diagram, Figure 23.7c. By graying some of the bars, the main points are more readily graspable, while still preserving the data relations. A December convention, for example, does not seem to have the effect of the other conventions in bringing in guests. It is shown in gray as residue in the pattern. The hotel manager suggests moving the convention to another month, where it might have more effect on increasing the occupancy of the hotel.

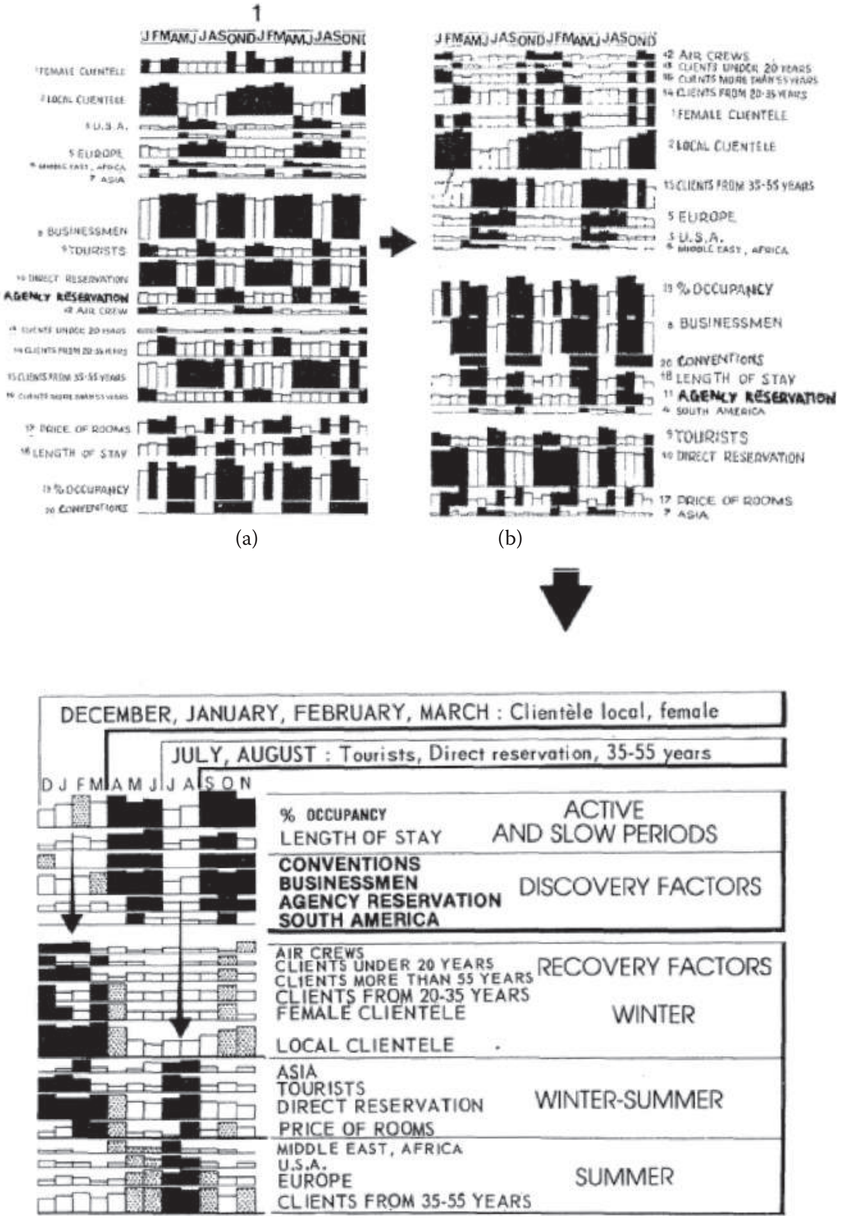
23.1.4 What Is Information Visualization?

The FilmFinder, the TreeMap, and the permutation matrix hotel analysis are all examples of the use of information visualization. We can define information visualization as "the use of computer-supported, interactive, visual representations of abstract data in order to amplify cognition" (Card, Mackinlay, and Shneiderman 1999).

Information visualization needs to be distinguished from related areas: *scientific visualization* is like information visualization, but it is applied to scientific data and typically is physically based. The starting point of a natural geometrical substrate for the data, whether the human body or earth geography, tends to emphasize finding a way to make visible the invisible (say, velocity of air flow) within an existing spatial framework. The chief problem for information visualization, in contrast, is often finding an effective mapping between abstract entities and a spatial representation. Both information visualization and scientific visualization belong to the broader field of *data graphics*, which is the use of abstract, nonrepresentational visual representations to amplify cognition. Data graphics, in turn, is part of *information design*, which concerns itself with external representations for amplifying cognition. At the highest level, we could consider information design a part of *external cognition*, the uses of the external world to accomplish some cognitive process. Characterizing the purpose of information visualization as *amplifying cognition* is purposely broad. Cognition can be the process of writing a scientific paper or shopping on the Internet for a cell phone. Generally, it refers to the intellectual processes in which information is obtained, transformed, stored, retrieved, and used. All of these can be advanced generally by means of external cognition, and in particular by means of information visualization.

23.1.5 Why Does Visualization Work?

Visualization aids cognition not because of some mystical superiority of pictures over other forms of thought and communication, but rather because visualization helps the user by making the world outside the mind a resource for thought in



(a)

(b)

(c)

FIGURE 23.7 Permutation matrix representation of hotel data (Berlin 1977/1981). (a) Initial matrix of variables. (b) Permuted matrix to group like patterns together.

specific ways. We list six groups of these in Table 23.2 (Card, Mackinlay, and Shneiderman 1999): Visualization amplifies cognition by (1) increasing the memory and processing resources available to the users, (2) reducing search for information, (3) using visual representations to enhance the detection of patterns, (4) enabling perceptual inference operations, (5) using perceptual attention mechanisms for monitoring, and (6) by encoding information in a manipulable medium. The FilmFinder, for example, allows the representation of a large amount of data in a small space in a way that allows patterns to be perceived visually in the data. Most important, the method of instantly responding in the display to the dynamic movement of the sliders allowed users to rapidly explore the multidimensional space of films. The TreeMap of the stock market allows monitoring and exploration of many equities. Again, much data is represented in little space. In this case, the display manages the user's attention, drawing it to those equities with unusually large changes, and supplying the means to drill down into the data to understand why these movements may be happening. In the hotel management case, the visual representation makes it easier to notice similarities of behavior in a multidimensional attribute space, then to cluster and represent these. The final product is a compact (and simplified) representation of the original data that supports a set of forward decisions. In all of these cases, visualization allows the user to (a) examine a large amount of information, (b) keep an overview of the whole while pursuing details, (c) keep track of (by using the display as an

TABLE 23.2
How Information Visualization Amplifies Cognition

1. Increased Resources	
High-bandwidth hierarchical interaction	Human moving gaze system partitions limited channel capacity so that it combines high spatial resolution and wide aperture in sensing the visual environments (Larkin and Simon 1987).
Parallel perceptual processing	Some attributes of visualizations can be processed in parallel compared to text, which is serial.
Offload work from cognitive to perceptual system	Some cognitive inferences done symbolically can be recoded into inferences done with simple perceptual operations (Larkin and Simon 1987).
Expanded working memory	Visualizations can expand the working memory available for solving a problem (Norman 1993).
Expanded storage of information	Visualizations can be used to store massive amounts of information in a quickly accessible form (e.g., maps).
2. Reduced Search	
Locality of processing	Visualizations group information used together reducing search (Larkin and Simon 1987).
High data density	Visualizations can often represent a large amount of data in a small space (Tufte 1983).
Spatially-indexed addressing	By grouping data about an object, visualizations can avoid symbolic labels (Larkin and Simon 1987).
3. Enhanced Recognition of Patterns	
Recognition instead of recall	Recognizing information generated by a visualization is easier than recalling that information by the user.
Abstraction and aggregation	Visualizations simplify and organize information, supplying higher centers with aggregated forms of information through abstraction and selective omission (Card, Robertson, and Mackinlay 1991; Resnikoff 1989).
Visual schemata for organization	Visually organizing data by structural relationships (e.g., by time) enhances patterns.
Value, relationship, trend	Visualizations can be constructed to enhance patterns at all three levels (Bertin 1967/1983).
4. Perceptual Inference	
Visual representations make some problems obvious	Visualizations can support a large number of perceptual inferences that are very easy for humans (Larkin and Simon 1987).
Graphical computations	Visualizations can enable complex specialized graphical computations (Hutchins 1996).
5. Perceptual Monitoring	Visualizations can allow for the monitoring of a large number of potential events if the display is organized so that these stand out by appearance or motion.
6. Manipulable Medium	Unlike static diagrams, visualizations can allow exploration of a space of parameter values and can amplify user operations.

external working memory) many things, and (d) produce an abstract representation of a situation through the omission and recoding of information.

23.1.6 Historical Origins

Drawn visual representations have a long history. Maps go back millennia. Diagrams were an important part of Euclid's books on geometry. Science, from earliest times, used diagrams to (a) record observations, (b) induct relationships, (c) explicate methodology of experiments, and (d) classify and conceptualize phenomena (for a discussion, see Robin 1992). For example, Figure 23.8 is a hand-drawn illustration in Newton's first scientific publication, illustrating how white light is really composed of many colors. Sunlight enters from the window at right and is refracted into many colors by a prism. One of these colors can be selected (by an aperture in a screen) and further refracted by another prism, but the light stays the same color, showing that it has already been reduced to its elementary components. As in Newton's illustration, early scientific and mathematical diagrams generally had a spatial, physical basis and were used to reveal the hidden, underlying order in that world.

Surprisingly, diagrams of abstract, nonphysical information are apparently rather recent. Tufte (1983) dates abstract diagrams to Playfair (1786) in the 18th century. Figure 23.9 is one of Playfair's earliest diagrams. The purpose was to convince readers that English imports were catching up with exports. Starting with Playfair, the classical methods of plotting data were developed—graphs, bar charts, and the rest.

Recent advances in the visual representation of abstract information derive from several strands that became intertwined. In 1967, Bertin (1967/1983, 1977/1981), a French cartographer, published his theory of *The Semiology of Graphics*. This theory identified the basic elements of diagrams and their combination. Tufte (1983, 1990, 1997), from the fields of visual design and data graphics, published a series of seminal books that set forth principles for the design of data graphics and emphasized maximizing the density of useful information. Both Bertin's and Tufte's theories became well known and influential. Meanwhile, within statistics, Tukey (1977) began a movement on exploratory data analysis. His emphasis was not on the quality of graphical presentation, but on the use of pictures to give rapid, statistical insight into data relations. For example, "box and whisker plots" allowed an analyst to get a rapid characterization of data distributions. Cleveland and McGill (1988) wrote an influential book, *Dynamic Graphics for Statistics*, explicating new visualizations of data with particular emphasis on the visualization of multidimensional data.

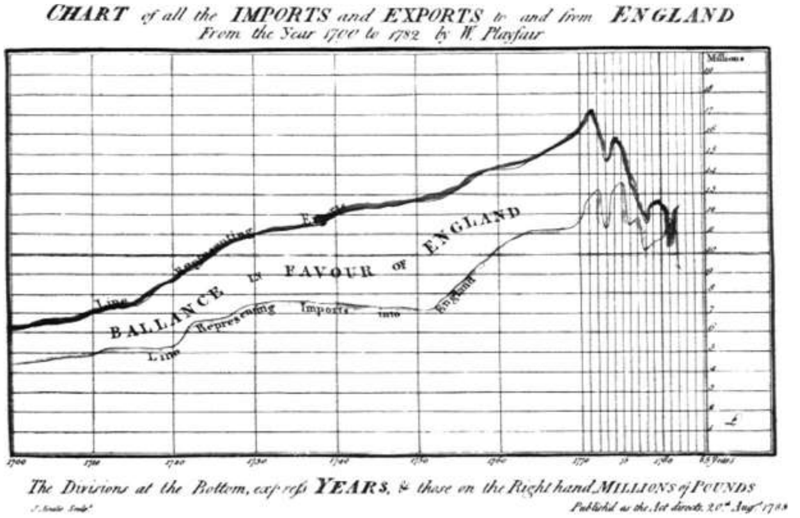

FIGURE 23.9 Playfair's charts of English imports and exports. (Data from Tufte, E. R. 1983. *The Visual Display of Quantitative Information*. Cheshire, CT: Graphics Press.)

In 1985, NSF launched an initiative on *scientific visualization* (McCormick and DeFanti 1987). The purpose of this initiative was to use advances in computer graphics to create a new class of analytical instruments for scientific analysis, especially as a tool for comprehending large, newly produced datasets in the geophysical and biological sciences. Meanwhile, the computer graphics and artificial intelligence communities were interested in the automatic design of visual presentations of data. Mackinlay's (1986a,b) thesis APT formalized Bertin's design theory, added psychophysical data, and used these to build a system for automatically generating diagrams of data, tailored for some purpose. Roth and Mattis (1990) built a system to do more complex visualizations, such as some of those from Tufte. Casner (1991) added a representation of tasks. This community was interested not so much in the quality of the graphics as in the automation of the match between data characteristics, presentational purpose, and graphical presentation. Finally, the user interface community saw advances in graphics hardware opening the possibility of a new generation of user interfaces. The first use of the term "information visualization" was probably in Robertson, Card, and Mackinlay (1989). Early studies in this community focused on user interaction with large amounts of information: Feiner and Beshers (1990) presented a method, worlds within worlds, for showing six-dimensional financial data in an immersive virtual reality. Shneiderman (1992) developed a technique called "dynamic queries" for interactively selecting subsets of data items and TreeMaps, a space-filling representation for trees. Robertson, Card, and Mackinlay (1993) presented ways of using animation and distortion to interact with large data sets in a system called the Information Visualizer, which used *focus + context* displays to nonuniformly present large amounts of information. The emphasis for these studies was on the means for cognitive amplification, rather than on the quality of the graphics presentations.

The remainder of this chapter will concentrate on the techniques that have been developed for mapping abstract information to interactive visual form to aid some intellectual task. The perceptual foundations of this effort are beyond the scope of this chapter, but are covered in Ware (2000). Further details on information visualization techniques are addressed in a text by Spence (2000). The classic papers in information visualization are collected in Card, Mackinlay, and Shneiderman (1999).

23.2 VISUALIZATION REFERENCE MODEL

23.2.1 Mapping Data to Visual Form

Despite their seeming variability, information visualizations can be systematically analyzed. Visualizations can be thought of as adjustable mappings from data to visual form to the human perceiver. In fact, we can draw a simple Visualization Reference Model of these mappings (Figure 23.10). Arrows follow from *raw data* (data in some idiosyncratic format) on the left, though a set of *data transformations* into *data tables* (canonical descriptions of data in a variables x cases format extended to include metadata). The most important mapping is the arrow from data tables to *visual structures* (structures that combine values an available vocabulary of visual elements—spatial substrates, marks, and graphical properties). Visual structures can be further transformed by *view transformations*, such as visual distortion or 3D viewing angle, until it finally forms a *view* that can be perceived by human users. Thus, raw data might start out as text represented as indexed strings or arrays. These might be transformed into *document vectors*, normalized vectors in a space with dimensionality as large as the number of words. Document vectors, in turn, might be reduced by multidimensional scaling to create the analytic abstraction to be visualized, expressed as a data table of x, y, z coordinates that could be displayed. These coordinates might be transformed into a visual structure—that is, a surface on an information landscape—which is then viewed at a certain angle.

Similar final effects can be achieved by transformations at different places in the model: When a point is deleted from the visualization, has the point been deleted from the dataset? Or is it still in the data merely not displayed? Chi and Riedl (1998) called this the *view-value distinction*, and it is an example of just one issue where identifying the locus of a transformation using the Visualization Reference Model helps to avoid confusion.

Information visualization is not just about the creation of visual images, but also the interaction with those images in the service of some problem. In the Visualization Reference Model, another set of arrows flow back from the human at the right into the transformations themselves, indicating the adjustment of these transformations by user-operated controls. It is the rapid reciprocal reaction between the generation of images by machine and the selection and parametric adjustment of those images, giving rise to new images that gives rise to the attractive power of interactive information visualization.

23.2.2 Data Structures

It is convenient to express data tables as tables of objects and their attributes, as in Table 23.3. For example, in the

TABLE 23.3
Data Table about Films

FilmID	**230**	**105**	**540**	**. . .**

Raw data: idiosyncratic formats
Data tables: relations (cases by variables) + meta-data
Visual structures: spatial substrates + marks + graphical properties
Views: graphical parameters (position, scaling, clipping, . . .)

FIGURE 23.10 Reference model for visualization. Visualization can be described as the mapping of data to visual form that supports human interaction in a workplace for visual sense making. (Data from Card, S. K., J. D. Mackinlay, and G. G. Robertson. 1991. The Information Visualizer: An Information Workspace. *ACM Conference on Human Factors in Computing Systems (CHI '91)*, 181–8.)

FilmFinder, the basic objects (or "cases") are films. Each film is associated with a number of attributes or variables, such as title, stars, year of release, genre type, and so forth. The vertical double black line in the table separates data in the table to the left of the line from the metadata, expressed as variable names, to the left of the line. The horizontal black line across the table separates input variables from output variables—that is, the table can be thought of as a function.

$$f(\text{input variables}) = \text{output variables}$$

So,

$$\mathit{Year}\ (\mathit{FilmID} = 105) = 1959$$

Variables imply a scale of measurement, and it is important to keep these straight. The most important to distinguish are

N = *Nominal (are only = or ≠ to other values)*
O = *Ordinal* (obeys a < relation)
Q = *Quantitative* (can do arithmetic on them)

A nominal variable N is an unordered set, such as film titles {Goldfinger, Ben Hur, Star Wars}. An ordinal variable O is a tuple (ordered set), such as film ratings ⟨G, PG, PG-13, R⟩. A quantitative variable Q is a numeric range, such as film length [0, 360].

In addition to the three basic types of variables, subtypes represent important properties of the world associated with specialized visual conventions. We sometimes distinguish the subtype *Quantitative Spatial* (Q_s) for intrinsically spatial variables common in scientific visualization and the subtype *Quantitative Geographical* (Q_g) for spatial variables that are specifically geophysical coordinates. Other important subtypes are similarity metrics *Quantitative Similarity* (Q_m), and the temporal variables *Quantitative Time* (Q_t) and *Ordinal Time* (O_t). We can also distinguish Interval Scales (I) (like Quantitative Scales, but since there is not a natural zero point, it is not meaningful to take ratios). An example would be dates. It is meaningful to subtract two dates (June 5, 2002 – June 3, 2002 = 2 days), but it does not make sense to divide them (June 5, 2002 ÷ June 23, 2002 = Undefined). Finally, we can define an *Unstructured* Scale (U), whose only value is present or absent (e.g., an error flag). The scales are summarized in Table 23.4.

Scale types can be altered by transformations, and this practice is sometimes convenient. For example, quantitative variables can be mapped by data transformations into ordinal variables

$$Q \rightarrow O$$

by dividing them into ranges. For example, film lengths [0, 360] minutes (type Q) can be broken into the ranges (type O),

$$[0, 360] \text{ minutes} \rightarrow \langle \text{SHORT, MEDIUM, LONG} \rangle$$

This common transformation is called "classing," because it maps values onto classes of values. It creates an accessible summary of the data, although it loses information. In the other direction, nominal variables can be transformed to ordinal values

$$N \rightarrow O$$

based on their name. For example, film titles {GOLDFINGER, BEN HUR, STAR WARS} can be sorted lexicographically

$$\{\text{GOLDFINGER, BEN HUR, STAR WARS}\} \rightarrow$$
$$\langle \text{BEN HUR, GOLDFINGER, STAR WARS} \rangle$$

Strictly speaking, we have not transformed their values, but in many uses (e.g., building alphabetically arranged dictionaries of words or sliders in the FilmFinder), we can act as if we had.

TABLE 23.4
Classes of Data and Visual Elements

	Data Classes		**Visual Classes**	
Class	**Description**	**Example**	**Description**	**Example**
U	*Unstructured* (can only distinguish presence or absence)	ErrorFlag	*Unstructured* (no axis, indicated merely whether something is present or absent)	Dot
N	*Nominal* (can only distinguish whether two values are equal)	{Goldfinger, Ben Hur, Star Wars}	*Nominal Grid* (a region is divided into subregions, in which something can be present or absent)	Colored circle
O	*Ordinal* (can distinguish whether one value is less or greater but not difference or ratio)	⟨Small, Medium, Large⟩	*Ordinal Grid* (order of the subregions is meaningful)	Alpha slider
I	*Interval* (can do subtraction on values, but no natural zero and can't compute ratios)	[10 Dec. 1978–4 Jun. 1982]	*Interval Grid* (region has a metric but no distinguished origin)	Year axis
Q	*Quantitative* (can do arithmetic on values)	[0–100] kg	*Quantitative Grid* (a region has a metric)	Time slider
Q_s	*—Spatial variables*	[0–20] m	*—Spatial grid*	
Q_m	*—Similarity*	[0–1]	*—Similarity space*	
Q_g	*—Geographical coord.*	[30°N–50°N]Lat.	*—Geographical coord.*	
Q_t	*—Time variable*	[10–20] µsec	*—Time grid*

Variable scale types form an important class of metadata that, as we shall see, is important for proper information visualization. We can add scale type to our Data Table in Table 23.3 together with cardinality or range of the data to give us essentially a codebook of variables as in Table 23.5.

23.2.3 Visual Structures

Information visualization maps data relations into visual form. At first, it might seem that a hopelessly open set of visual forms can result. Careful reflection, however, reveals what every artist knows: that visual form is subject to strong constraints. Visual form that reflects the systematic mapping of data relations onto visual form, as in information visualization or data graphics, is subject to even more constraints. It is a genuinely surprising fact, therefore, that most information visualization involves the mapping data relations onto only a half dozen components of visual encoding:

1. *Spatial substrate*
2. *Marks*
3. *Connection*
4. *Enclosure*
5. *Retinal properties*
6. *Temporal encoding*

Of these mappings, the most powerful is how data are mapped onto the spatial substrate—that is, how data are mapped into spatial position. In fact, one might say that the design of an information visualization consists first of deciding which variables are going to get the spatial mappings, and then how the rest of the variables are going to make do with the coding mappings that are left.

23.2.3.1 Spatial Substrate

As we have just said, the most important choice in designing an information visualization is which variables are going to map onto spatial position. This decision gives importance to spatially encoded variables at the expense of variables encoded using other mappings. Space is perceptually dominant (MacEachren 1995); it is good for discriminating values and picking out patterns. It is easier, for example, to identify the difference between a sine and a tangent curve when encoded as a sequence of spatial positions than as a sequence of color hues.

Empty space itself, as a container, can be treated as if it had metric structure. Just as we classified variables according to their scale type, we can think of the properties of space in terms of the scale type of an axis of space (cf. Engelhardt et al. 1996). Axis scale types correspond to the variable scale types (see Table 23.4). The most important axes are

U = Unstructured (no axis, indicated merely whether something is present or absent)
N = Nominal Grid (a region is divided into subregions, in which something can be present or absent)
O = Ordinal Grid (the ordering of these subregions is meaningful), and
Q = Quantitative Grid (a region has a metric)

Besides these, it is convenient to make additional distinctions for frequently used subtypes, such as Spatial axes (Qs).

Axes can be linear or radial; essentially, they can involve any of the various coordinate systems for describing space. Axes are an important building block for developing Visual Structures. Based on the Data Table for the FilmFinder in Table 23.5, we represent the scatterplot as composed of two orthogonal quantitative axes:

$$Year \rightarrow Q_x$$
$$Popularity \rightarrow Q_y$$

The notation states that the Year variable is mapped to a quantitative X-axis and the Popularity variable is mapped to a quantitative Y-axis. Other axes are used for the FilmFinder query widgets. For example, an ordinal axis is used in the radio buttons for film ratings,

$$Ratings \rightarrow O_y$$

and a nominal axis is used in the radio buttons for film type,

$$FilmType \rightarrow N_x$$

23.2.3.2 Marks

Marks are the visible things that occur in space. There are four elementary types of marks (Figure 23.11):

1. P = Points (0D)
2. L = Lines (1D)
3. A = Areas (2D)
4. V = Volumes (3D)

Area marks include surfaces in three dimensions, as well as 2D-bounded regions.

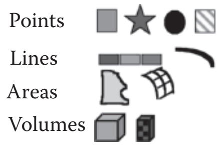

FIGURE 23.11 Types of marks.

Unlike their mathematical counterpart, point and line marks actually take up space (otherwise, they would be invisible) and may have properties such as shape.

23.2.3.3 Connection and Enclosure

Point marks and line marks can be used to signify other sorts of topological structure: graphs and trees. These allow showing relations among objects without the geometrical constraints implicit in mapping variables onto spatial axes. Instead, we draw explicit lines. Hierarchies and other relationships can also be encoded using enclosure. Enclosing lines can be drawn around subsets of items. Enclosure can be used for trees, contour maps, and Venn diagrams.

23.2.3.4 Retinal Properties

Other graphical properties were called retinal properties by Bertin (1967/1983), because the retina of the eye is sensitive to them independent of position. For example, the FilmFinder in Figure 23.1 uses color to encode information in the scatterplot:

$$FilmID(FilmType) \rightarrow P(Color)$$

This notation says that the FilmType attribute for any FilmID case is visually mapped onto the color of a point.

Figure 23.12 shows Bertin's six "retinal variables" separated into spatial properties and object properties according to which area of the brain they are believed to be processed (Kosslyn 1994). They are sorted according to whether the property is good for expressing the extent of a scale (has a natural zero point), or whether its principal use is for differentiating marks (Bertin 1977/1981). Spatial position, discussed earlier as basic visual substrate, is shown in the position it would occupy in this classification.

Other graphical properties have also been proposed for encoding information. MacEachren (1995) has proposed (a) crispness (the inverse of the amount of distance used to blend two areas or a line into an area), (b) resolution (grain with raster or vector data will be displayed), (c) transparency, and (d) arrangement (e.g., different ways of configuring dots). He further proposed dividing color into (a) value (essentially, the gray level of Figure 23.12), (b) hue, and (c) saturation. Graphical properties from the perception literature that can support preattentive processing have been suggested candidates for coding variables such as curvature, lighting direction, or direction of motion (see Healey, Booth, and Enns 1995). All of these suggestions require further research.

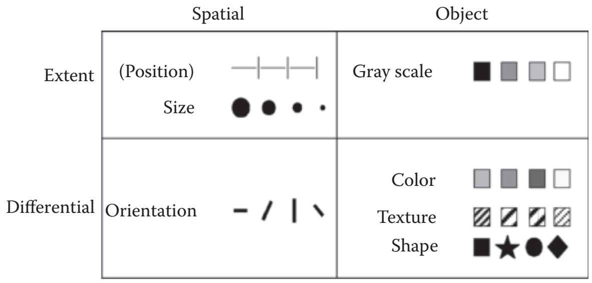

FIGURE 23.12 Retinal properties. The six retinal properties can be grouped by whether they form a scale with a natural zero point (extend) and whether they deal with spatial distance or orientation (spatial). (Data from Card, S. K., J. D. Mackinlay, and G. G. Robertson. 1991. The Information Visualizer: An Information Workspace. *ACM Conference on Human Factors in Computing Systems (CHI '91)*, 181–8.)

23.2.3.5 Temporal Encoding

Visual Structures can also temporally encode information; human perception is very sensitive to changes in mark position and the mark's retinal properties. We need to distinguish between temporal data variables to be visualized:

$$\mathrm{Q}_t \rightarrow \textit{some visual representation}$$

and animation, that is, mapping a variable into time,

$$\textit{some variable} \rightarrow \textit{Time}$$

Time as animation could encode any type of data (whether it would be an effective encoding is another matter). Time as animation, of course, can be used to visualize time as data.

$$\mathrm{Q}_t \rightarrow \textit{Time}$$

This is natural, but not always the most effective encoding. Mapping time data into space allows comparisons between two points in time. For example, if we map time and a function of time into space (e.g., time and accumulated rainfall),

$$Q_t \rightarrow Q_x \textit{ [make time be the X-axis]}$$
$$f(Q_t) \rightarrow Q_y \textit{ [make accumulated rainfall be the Y-axis]},$$

then we can directly experience rates as visual linear slope, and we can experience changes in rates as curves. This encoding of time into space for display allows us to make much more precise judgments about rates than would be possible from encoding time as time. Another use of time as animation is similar to the unstructured axes of space. Animation can be used to enhance the ability of the user to keep track changes of view or visualization. If the user clicks on some structure, causing it to enlarge and other structures to become smaller, animation can effectively convey the change and the identity of objects across the change, whereas simply viewing the two end states is confusing. Another use is to enhance a visual effect. Rotating a complicated object, for example, will induce 3D effects (hence, allow better reading of some visual mappings).

23.2.4 Expressiveness and Effectiveness

Visual mappings transform Data Tables into Visual Structure and then into a visual image. This image is not just an arbitrary image. It is an image that has a particular meaning it must express. That meaning is the data relation of which it is the visual transformation. We can think of the image as a sentence in a visual language (Mackinlay 1986b) that expresses the relations in the Data Table. To be a good information visualization, the mappings must satisfy some constraints. The first constraint is that the mapping must be expressive. A visualization is said to be *expressive* if and only if it encodes all the data relations intended and no other data relations. The first part of expressiveness turns out to be easier than the second. Suppose we plot FilmType against Year using the data-to-visual mapping in Figure 23.13. The problem of this mapping is that the nominal movie rating data are expressed by a quantitative axis. That is, we have tried to map:

$$FilmType(N) \rightarrow Position(Q)$$

In so doing, we have visually expressed all the data relation, but the visualization also implies relationships that do not exist. For example, the 1959 version of *Ben Hur* does not have a film type that is five times greater than the 1926 version of *Ben Hur,* as implied in the figure. Wisely, the authors of the FilmFinder chose the mapping:

$$FilmType(N) \rightarrow Color(N)$$

Of course, there are circumstances in which color could be read as ordinal, or even possibly quantitative, but the miscellaneous order of the buttons in Figure 23.1 discourages such an interpretation and the relatively low effectiveness of color for this purpose in Table 23.7 also discourages this interpretation.

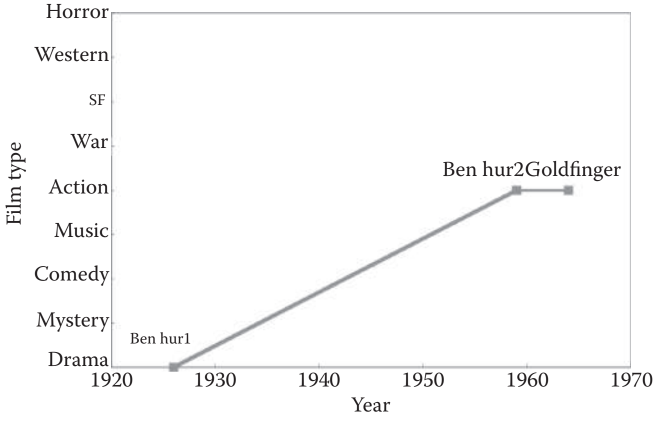

FIGURE 23.13 Mapping from data to visual form that violates expressiveness criterion.

Table 23.6 shows the mappings chosen by authors of the FilmFinder. The figure shows the Data Table's metadata and data and how they are mapped onto the Visual Structure. Note that the nominal data of the PG ratings is mapped onto a nominal visualization technique (colors). Note also, that names of directors and stars (nominal variables) are raised to ordinal variables (through alphabetization), and then mapped onto an ordinal axis. This is, of course, a common way to handle searching among a large number of nominal items.

Some properties are more effective than others for encoding information. Position is by far the most effective all-around representation. Many properties are more effective for some types of data than for others. Table 23.7 gives an approximate evaluation for the relative effectiveness of some encoding techniques based on (MacEachren 1995). We note that spatial position is effective for all scale types of data. Shape, on the other hand, is only effective for nominal data. Gray scale is most effective for ordinal data. Such a chart can suggest representations to a visualization designer.

23.2.5 Taxonomy of Information Visualizations

We have shown that the properties of data and visual representation generally constrain the set of mappings that form the basis for information visualizations. Taken together, these constraints form the basis of a taxonomy of information visualizations. Such a taxonomy is given in Table 23.8. Visualizations are grouped into four categories. First are *Simple Visual Structures*, the static mapping of data onto multiple spatial dimensions, trees, or networks plus retinal variables, depicted in Figure 23.10. Here it is worth distinguishing two cases. There is a perceptual barrier at three (or, in special cases, four) variables, a limit of the amount of data that can be perceived as an immediate whole. Bertin (1977, 1981) called this elementary unit of visual data perception the "image." Although this limit has not been definitively established in information visualization by empirical research, there must be a limit somewhere or else people could simultaneously comprehend a thousand variables. We therefore divide visualizations into those that can be comprehended in an elementary perceptual grasp (three, or in special cases, four variables)—let us call these *direct reading visualization*s—and those more complex than that barrier—which we call *articulated reading visualizations*, in which multiple actions are required.

Beyond the perceptual barrier, direct composition of data relationships in terms of 1, 2, or 3 spatial dimensions plus remaining retinal variables is still possible, but rapidly diminishes in effectiveness. In fact, the main problem of information visualization as a discipline can be seen as devising techniques for accelerating the comprehension of these more complex *n*-variable data relations. Several classes of techniques for *n*-variable visualization, which we call *Composed Visual Structures*, are based on composing Simple Visual Structures together by reusing their spatial axes. A third class of Visual Structures—*Interactive Visual Structures*—comes from using the rapid interaction capabilities of the computer. These visualizations invoke

the parameter-controlling arrows of Figure 23.10. Finally, a fourth class of visualizations—*Attention-Reactive Visual Structures*—comes from interactive displays where the system reacts to user actions by changing the display, even anticipating new displays, to lower the cost of information access and sensemaking to the user. To summarize,

I. Simple Visual Structures
Direct Reading
Articulated Reading
II. Composed Visual Structures
Single-Axis Composition
Double-Axis Composition
Recursive Composition
III. Interactive Visual Structure
IV. Attention-Reactive Visual Structure

These classes of techniques may be combined to produce visualizations that are more complex. To help us keep track of the variable mapping into visual structure, we will use a simple shorthand notation for listing the element of the Visual Structure that the Data Table has mapped into. We will write, for example, [XYR^2] to note that variables map onto the X-axis, the Y-axis, and two retinal encodings. [OX] will indicate that the variables map onto one spatial axis used to arrange the objects (that is, the cases), while another was used to encode the objects' values. Examples of this notation appear in Table 23.8 and Figure 23.21.

TABLE 23.8
Taxonomy of Information Visualization Techniques

II. Composed Visual Structures

Single-axis Composition [XY^n]
- Permutation matrices
- Parallel coordinates

Double-axis Composition [XY]
- Graphs

Recursive Composition
- 2D in 2D [(XY)^{XY}]
  - Scatterplot matrices
  - Prosection matrices
  - Hierarchical axes
- Marks in 2D [(XY)^R]
  - Stick figures
  - Color icons
  - Shape coding
  - Keim spirals
- 3D in 3D [(XYZ)^{XYZ}]
  - Worlds within worlds

III. Interactive Visual Structures

- Dynamic queries
- Magic lens
- Overview + detail
- Linking and brushing
- Extraction & comparison
- Attribute explorer

IV. Focus + Context Attention-reactive Visual Abstraction

Data-based Methods
- Filtering
- Selective aggregation

View-based Methods
- Micro-macro readings
- Highlighting
- Visual transfer functions
- Perspective distortion
- Alternate geometries

23.3 SIMPLE VISUAL STRUCTURES

The design of information visualizations begins with mappings from variables of the Data Table into the Visual Structure. The basic strategy for the visualization designer could be described as follows:

1. *Determine which variables of the Analytic Abstraction to map into spatial position in the Visual Structure.*
2. *Combine these mappings to increase dimensionality (e.g., by folding).*
3. *Use retinal variables as an overlay to add more dimensions.*
4. *Add controls for interaction.*
5. *Consider attention-reactive features to expand space and manage attention.*

We start by considering some of the ways in which variables can be mapped into space.

23.3.1 1-Variable

One-variable visual displays may actually use more than one visual dimension. This is because the data variable or attribute is displayed against some set of objects using some mark and because the mark itself takes space. Or, more subtly, it may be because one of the dimensions is used for arranging the objects and another for encoding via position of the variable. A simple example would be when the data are just visually mapped into a simple text list as in Figure 23.14a. The objects form a sequence on the Y-dimension, and the width of the marks (the text descriptor) takes space in the X-dimension. By contrast, a one-dimensional scattergraph (Figure 23.14b) does not use a dimension for the objects. Here, the Y-axis is used to display the attribute variable (suppose these are distances from home of gas stations); the objects are encoded in the mark (which takes a little bit of the X-dimension).

More generally, many single-variable visualizations are in the form $v = f(o)$, where v is a variable attribute and o is the object. Figure 23.14c is of this form and uses the Y-axis to encode the variable and the X-axis for the objects. Note that if the objects are, as usual, nominal, then they are reorderable: sorting the objects on the variable produces easily perceivable visual patterns. For convenience, we have used rectangular coordinates, but any other orthogonal coordinates could be used as the basis of decomposing space. Figure 23.14d uses θ from polar coordinates to encode, say, percentage voting for different presidential candidates. In Figure 23.14e, a transformation on the data side has transformed variable o into a variable representing the distribution, then mapped that onto points on the Y-axis. In Figure 23.14f, another transformation on the data side has mapped this distribution into 2nd quartiles, 3rd quartiles, and outlier points, which is then mapped on the visual side into a box plot on the Y-axis. Simple as they are, these techniques can be very useful, especially in combination with other techniques.

One special, but common, problem is how to visualize very large dimensions. This problem occurs for single-variable visualizations, but may also occur for one dimension of a multi-variable visualization. Figure 23.15 shows several techniques for handing the problem. In Figure 23.15a (Freeman and Fertig 1995), the visual dimension is laid out in perspective. Even though each object may take only one or a few pixels on the axis, the objects are actually fairly large and selectable in the diagram. In Figure 23.15b (Eick, Steffen, and Sumner 1992), the objects (representing lines of code) are laid out on a *folded* Y-axis. When the Y-axis reaches the bottom of the page, it continues offset at the top. In Figure 23.15c (Keim and Kriegel 1994), the axis is wrapped in a square spiral. Each object is a single pixel, and its value is coded as the retinal variable color hue. The objects have been sorted on another variable; hence, the rings show the correlation of this attribute with that of the sorting attribute.

One-variable visualizations are also good parts of controls. Controls, in the form of slides, also consume considerable space on the display (for example, the controls in Figure 23.1) that could be used for additional information communication. Figure 23.15d shows a slider on whose surface is a distribution representation of the number of objects for each value of the input variable, thereby communicating information about the slider's sensitivity in different data ranges. The slider on the left of Figure 23.15b has a one-variable visualization that serves as a legend for the main visualization: it associates color hues with dates and allows the selection of date ranges.

FIGURE 23.15 Uses of 1-variable visual abstractions.

23.3.2 2-Variables

As we increase the number of variables, it is apparent that their mappings form a combinatorial design space. Figure 23.16 schematically plots the structure of this space, leaving out the use of multiple lower variable diagrams to plot higher variable combinations. Two-variable visualizations can be thought of as a composition of two elementary axes (Bertin 1977, 1981; Mackinlay 1986b), which use a single mark to encode the position on both those axes. Mackinlay called this *mark composition*, and it results in a 2D scattergraph (Figure 23.16g). Note that instead of mapping onto two positional visual encodings, one positional axis could be used for the objects, and the data variables could be mapped onto a position encoding and a retinal encoding (size), as in Figure 23.16f.

23.3.3 3-Variables and Information Landscapes

By the time we get to three data variables, a visualization can be produced in several ways. We can use three separate visual dimensions to encode the three data variables in a *3D scattergraph* (Figure 23.16j). We could also use two spatial dimensions and one retinal variable in a *2D retinal scattergraph* (Figure 23.16k). Or we could use one spatial dimension as an object dimension, one as a data attribute dimension, and two retinal encodings for the other variables, as in an *object chart* such as in Figure 23.16i. Because Figure 23.16i uses multiple retinal encodings, however, it may not be as effective as other techniques. Notice that because they all encode three data variables, we have classified 2D and 3D displays together. In fact, one popular 3-variable information visualization that lies between 2D and 3D is the *information landscape* (Figure 23.16m). This is essentially a 2D scattergraph with one data variable extruded into the third spatial dimension. Its essence is that two of the spatial dimensions are more tightly coupled and often relate to a 2D visualization. For example, the two dimensions might form a map with the bars showing the GDP of each region.

Another special type of 3-variable information visualization is a 2D *information topography.* In an information typography, space is partly defined by reference to external structure. For example, the topography of Figure 23.17a is a map of San Francisco, requiring two spatial variables. The size of blue dots indexes the number of domain names registered to San Francisco street addresses. Looking at the patterns in the visualization shows that Internet addresses have especially concentrated in the Mission and South of Mission districts. Figure 23.17a uses a topography derived from real geographical space. Various techniques, such as multidimensional scaling, factor analysis, or connectionist self-organizing algorithms, can create abstract spaces based on the similarities among collections of documents or other objects. These abstract similarity spaces can function like a topography. An example can be seen in Figure 23.17b, where the pages in a website are depicted as regions in a similarity space. To create this diagram,* a web crawler crawls the site and indexes all the words and pages on the site. Each page is then turned into a document vector to represent the semantic content of that page. The regions are created using a neural network learning algorithm (see Lin, Soergel, and Marchionini 1991). This algorithm organizes the set of web pages into regions. A visualization algorithm then draws boundaries around the regions, colors them, and names them. The result, called a *Kahonen diagram* after its original inventor, is a type of *retinal similarity topography.*

Information landscapes can also use marks that are surfaces. In Figure 23.18a, topics are clustered on a similarity surface, and the strength of each topic is indicated by a 3D contour. A more extreme case is Figure 23.18b, where an information landscape is established in spherical coordinates, and the amount of ozone is plotted as a semitransparent overlay on the ρ-axis.

23.3.4 *n*-Variables

Beyond three variables, direct extensions of the methods we have discussed become less effective. It is possible, of course to make plots using two spatial variables and *n*–2 retinal variables, and the possibilities for four variables are shown in Figure 23.16. These diagrams can be understood, but at the cost of progressively more effort as the number of variables increases. It would be very difficult to understand an [XYR^{20}] retinal scattergraph, for example.

23.3.5 Trees

An interesting alternative to showing variable values by spatial positioning is to use explicitly drawn linkages of some kind. Trees are the simplest form of these. Trees map cases into subcases. One of the data variables in a Data Table (for example, the variable Reports To in an organization chart) is used to define the tree. There are two basic methods for visualizing a tree: (1) Connection and (2) Enclosures.

23.3.5.1 Connection

Connection uses lines to connect marks signifying the nodes of the tree. Logically, a tree could be drawn merely by drawing lines between objects randomly positioned on the plane, but such a tree would be visually unreadable. Positioning in space is important. Figure 23.19a is a tree from Charles Darwin's notebook (Robin 1992) drawn to help him work out the theory of evolution. Lines proceed from ancestor species to new species. Note that even in this informal setting intended for personal use that the tree uses space systematically (and opportunistically). There are no crossed lines. A common way of laying out trees is to have the depth in the tree map onto one ordinal access, as in Figure 23.19b, while the other axis is nominal and used to separate nodes.

FIGURE 23.19 Trees.

Of course, trees could also be mapped into other coordinate systems: for example, there can be circular trees in which the *r*-axis represents depth and the θ-axis is used to separate nodes as in the representation of the evolution species in Figure 23.19c.* It is because trees have no cycles that one of the spatial dimensions can be used to encode tree depth. This partial correlation of tree structure and space makes trees relatively easy to lay out and interpret, compared to generalized networks. Hierarchical displays are important not only because many interesting collections of information, such as organization charts or taxonomies, are hierarchical data, but also because important collections of information, such as websites, are *approximately* hierarchical. Whereas practical methods exist for displaying trees up to several thousand nodes, no good methods exist for displaying general graphs of this size. If a visualization problem involves the displaying of network data, a practical design heuristic is to see whether the data might not be forced into a display as a modified tree, such as a tree with a few non-tree links. A significant disadvantage of trees is that as they get large, they acquire an extreme aspect ratio, because the nodes expand exponentially as a function with depth. Consequently, any sufficiently large tree (say, >1000 nodes) resembles a straight line. Circular trees such as Figure 23.19c are one way of trying to buy more space to mitigate this problem. Another disadvantage of trees is the significant empty space between nodes to make their organization easily readable. Various tricks can be used to wrap parts of the tree into this empty space, but at the expense of the tree's virtues of readability.

* This figure is from David Hillis, University of Texas.

23.3.5.2 Enclosure

Enclosure uses lines to hierarchically enclose nested subsets of the tree. Figure 23.19d is an enclosure tree encoding of Darwin's tree in Figure 23.19a. We have already seen one attempt to use tree enclosure, TreeMaps (Figure 23.5). TreeMaps make use of all the space and stay within prescribed space boundaries, but they do not represent the nonterminal nodes of the tree very well and similar leaves can have wildly different aspect ratios. Recent variations on TreeMaps found ways to "squarify" nodes (Shneiderman and Wattenberg 2001), mitigating this problem.

23.3.6 Networks

Networks are more general than trees and may contain cycles. Networks may have directional links. They are useful for describing communication relationships among people, traffic in a telephone network, and the organization of the Internet. Containment is difficult to use as a visual encoding for network relationships, so most networks are laid out as node and link diagrams. Unfortunately, straightforward layouts of large node and link diagrams tend to resemble a large wad of tangled string.

We can distinguish the same types of nodes and links in network Visual Structures that we did for spatial axes: (a) Unstructured (unlabeled), (b) Nominal (labeled), (c) Ordinal (labeled with an ordinal quantity), or (d) Quantitative (weighted links). Retinal properties, such as size or color, can be used to encode information about links and nodes. As in the case of trees, spatial positioning of the nodes is extremely important. Network visualizations escape from the strong spatial constraints of simple Visual Structures only to encounter another set of strong spatial constraints of node links crossing and routing. Networks and trees are not so much an alternative of the direct graphical mappings we have discussed so far as they are another set of techniques that can be overlaid on these mappings. Small node and link diagrams can be laid out opportunistically by hand or by using graph drawing algorithms that have been developed (Battista et al. 1994; Cruz and Tamassia 1998; Tamassia 1996) to optimize minimal link crossing, symmetry, and other aesthetic principles.

For very large node and link diagrams, additional organizing principles are needed. If there is an external topographic structure, it is sometimes possible to use the spatial variables associated with the nodes. Figure 23.20a shows a network based on call traffic between cities in the United States (Becker, Eick, and Wilks 1995). The geographical location of the cities is used to lay out the nodes of the network. Another way to position nodes is by associating nodes with positions in a similarity space, such that the nodes that have the strongest linkages to each other are closest together. There are several methods for computing node nearness in this way. One is to use multidimensional scaling (MDS) (Fairchild, Poltrock, and Furnas 1988). Another is to use a "spring" technique, in which each link is associated with a Hooke's Law spring weighted by strength of association and the system of springs is solved to obtain node

FIGURE 23.20 Network methods.

position. Eick and Willis (1993) have argued that the MDS technique places too much emphasis on smaller links. They have derived an alternative that gives clumpier (and hence, more visually structured) clusters of nodes. If positioning of nodes corresponds perfectly with linkage information, then the links do not add more visual information. If positioning does not correspond at all with linkage information, then the diagram is random and obscure. In large graphs, node positions must have a partially correlated relationship to linkage in order to allow the emergence of visual structure. Note that this is what happens in the telephone traffic diagram, Figure 23.20a. Cities are positioned by geographical location. Communication might be expected to be higher among closer cities, so the fact that communications is heavy between coasts stands out.

A major problem in a network such as Figure 23.20a is that links may obscure the structure of the graph. One solution is to route the links so that they do not obscure each other. The links could even be drawn outside the plane in the third dimension; however, there are limits to the effectiveness of this technique. Another solution is to use *thresholding*, as in Figure 23.20b. Only those links representing traffic greater than a certain threshold are included; the others are elided, allowing us to see the most important structure. Another technique is *line shortening*, as in Figure 23.20c. Only the portion of the line near the nodes is drawn. At the cost of giving up the precise linkage, it is possible to read the density of linkages for the different nodes. Figure 23.20d is a technique used to find patterns in an extremely large network. Telephone subscribers are represented as nodes on a hexagonal array. Frequent pairs are located near each other on the array. Suspicious patterns are visible because of the sparseness of the network.

The insightful display of large networks is difficult enough that many information visualization techniques depend on interactivity. One important technique, for example, is node aggregation. Nodes can be aggregated to reduce the number of links that have to be drawn on the screen. Which nodes are aggregated can depend on the portion of the network on which the user is drilling down. Similarly, the sets of nodes can be interactively restricted (e.g., telephone calls greater than a certain volume) to reduce the visualization problem to one within the capability of current techniques.

23.4 COMPOSED VISUAL STRUCTURES

So far, we have discussed simple mappings from data into spatial position axes, connections and enclosures, and retinal variables. These methods begin to run into a barrier around three variables as the spatial dimensions are used up and as multiples of the less efficient retinal variables needed. Most interesting problems involve many variables. We shall therefore look at a class of methods that reuse precious spatial axes to encode variables. This is done by composing a compound Visual Structure out of several simple Visual Structures. We will consider five subclasses of such composition: (a) single-axis composition, (b) double-axis composition, (c) mark composition, (d) case composition, and (e) recursive composition. Schematically, we illustrate these possibilities in Figure 23.21.

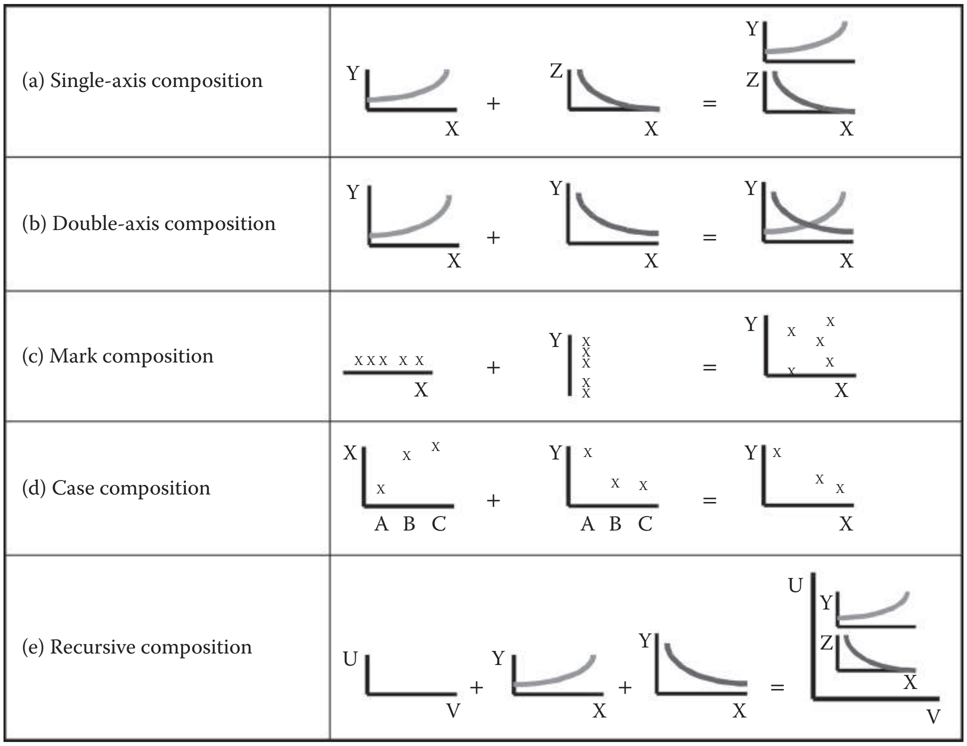

FIGURE 23.21 Composition types.

23.4.1 Single-Axis Composition

In single-axis composition, multiple variables that share a single axis are aligned using that axis, as illustrated in Figure 23.21a. An example of single-axis composition is a method due to Bertin called *permutation matrices* (Bertin 1977/1981). In a permutation matrix (Figure 23.16o, for example), one of the spatial axes is used to represent the cases and the other a series of bar charts (or rows of circles of different size or some other depiction of the value of each variable) to represent the values. In addition, bars for values below average may be given a different color, as in Figure 23.7, in order to enhance the visual patterns. The order of the objects and the order of the variables may both be permuted until patterns come into play. Permutation matrices were used in our hotel analysis example. They give up direct reading of the data space in order to handle a larger number of variables. Of course, as the number of variables (or objects) increases, manipulation of the matrices becomes more time-consuming and visual interpretation more complex. Still, permutation matrices or their variants are one of the most practical ways of representing multi-variable data.

If we superimpose the bar charts of the permutation matrix atop one another, and then replace the bar chart with a line linking together the tops of the bars, we get another method for handling multiple variables by single-axis composition—*parallel coordinates* (Inselberg 1997; Inselberg and Dimsdale 1990), as shown in Figure 23.22. A problem is analyzed in parallel coordinates by interactively restricting the objects displayed (the lines) in order to look at cases with common characteristics. In Figure 23.22, parallel coordinates are used to analyze the problem of yield from a certain processor chip. X1 is chip yield, X2 is quality, X3 through X12 are defects, and the rest of the variables are physical parameters. The analysis, looking at those subsets of data with high yield and noticing the distribution of lines on the other parameters, was able to solve a significant problem in chip processing.

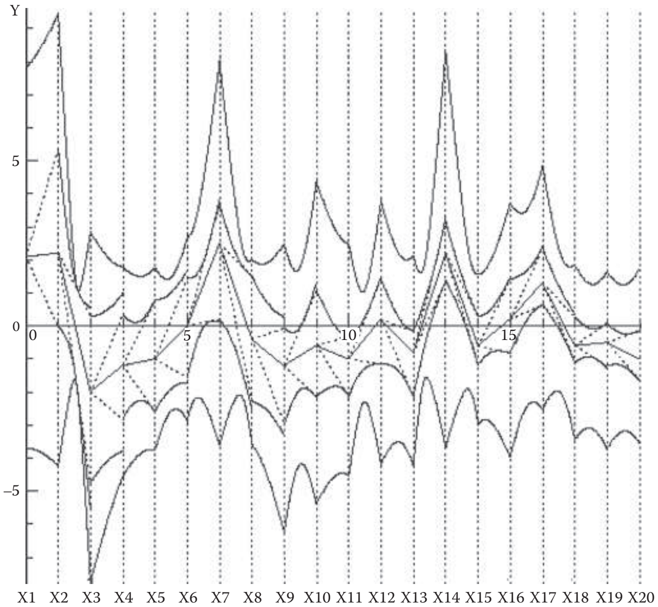

FIGURE 23.22 Single-axis composition: parallel coordinates.

Both permutation matrices and parallel coordinates allow analyses in multi-dimensional space, because they are efficient in the use (and reuse) of spatial position and the plane. Actually, they also derive part of their power from being interactive. In the case of permutation matrices, interactivity comes in reordering the matrices. In the case of parallel coordinates, interactivity comes in selecting subsets of cases to display.

23.4.2 Double-Axis Composition

In double-axis composition, two visual axes must be in correspondence, in which case the cases are plotted on the same axes as a multivariable graph (Figure 23.21b). Care must be taken that the variables are plotted on a comparable scale. For this reason, the separate scales of the variables are often transformed to a common proportion change scale. An example would be change in price for various stocks. The cases would be the years, and the variables would be the different stocks.

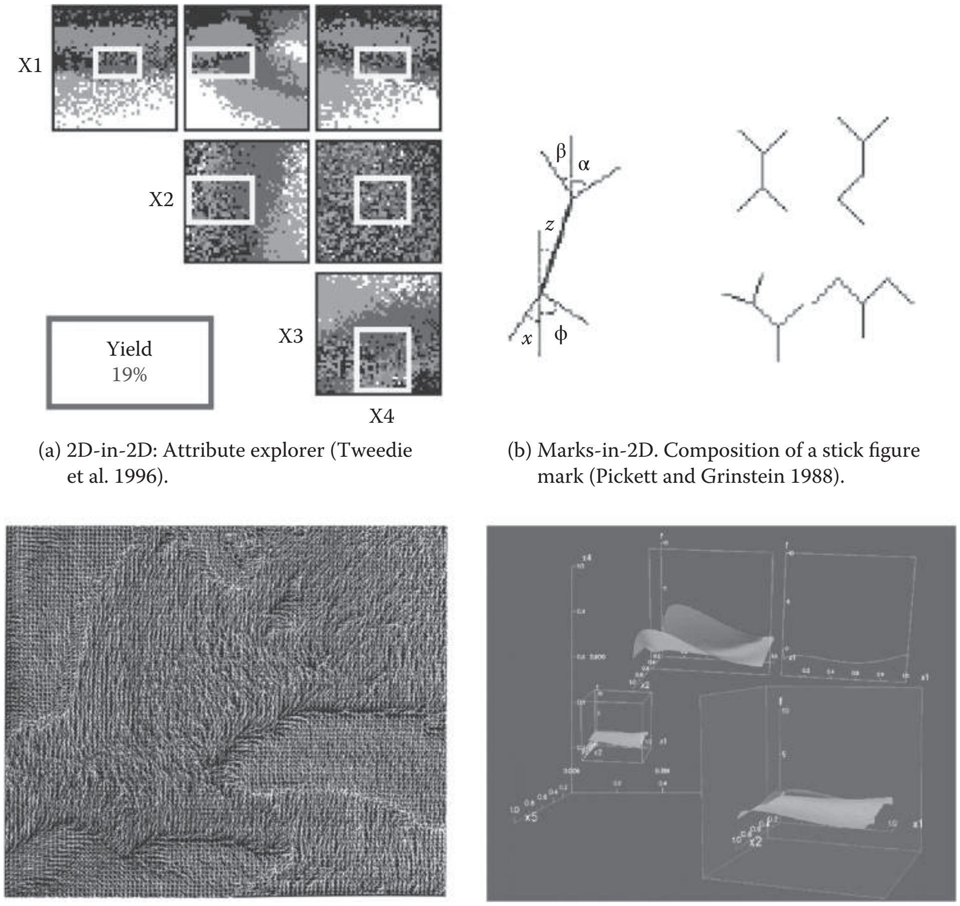
23.4.3 Mark Composition and Case Composition

Composition can also fuse diagrams. We discussed that each dimension of visual space can be said to have properties, as summarized in Table 23.4. The visual space of a diagram is composed from the properties of its axis. In *mark composition* (Figure 23.21c), the mark on one axis can fuse with the corresponding mark on another axis to form a single mark in the space formed by the two axes. Similarly, two object charts can be fused into a single diagram by having a single mark for each case. We call this latter form *case composition* Figure 23.21d.

23.4.4 Recursive Composition

Recursive composition divides the plane (or 3D space) into regions, placing a subvisualization in each region (Figure 23.21e). We use the term somewhat loosely, since regions have different types of subvisualizations. The FilmFinder in Figure 23.1 is a good example of a recursive visualization. The screen breaks down into a series of simple Visual Structures and controls: (a) a 3-variable retinal scattergraph (Year, Rating, FilmType) + (b) a 1-variable slider (Title) + (c) a 1-variable slider (Actors) + (d) a 1-variable slider (Actresses) + (e) a 1-variable slider (Director) + (f) a 1-variable slider (FilmLength) + (g) a 1-variable radio button control (Rating) + (h) a 1-variable button-set (FilmType).

Three types of recursive composition deserve special mention: (a) 2D-in-2D, (b) marks-in-2D, and (c) 3D-in-3D. An example of *2D-in-2D composition* is the "prosection matrix" (Tweedie et al. 1996) shown in Figure 23.23a. Each smaller square in the prosection matrix represents a pair of parameters plotted against each other. The coloring shows which values of the plotted pair give excellent (red region) or partly good (gray regions) performance for the design of some device. The arrangement of the individual matrices into a supermatrix redefines the spatial dimensions (that is, associates it



(a) 2D-in-2D: Attribute explorer (Tweedie et al. 1996).

(b) Marks-in-2D. Composition of a stick figure mark (Pickett and Grinstein 1988).

(d) 3D-in-3D: Worlds-within-worlds (Feiner and Beshers 1990).

FIGURE 23.23 Recursive composition.

with different variables) within each of the cells, and the cells themselves are arranged in an overall scheme that systematically uses space. In this way, the precious spatial dimension is effectively expanded to where all the variables can reuse it. An important property of techniques similar to this one is that space is defined at more than one *grain size*, and these levels of grain become the basis for a *macro-micro reading.*

An example of *marks-in-2D composition* is the use of “stick figure” displays. This is an unusual type of visualization in which the recursion is within the mark instead of within the use of space. Figure 23.23b shows a mark that is itself composed of submarks. The mark is a line segment with four smaller line segments protruding from the ends. Four variables are mapped onto angles of these smaller line segments and a fifth onto the angle of the main line segment. Two additional variables are mapped onto the position of this mark in a 2D display. A typical result is the visualization in Figure 23.23c, which shows five weather variables around Lake Ontario, the outline of which clearly appears in the figure.

Feiner and Beshers (1990) provided an example of the third recursive composition technique, *3D-in-3D composition*. Suppose a dependent variable is a function of six continuous variables, $y = f(x, y, z, w, r, s)$. Three of these variables are mapped onto a 3D coordinate system. A position is chosen in that space, say, $x1$, $y1$, $z1$. At that position, a new 3D coordinate system is presented with a surface defined by the other three variables (Figure 23.23d). The user can thus view $y = f(x1, y1, z1, w, r, s)$. The user can slide the second-order coordinate system to any location in the first, causing the surface to change appropriately. Note that this technique combines a composed visual inter-action with interactivity on the composition. Multiple second-order coordinate systems can be displayed at the space simultaneously, as long as they do not overlap by much.

23.5 INTERACTIVE VISUAL STRUCTURES

In the examples we have considered so far, we have often seen that information visualization techniques were enhanced by being interactive. Interactivity is what makes visualization a new medium, separating it from generations of excellent work on scientific diagrams and data graphics. Interactivity means controlling the parameters in the visualization reference model (Figure 23.10). This naturally means that there are different types of interactivity, because the user could control the parameters to data transformations, to visual mappings, or to view transformations. It also means that there are different forms of interactivity based on the response cycle of the interaction. As an approximation, we can think of there being three time constants that govern interactivity, which we take to be 0.1 sec, 1 sec, and 10 sec (Card, Moran, and Newell 1986) (although the ideal value of these may be somewhat less, say, 0.07 sec, 0.7 sec, and 7 sec). The first time constant is the time in which a system response must be made, if the user is to feel that there is a direct physical manipulation of the visualization. If the user clicks on a button or moves a slider, the system needs to update the display in less than 0.1 sec. Animation frames need to take less than 0.1 sec. The second time constant, 1 sec, is the time to complete an immediate action, for example, an animated sequence such as zooming in to the data or rotating a tree branch. The third time constant 10 sec (meaning somewhere in the 5 to 30 sec interval) is the time for completing some cognitive action, for example deleting an element from the display. Let us consider a few well-known techniques for interactive information visualizations.

23.5.1 Dynamic Queries

A general paradigm for visualization interaction is dynamic queries, the interaction technique used by the FilmFinder in Figure 23.1. The user has a visualization of the data and a set of controls, such as sliders, by which subsets of the Data Table can be selected. For example, Table 23.9 shows the mappings of the Data Table and controls for the FilmFinder. The sliders and other controls will select which subset of the data is going to be displayed. In the FilmFinder, the control for Length is a two-sided slider. Setting one end to 90 minutes and the other end to 120 minutes will select for display only those cases of the Data Table whose year variable lies between these limits. The display needs to change within the 0.1 sec of changing the slider.

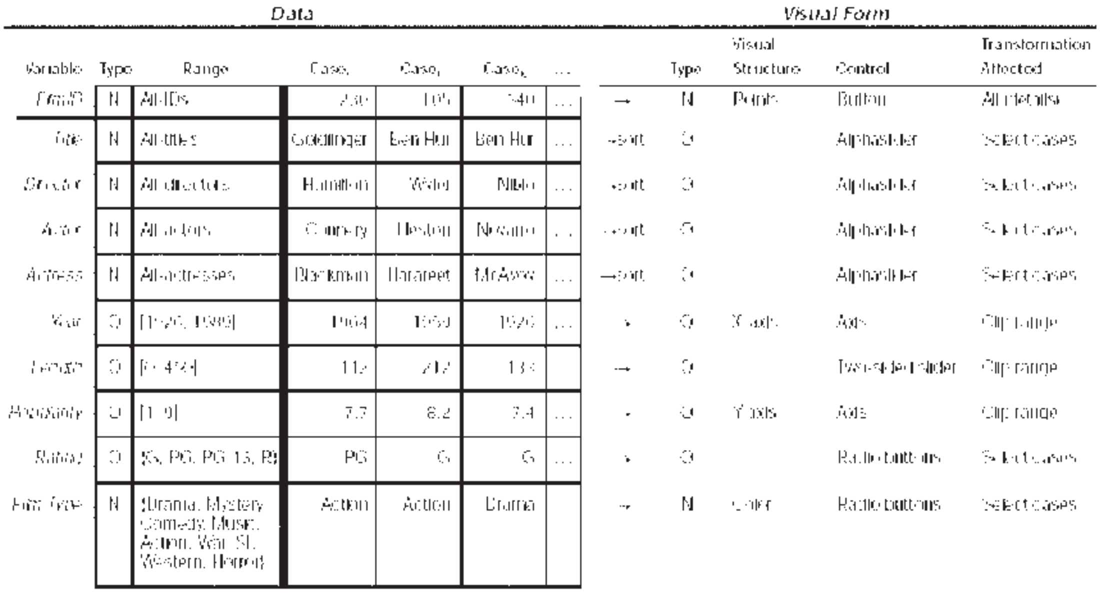
23.5.2 Magic Lens (Movable Filter)

Dynamic queries is one type of interactive filter. Another type is a movable filter that can be moved across the display, as in Figure 23.24a. These *magic lenses* are useful when it is desired to filter only some of the display. For example, a magic lens could be used with a map that showed the population of any city it was moved over. Multiple magic lenses can be used to cascade filters.

23.5.3 Overview Detail

We can think of an overview + detail display (Figure 23.24b) as a particular type of magic lens, one that magnifies the display and has the magnified region off to the side so as not to occlude the region. Displays have information at different grain sizes. A GIS map may have information at the level of a continent as well as at the level of a city. If the shape of the continent can be seen, the display is too coarse to see the roadways of a city. Overview + detail displays show that data at more than one level, but they also show where the finer grain display fits into the larger grain display. In Figure 23.24b, from SeeSoft (Eick, Steffen, and Sumner 1992), a system for visualizing large software systems, the amount of magnification in the detail view is large enough that two concatenated overview + detail displays are required. Overview

TABLE 23.9
Visual Marks and Controls for FilmFinder



Data							Visual Form				
Variable	Type	Range	$Case_i$	$Case_j$	$Case_k$	...		Type	Visual Structure	Control	Transformation Affected
FilmID	N	All IDs	230	105	340	...	→	N	Points	Button	All (details)

FIGURE 23.24 Interaction techniques.

+ detail displays are thus very helpful for data navigation. Their main disadvantage is that they require coordination of two visual domains.

23.5.4 Linking and Brushing

Overview + detail is an example of coordinating dual representations of the same data. These can be coordinated interactively with *linking and brushing*. Suppose, for example, we wish to show power consumption on an airplane, both in terms of the physical representation of the airplane and a logical circuit diagram. The two views could be shown and *linked* by using the same color for the same component types. Interactivity itself can be used for a dynamic form of linking called *brushing*. In brushing, running the cursor over a part of one of the views causes highlighting both in that view and in the other view.

23.5.5 Extraction and Comparison

We can also use interaction to extract a subset of the data to compare with another subset. An example of this is in the SDM system (Chuah et al. 1995) in Figure 23.24c. The data are displayed in a 3D information landscape, but the perspective interferes with the ability to compare it. Information is therefore *extracted* from the display (leaving ghosts behind) and placed in an orthogonal viewing position where it can be *compared* using 2D. It could also be dropped into another display. Interactivity makes possible these manipulations, while keeping them coordinated with the original representations.

23.5.6 Attribute Explorer

Several of these interactive techniques are combined in the Attribute Explorer (Tweedie et al. 1996). Figure 23.24d shows information on four attributes of houses. Each attribute is displayed by a histogram, where each square making up the histogram represents an individual house. The user selects a range of some attribute, say price. Those pixels making up the histogram on price have their corresponding pixels linked representing houses highlighted on the other attributes. Those houses meeting all the criteria are highlighted in one color; those houses meeting, say, all but one are highlighted in another color. In this way, the user can tell about the "near misses." If the users were to relax one of the criteria only a little (say, reducing price by $100), then the user might be able to gain more on another criterion (say, reducing a commute by 20 miles).

23.6 FOCUS + CONTEXT ATTENTION-REACTIVE ABSTRACTIONS

So far, we have considered visualizations that are static mappings from Data Table to Visual Structure and those where the mappings Data Table to Visual Structure are interactively controlled by the user. We now consider visualizations in which the machine is no longer passive, but its mappings from Visual Structure to View are altered by the computer according to its model of the user's *degree of interest*. We can, in principle, associate a cost of access with every element in the Data Table. Take the FilmFinder in Figure 23.3. Details about the movie *Murder on the Orient Express* are accessible at low cost in terms of time because they are presently visible on the screen. Details of *Goldfinger*, a movie with only a mark on the display, take more time to find. Details of *Last Year at Marienbad*, a movie with no mark on the display, would take much more time. The idea is that with a model for predicting users' changes in interest, the system can adjust its displays to make costs lower for information access. For example, if the user wants some detail about a movie, such as the director, the system can anticipate that the user is more likely to want other details about the movie as well and therefore display them all at the same time. The user does not have to execute a separate command; the cost is therefore reduced.

Focus + context views are based on several premises: First, the user needs both overview (context) and detail information (focus) during information access, and providing these in separate screens or separate displays is likely to cost more in user time. Second, information needed in the overview may be different from that needed in the detail. The overview needs to provide enough information to the user to decide where to examine next or to give a context to the detailed information rather than the detailed information itself. As Furnas (1981) has argued, the user's interest in detail seems to fall away in a systematic way with distance as information objects become farther from current interest. Third, these two types of information can be combined within a single dynamic display, much as human vision uses a two-level focus and context strategy. Information broken into multiple displays (separate legends for a graph, for example) seems to degrade performance due to reasons of visual search and working memory.

Furnas (1981) was the first to articulate these ideas systematically in his theory of *fish-eye views*. The essence of focus + context displays is that the average cost of accessing information is reduced by placing the most likely needed information for navigation and detail where it is fastest to access. This can be accomplished by working on either the data side or the visual side of the visual reference model (Figure 23.10). We now consider these techniques in more detail.

23.6.1 Data-Based Methods

23.6.1.1 Filtering

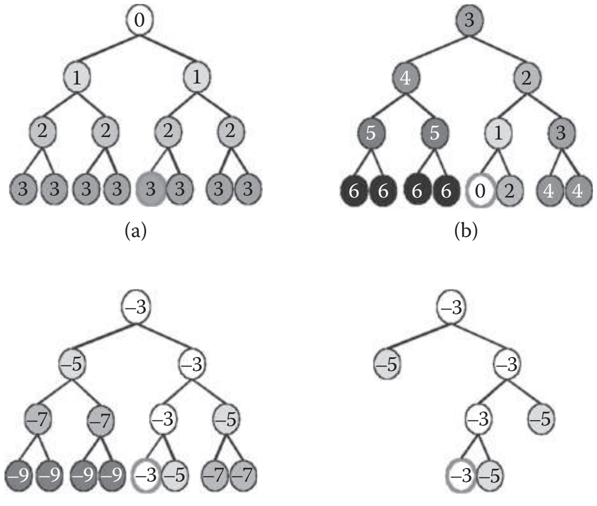
On the data side, focus + context effects can be achieved by filtering out which items from the Data Table are actually displayed on the screen. Suppose we have a tree of categories taken from *Roget's Thesaurus*, and we are interacting with one of these, "Hardness."

Matter
ORGANIC
Vitality
Vitality in general
Specific vitality
Sensation
Sensation in general
Specific sensation
INORGANIC
Solid
Hardness
Softness
Fluid
Fluids in general
Specific fluids

Of course, this is a small example for illustration. A tree representing a program listing or a computer directory or a taxonomy could easily have thousands of lines, a number that would vastly exceed what could fit on the display and hence would have a high cost of accessing. We calculate a degree-of-interest (DOI) for each item of the tree, given that the focus is on the node Hardness. To do this, we split the DOI into an intrinsic part and a part that varies with distance from the current center of interest and use a formula from Furnas (1981).

$$DOI = Intrinsic\ DOI + Distance\ DOI$$

Figure 23.25 shows schematically how to perform this computation for our example. We assume that the intrinsic DOI of a node is just its distance of the root (Figure 23.25a). The distance part of the DOI is just the traversal distance to a node from the current focus node (Figure 23.25b; it turns out to be convenient to use negative numbers for this



(a) (b)

(c) (d)

FIGURE 23.25 Degree-of-Interest calculation for fish-eye visualization.

computation, so that the maximum amount of interest is bounded, but not the minimum amount of interest). We add these two numbers together (Figure 23.25c) to get the DOI of each node in the tree. Then we apply a minimum threshold of interest (–5 in this case) and only show nodes more interesting than that threshold. The result is the reduced tree:

Matter
  INORGANIC
  ORGANIC
    Solid
      Hardness
      Softness
    Fluid

The reduced tree gives local context around the focus node and progressively less detail farther away. But it does seem to give the important context.

23.6.1.2 Selective Aggregation

Another focus1context technique from the data side is selective aggregation. Selective aggregation creates new cases in the Data Table that are aggregates of other cases. For example, in a visualization of voting behavior in a presidential election, voters could be broken down by sex, precinct, income, and party affiliation. As the user drills down on, say, male Democrats earning between $25,000 and $50,000, other categories could be aggregated, providing screen space and contextual reference for the categories of immediate interest.

23.6.2 View-Based Methods

23.6.2.1 Micro-Macro Readings

Micro-macro readings are diagrams in which “detail cumulates into larger coherent structures” (Tufte 1990). The diagram can be graphically read at the level of larger contextual structure or at the detail level. An example is Figure 23.26. The micro reading of this diagram shows three million observations of the sleep (lines), wake (spaces), and feeding (dots) activity of a newborn infant. Each day’s activity is repeated three times on a line to make the cyclical aspect of the activity more clearly visible. The macro reading of the diagram, emphasized by the thick lines, shows the infant transitioning from the natural human 25-hour cycle at birth to the 24-hour solar day. The macro reading serves as context and index into the micro reading.

23.6.2.2 Highlighting

Highlighting is a special form of micro-macro reading in which focal items are made visually distinctive in some way. The overall set of items provides a context for the changing focal elements.

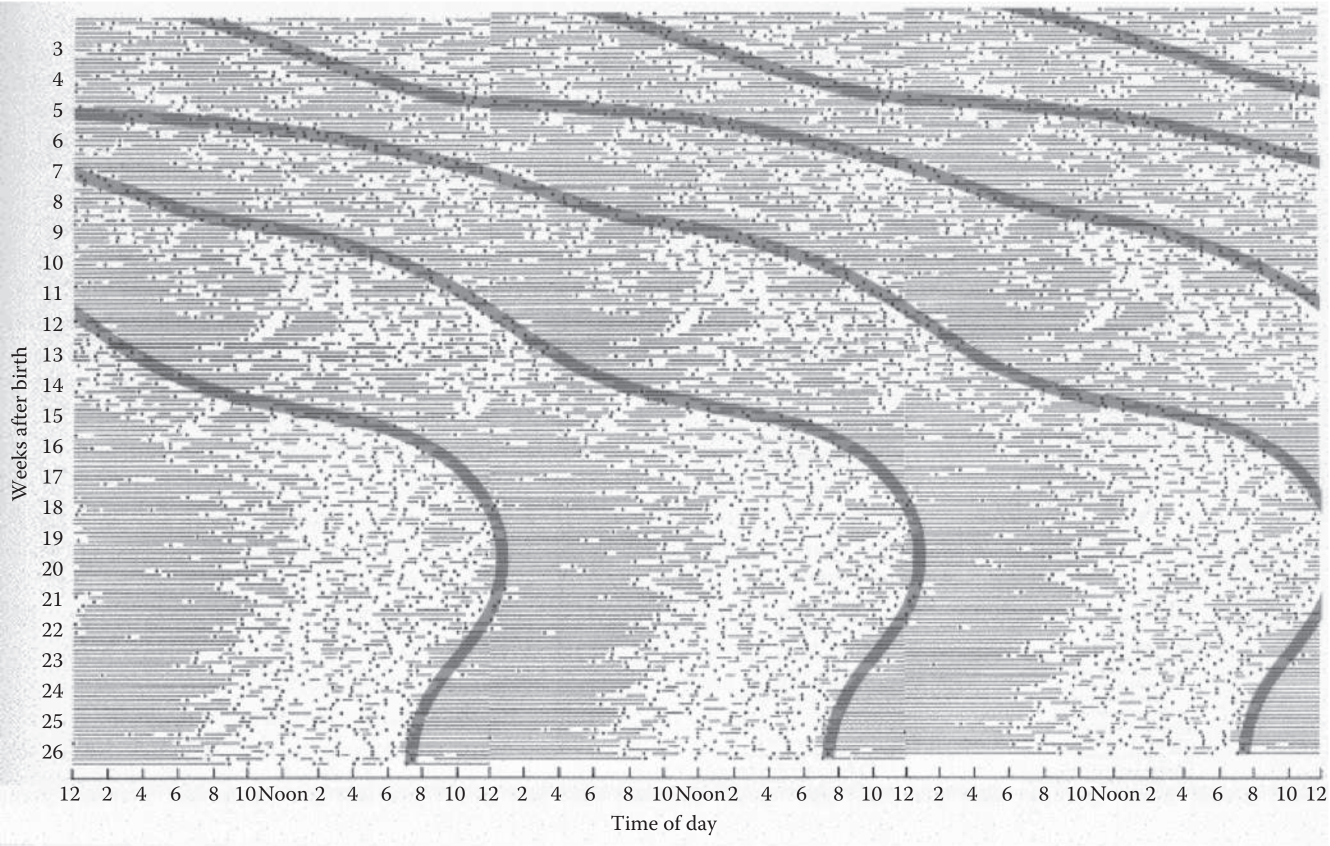


FIGURE 23.26 Micro-macro reading. (Courtesy Scientific American Library.)

23.6.2.3 Visual Transfer Functions

We can also warp the view with viewing transformations. An example is a visualization called the *bifocal lens* (Spence and Apperley 1982). Figure 23.27a shows a set of documents the user would like to view, but which is too large to fit on the screen. In a bifocal lens, documents not in a central focal region are compressed down to a smaller size. This could be a strict visual compression. It could also involve a change in representation. We can talk about the visual compression in terms of a visual transfer function in Figure 23.27b, sometimes conveniently represented in terms of its first derivative in Figure 23.27c. This function shows how many units of an axis in the original display are mapped into how many units in the resultant display. The result could be compression or enlargement of a section of the display. As a result of applying this visual transfer function to Figure 23.27a, the display is compressed to Figure 23.27d. Actually, the documents in the compressed region have been further altered by using a semantic zooming function to give them a simplified visual form. The form of Figure 23.27c shows that this is essentially a step function of two different slopes. An example of a two-dimensional step function is the Table Lens (Figure 23.28a). The Table Lens is a spreadsheet in which the columns of selected cells are expanded to full size in X and the rows of selected cells are expanded to full size in Y. All other cells are compressed, and their content represented only by a graphic. As a consequence, spreadsheets up to a couple orders of magnitude larger can be represented.

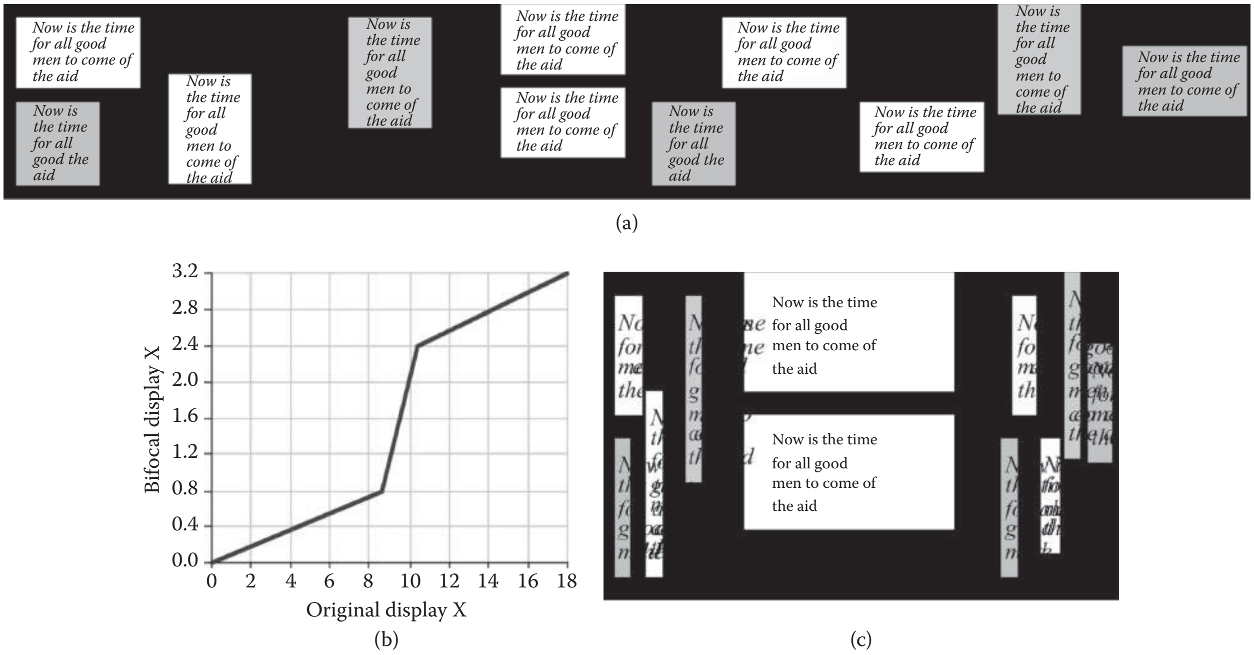
By varying the visual transfer function (see, for example, the review by Leung and Apperley 1994), a wide variety of distorted views can be generated. Figure 23.28b shows an application in which a visual transfer function is used to expand a bubble around a local region on a map. The expanded space in the region is used to show additional information about that region. Distorted views must be designed carefully so as not to damage important visual relationships. Bubble distortions of maps may change whether roads appear parallel to each other. However, distorted views can be designed with “flat” and “transition” regions to address this problem. Figure 23.27a does not have curvilinear distortions. Focus + context visualizations can be used as part of compact user controls. Keahey (2001) has created an interactive scheme in which the bubble is used to “preview” a region. When the user releases a button over the region, the system zooms in far enough to flatten out the bubble. Bederson has developed a focus1context pull-down menu (Bederson 2000) that allows the viewing and selection of large lists of typefaces in text editor, Figure 23.27c.

23.6.2.4 Perspective Distortion

One interesting form of distorting visual transfer functions is 3D perspective. Although it can be described with a 2D distorting visual transfer function, it is usually not experienced as distorting by users due to the special perceptual mechanisms humans have for processing 3D. Figure 23.28c shows the Perspective Wall (Mackinlay, Robertson, and Card 1991). Touching any place on the walls animates its transition into the central focal area. The user perceives the context area of the wall as an undistorted 2D image in a 3D space, rather than as a distorted 2D image; however, the same sort of compression is still achieved in the nonfocus area.

23.6.2.5 Alternate Geometries

Instead of altering the size of components, focus + context effects can also be achieved by changing the geometry of the spatial substrate itself. One example is the hyperbolic tree (Lamping and Rao 1994). A visualization such as a tree is laid out in hyperbolic space (which itself expands exponentially,



(a)

(b)

(c)

FIGURE 23.27 Bifocal + transfer function.

(d) Perspective wall (Mackinlay, Robertson, and Card 1991).

FIGURE 23.28 Attention-Reactive Visualizations.

just like the tree does), and then projected on to the Euclidean plane. The result is that the tree seems to expand around the focal nodes and to be compressed elsewhere. Selecting another node in the tree animates that portion to the focal area. Munzner (Munzner and Burchard 1995) has extended this notion to 3D hyperbolic trees and used them to visualize portions of the Internet.

23.7 SENSEMAKING WITH VISUALIZATION

23.7.1 Knowledge Crystallization

The purpose of information visualization is to amplify cognitive performance, not just to create interesting pictures. Information visualizations should do for the mind what automobiles do for the feet. So here, we return to the higher level cognitive operations of which information visualization is a means and a component. A recurrent pattern of cognitive activity to which information visualization would be useful (though not the only one!) is "knowledge crystallization." In knowledge crystallization tasks, there is a goal (sometimes ill-structured) that requires the acquisition and making sense of a body of information, as well as the creative formulation of a knowledge product, decision, or action. Examples would be writing a scientific paper, business or military intelligence, weather forecasting, or buying a laptop computer. For these tasks, there is usually a concrete outcome of the task—the submitted manuscript of a paper, a delivered briefing, or a purchase. Knowledge crystallization does have characteristic processes, however, and it is by amplifying these that information visualization seeks to intervene and amplify the user's cognitive powers. Understanding of this process is still tentative, but the basic parts can be outlined:

> Acquire information. Make sense of it. Create something new. Act on it.

In Table 23.10, we have listed some of the more detailed activities these entail. We can see examples of these in our initial examples.

23.7.1.1 Acquire Information

The FilmFinder is concentrated largely on acquiring information about films. *Search* is one of the methods of acquiring

TABLE 23.10
Knowledge Crystallization Operators

Acquire information	Monitor
	Search
	Capture (make implicit knowledge explicit)
Make sense of it	Extract information
	Fuse different sources
	Find schema
	Recode information into schema
Create something new	Organize for creation
	Author
Act on it	Distribute
	Apply
	Act

information in Table 23.10, and the FilmFinder is an instance of the use of information visualization in search. In fact, Shneiderman (Card, Mackinlay, and Shneiderman 1999) has identified a heuristic for designing such systems:

> Overview first, zoom and filter, then details-on-demand

The user starts with an overview of the films, and then uses sliders to filter the movies, causing the overview to zoom in on the remaining films. Popping up a box gives details on the particular films. The user could use this system as part of a knowledge crystallization process, but the other activities would take place outside the system. The SmartMoney system also uses the TreeMap visualization for acquiring information, but this time the system is oriented toward *monitoring,* another of the methods in Table 23.10. A glance at the sort of chart in Figure 23.5 allows an experienced user to notice interesting trends among the hundreds of stocks and industries monitored. Another method of acquiring information, *capture*, refers to acquiring information that is tacit or implicit. For example, when users browse the World Wide Web, their paths contain information about their goals. This information can be captured in logs, analyzed, and visualized (Chi and Card 1999). It is worth making the point that acquiring information is not something that the user must necessarily do explicitly. Search, monitoring, and capture can be implicitly triggered by the system.

23.7.1.2 Make Sense of It

The heart of knowledge crystallization is sensemaking. This process is by no means as mysterious as it might appear. Because sensemaking involving large amounts of information must be externalized, the costs of finding, organizing, and moving information around have a major impact on its effectiveness. The actions of sensemaking itself can be analyzed. One process is *extraction.* Information must be got out of its sources. In our hotel example, the hotel manager extracted information from hotel records. A more subtle issue is that information from different sources must be *fused*—that is, registered in some common correspondence. If there are six called-in reports of traffic accidents, does this mean six different accidents, one accident called in six times, or two accidents reported by multiple callers? If one report merely gives the county, while another just gives the highway, it may not be easy to tell. Sensemaking involves finding some *schema*—that is, some descriptive language—in terms of which information can be compactly expressed (Russell et al. 1993). In our hotel example, permuting the matrices brought patterns to the attention of the manager. These patterns formed a schema she used to organize and represent hotel stays compactly. In the case of buying a laptop computer, the schema may be a table of features by models. Having a common schema then permits compact description. Instances are *recoded* into the schema. Residual information that does not fit the schema is noted and can be used to adjust the schema.

23.7.1.3 Create Something New

Using the schema, information can be reorganized to create something new. It must be *organized* into a form suitable for the output product and that product must be *authored.* In the case of the hotel example, the manager created the presentation of Figure 23.7c.

23.7.1.4 Act on It

Finally, there is some consequential output of the knowledge crystallization task. That action may be to distribute a report or give a briefing, to act directly in some way, such as setting up a new promotion program for the hotel or buying a laptop on the basis of the analysis, or by giving directives to an organization.

23.7.2 Levels For Applying Information Visualization

Information visualization can be applied to facilitate the various subprocesses of knowledge crystallization just described. It can also be applied at different architectural levels in a system. These have been depicted in Figure 23.29. At one level is the use of visualization to help users access information outside the immediate environment—the *infosphere*—such as information on the Internet or from corporate digital libraries. Figure 23.30a shows such a visualization of the Internet (Bray 1996). Websites are laid out in a space such that sites closer to each other in the visualization tend to have more traffic. The size of the disk represents the number of pages in the site. The globe size represents the number of out-links. The globe height shows the number of in-links.

The second level is the *information workspace.* The information workspace is like a desk or workbench. It is a staging area for the integration of information from different sources. An information workspace might contain several visualizations related to one or several tasks. Part of the purpose of an information workspace is to make the cost of access low for information in active use. Figure 23.30b shows a 3D workspace for the Internet, the Web Forager (Card, Robertson, and York 1996). Pages from the World Wide Web, accessed by users through clicking on URLs or searches, appear in the space. These can be organized into piles or books related to different topics. Figure 23.30c shows

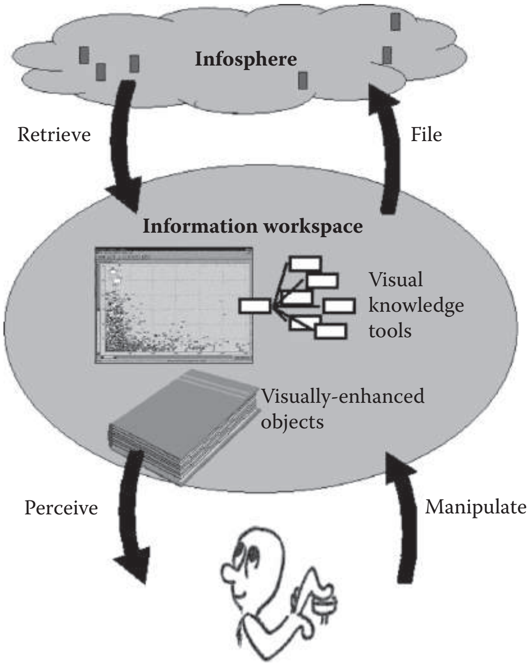

FIGURE 23.29 Levels of use for information visualization.

another document workspace, STARLIGHT (Risch et al. 1997). Documents are represented as galaxies of points in space such that similar documents are near each other. In the workspace, various tools allow linking the documents to maps and other information and analytical resources.

The third level is *visual knowledge tools.* These are tools that allow schema forming and rerepresentation of information. The permutation matrices in Figure 23.7, the SeeSoft system for analyzing software in Figure 23.15b, and the Table Lens in Figure 23.27a are examples of visual knowledge tools. The focus is on determining and extracting the relationships.

The final level is *visually enhanced objects*, coherent information objects enhanced by the addition of information visualization techniques. An example is Figure 23.30d, in which voxel data of the brain have been enhanced through automatic surface rendition, coloring, slicing, and labeling. Abstract data structures representing neural projects and anatomical labels have been integrated into a display of the data. Visually enhanced objects focus on revealing more information from some object of intrinsic visual form.

Information visualization is a set of technologies that use visual computing to amplify human cognition with abstract information. The future of this field will depend on the uses to which it is put and how much advantage it gives to these.

FIGURE 23.30 Information visualization applications.

Information visualization promises to help us speed our understanding and action in a world of increasing information volumes. It is a core part of a new technology of human interfaces to networks of devices, data, and documents.

23.8 ACKNOWLEDGMENTS

This chapter benefited from detailed and generous discussion with Jock Mackinlay and tutorial collaborations with Ed Chi of PARC.

24 Collaboration Technologies

Gary M. Olson and Judith S. Olson

CONTENTS

24.1 INTRODUCTION

Computing and communication technologies have provided us with useful and powerful information resources, remote instruments, and tools for interacting with each other. These possibilities have also led to numerous social and organizational effects. These tools are of course just the latest in a long line of modern technologies that have changed human experience. Television and radio long ago broadened our awareness of and interest in activities all over the world. The telegraph and telephone enabled new forms of organization to emerge. The new technologies of computer-supported cooperative work (CSCW) are giving us greater geographical and temporal flexibility in carrying out our activities. They have also given us new modes of socializing.

In this chapter, we will review software designed to run over a network in support of the activities of a group or organization. These activities can occupy any of several combinations of same/different places and same/different times. Software has been designed for all four of these combinations. Early applications tended to focus on only one of these cells, but more recently, software that supports several cells and the transitions among them has emerged. These technologies support collaborative activities at many levels of social aggregation. Both the individual members of groups and the organizations in which they are embedded affect and are affected by collaborative technologies.

A brief note on terminology: in the several decades since networked computing made possible the kinds of software functions we review in this chapter, terms have changed. It was quite popular in the 1990s, for example, to refer to such software as “groupware.” However, as Grudin and Poltrock (2011) point out in their excellent historical review of trends in CSCW, this term has largely been supplanted by terms more neutral as to the level of social aggregation involved. Hence, in this chapter we will use the term collaboration technology. All of the technologies we review have some bearing on how people collaborate with each other. And, again as Grudin and Poltrock point out, the field has moved beyond the focus on work only (see also Crabtree, Rodden, and Benford [2005]), though in some quarters this has been lamented (Schmidt [2010] sets forth the view that the focus on work is significant enough to merit an undiluted field of study).

CSCW emerged as a formal field of study in the mid-1980s, with conferences, journals, books, and university courses appearing that used this name. There were a number of important antecedents. The earliest efforts to create groupware used time-shared systems but were closely linked to the development of key ideas that propelled the personal computer revolution. Bush (1945) described a vision of something similar to today's World Wide Web in an influential essay published shortly after the end of World War II. Doug Engelbart's famous demonstration at the 1968 International Federation of Information Processing Societies meeting in San Francisco included a number of key groupware components (see Engelbart and English [1968]). These components included support for real-time face-to-face (FTF) meetings, audio and video conferencing, discussion databases, information repositories, and workflow support. Group decision-support systems and computer-supported meeting rooms were explored in a number of business schools (see McLeod [1992]; Kraemer and Pinsonneault [1990]). Work on office automation included many groupware elements, such as group workflow management, calendaring, e-mail, and document sharing (Ellis and Nutt 1980). A good summary of early historical trends as well as reprints of key early articles appear in three early anthologies: Greif (1988), Marca and Bock (1992), and Baecker (1993).

Today, there are a large number of commercial collaboration products. In addition, collaboration functions are now appearing as options in operating systems or specific applications (e.g., Windows, Mac, and Linux operating systems, suites of tools by Microsoft, Google, Yahoo!, and many others). Collaborative functionality has become widespread and familiar. However, there are still many research issues about how to design such systems and what effects they have on the individuals, groups, and organizations that use them.

Let us clarify what this chapter is about. It is not a general review of the field of CSCW—that would be an enormously larger task than we can take on here. Rather, we are going to focus on the kinds of collaborative applications that have emerged and achieved wide adoption. We will describe their characteristics, in terms of what functions they serve, and we will mention *some* of the studies done to evaluate them. These studies are a mix of controlled laboratory studies and studies of the technologies in real organizations. For many of the technologies we review, entire chapters could be written about the work that has been done with them. So we will, of necessity, have to be selective in our coverage. Our goal is to be *representative*, not exhaustive.

24.2 ADOPTING GROUPWARE IN CONTEXT

Collaborative systems are often intended to support groups, which are usually embedded in an organization. As a result, there are a number of issues that bear on the success of such systems. In a justly famous set of papers, Grudin (1988, 1994) pointed out a number of problems that such systems have (see also Markus and Connolly [1990]). In brief, he pointed out that developers of such systems need to be concerned with the following issues (Grudin 1994, p. 97; we here use the groupware terminology that he used in these original articles):

1. Disparity in work and benefit. Groupware applications often require additional work from individuals who do not perceive a direct benefit from the use of the application.
2. Critical mass and Prisoner's dilemma problems. Groupware may not enlist the "critical mass" of users required to be useful, or can fail because it is never in any one individual's advantage to use it.
3. Disruption of social processes. Groupware can lead to activity that violates social taboos, threatens existing political structures, or otherwise de-motivates users crucial to its success.
4. Exception handling. Groupware may not accommodate the wide range of exception handling and improvisation that characterizes much group activity.
5. Unobtrusive accessibility. Features that support group processes are used relatively infrequently, requiring unobtrusive accessibility and integration with more heavily used features.
6. Difficulty of evaluation. The almost insurmountable obstacles to meaningful, generalizable analysis and evaluation of groupware prevent us from learning from experience.
7. Failure of intuition. Intuitions in product development environments are especially poor for multiuser applications, resulting in bad management decisions and error-prone design processes.
8. The adoption process. Groupware requires more careful implementation (introduction) in the workplace than product developers have confronted.

There are reasons, however, for optimism. One specific example is Palen and Grudin's (2002) follow-up study of the adoption of group calendars. They found that organizational conditions in the 1990s were much more favorable for the adoption of group tools than they were in the 1980s. Further, the tools themselves had improved in reliability, functionality, and usability. There is increased "collaboration readiness" and "collaboration technology readiness" (Olson and Olson 2000) that has made for increased success of such applications. Indeed, the very rapid take-up of technologies like Wikipedia, Facebook, Twitter, and multiplayer games (and many other examples) is testament to the changed circumstances in current times. Certainly items 5 and 6 in Grudin's list are not as much of a challenge at present. But many of the others persist as serious challenges.

24.3 TECHNICAL INFRASTRUCTURE

Collaborative technology requires networks, and network infrastructure is a key enabler as well as a constraint on such systems. High-quality broadband networking has emerged across most parts of the developed world. Good access to the Internet is now common in many places other than the office, such as homes, hotels, coffee shops, airports, and even in many open spaces like parks. It is also the case that networking infrastructure is spreading throughout the world. However, heterogeneity in network conditions remains a major technical challenge. For instance, doing web conferencing when some participants are on slow dial-up lines and others are on fast advanced networks requires special coordination. Some good resources on the latest developments in networking are Comer (2008) and Kurose and Ross (2009).

The World Wide Web and its associated tools and standards have had a major impact on the possibilities for collaboration (Schatz and Hardin 1994; Berners-Lee 1999). Early collaboration technologies mostly consisted of standalone applications that had to be downloaded and run on each client machine. Increasingly, collaborative tools are written for the web, requiring only a web browser and perhaps some plug-ins. This makes it much easier for the user and also helps with matters such as version control. It also enables better interoperability across hardware and operating systems. The emergence of Web 2.0 has helped create a plethora of interesting applications in a wide variety of areas. For example, many conferencing tools are now accessed through a web browser. See Bell (2009) and Campasoto and Nilson (2011) for a variety of examples and details.

Another major technical advancement has been the explosion of collaborative functions on mobile devices. Laptops, personal digital assistants, wearables, pads, and cell phones provide access to information and people from almost anywhere. More and more applications are being written to operate across these diverse environments (e.g., Tang et al. 2001; Starner and Rhodes 2004; Wiltse and Nichols 2009; Gunaratne and Brush 2010). These devices vary in computational power, display size and characteristics, network bandwidth, and connection reliability, providing interesting technical challenges to make them all interoperate smoothly. For instance, accessing websites from a cell phone requires special user interface methods to make the tiny displays usable (Jones and Marsden 2006). More information about these advances is available in Ling and Donner (2009), and an interesting analysis of the implications of these advances in mobile communication is in Rheingold (2002).

Security on the Internet continues to be a major challenge for collaboration technologies. In some sense, the design of Internet protocols are to blame, since the Internet grew up in a culture of openness and sharing (Longstaff et al. 1997; Abbate 1999; Tanenbaum 2011). E-commerce and sensitive application domains like medicine have been a driver for advances in security, but there is still much progress to be made (Longstaff et al. 1997; Camp 2000). Coping with firewalls that block access to certain organizations can limit the flexibility of web conferencing. A good recent discussion of these issues is in Wong and Yeung (2009).

Additional flexibility is being provided by the development of infrastructure that lies between the network itself and the applications that run on client workstations, called "middleware." This infrastructure makes it easier to link together diverse resources to accomplish collaborative goals. For instance, the emerging Grid technologies allow the marshalling of powerful, scattered computational resources (Foster and Kesselman 2004). Middleware provides such services as identification, authentication, authorization, directories, and security in uniform ways that facilitate the interoperability of diverse applications. All of these technical elements are components of cyber infrastructure (Atkins et al. 2003). There is considerable interest in the development of this infrastructure because of its large impact on research, education, and commerce.

24.3.1 Communication Tools

We now turn to a review of specific kinds of collaboration technologies, highlighting their various properties and uses. We have grouped this review under several broad headings. We do not aim to be exhaustive, but rather seek to illustrate the variety of kinds of tools that have emerged to support human collaborative activities over networked systems. We also highlight various research issues pertaining to these tools.

24.3.2 E-mail

E-mail has become a ubiquitous communication tool. The early adoption of standards made it possible for messages to be exchanged across networks and different base machines and software applications. E-mail is now also done from cell phones, personal digital assistants (PDAs), television sets, and kiosks in public sites. Documents of many types can be easily exchanged. Because of its widespread use, it has often been called the first successful collaboration technology (Sproull and Kiesler 1991; Satzinger and Olfman 1992; O'Hara-Devereaux and Johnson 1994; Anderson et al. 1995). Indeed, it has become so successful that e-mail overload has become a major problem (Whittaker and Sidner 1996). And of course, it has become a vector for viruses, worms, and other malware.

Researchers have shown that this widespread use has had a number of effects on how people behave. It has had large effects on communication in organizations: it changes the social network of who talks to whom (Sproull and Kiesler 1991; DeSanctis, et al. 1996), the power of people who formerly had little voice in decisions (Finholt, Sproull, and Kiesler 1990), and the tone of what is said and how it is interpreted (Sproull and Kiesler 1991). For example, with e-mail, people who were shy found a voice; they could overcome their reluctance to speak to other people by composing text, not speech to another face. This invisibility, however, also has a more general effect—without the social cues in the recipient's face being visible to the sender, people will "flame," send harsh or extremely emotive (usually negative) messages (Arrow et al. 1996; Hollingshead, McGrath, and O'Connor 1993).

As with a number of other "designed" technologies, people use e-mail for things other than the original intent. People use it for managing time, reminding them of things to do, and keeping track of steps in a workflow (Mackay 1989; Carley and Wendt 1991; Whittaker and Sidner 1996). But because e-mail was not designed to support these tasks, it does not do it very well; people struggle with reading signals about whether they have replied or not (and to whom it was cc'd); they manage folders poorly for reminding them to do things, and so forth.

In addition, because e-mail is so widespread, and it is easy and free to distribute a single message to many people, people experience information overload. Many people get hundreds of e-mail messages each day, many of them mere broadcasts of things for sale or events about to happen, much like "classifieds" in the newspaper. Several early efforts to use artificial intelligence techniques to block and/or sort incoming e-mail were tried, and this has continued to be a very active area of work (Malone et al. 1989; Winograd 1988). There are two broad classes of uses of e-mail filters. One use is to automatically sort incoming mail into useful categories. This is relatively easy for mail that has simple properties, such as a person's name. It is more difficult for subtle properties. The other major use is to weed out unwanted mail, such as spam. The state-of-the-art in spam filtering was in the range of 80%–90% effectiveness in 2005 (e.g., Federal Trade Commission 2005). Such filters are so good that many institutions automatically filter mail as it comes in to the organization's gateway, sparing users the need to do it in their own clients. Similarly, many clients now come with built-in spam filters that can be tuned by the user (e.g., Google's Gmail).

These problems have led to the "reinvention" of e-mail (Whittaker, Bellotti, and Moody 2005). For example, given that e-mail is often used in the context of managing projects, systems have been explored that have a more explicit scheme for task management (Whittaker 2005; Bellotti et al. 2005). To deal with problems of e-mail overload, new schemes for filtering e-mail have been explored, such as routing messages differently to different kinds of clients (e.g., cell phone vs. desktop machine; see Schmandt and Marti [2005]). Another approach has been to explore pricing mechanisms for e-mail that are analogous to pricing for regular mail (Kraut et al. 2005). In such schemes one would pay to send e-mail, with higher prices presumably indicating higher priority, analogous to the difference between first class postage and bulk rates. These schemes are exploratory, but are likely to result in new options in future e-mail clients.

Kraut et al. (1998) reported that greater Internet use, which in their sample was mostly e-mail, led to declines in social interactions with family members and an increase in depression and loneliness. Not surprising, these results triggered widespread discussion and debate, both over the substance of the results and the methods used to obtain them. Kraut, Gergle, and Fussell (2002) reported new results that suggested these initial negative effects may not persist. Interpersonal communication is one of the principal uses of the Internet, and the possible implications of this kind of communication for social life are important to understand (see reviews by Bargh and McKenna [2004] and Benkler [2006]). Indeed, Putnam (2000) has wondered whether the Internet can be a source of social cohesiveness. These kinds of questions need to be addressed by additional large-scale studies of the kind carried out by Kraut and his colleagues (see review by Resnick [2002]).

24.3.3 Conferencing Tools: Voice, Video, Text

There are many options available today for on-line conferencing among geographically dispersed members of a group. So-called computer-mediated communication (CMC) has become widespread. There are three principal modes of interaction, but each has numerous subtypes:

- Video + Audio
  - Full-scale video conferencing room; many options for specific design
  - Individual desktop video; many options for quality, interface
  - Conferencing options on mobile devices
- Audio
  - Phone conference
  - Voice over IP (Skype being a very popular application)
- Text
  - Instant messaging, chat, SMS on mobile phones

CMC was an early research focus for CSCW, and much of what we know dates from the early studies. To be sure, there have been some recent refinements of this literature, for which we will mention a few examples.

There are many studies that compare FTF with various forms of CMC. There are some clear generalizations from such work. The main one is that CMC is more difficult to do than FTF and requires more preparation and care (Hollingshead, McGrath, and O'Connor 1993; McLeod 1992; Olson, Olson, and Meader 1995; Siegel et al. 1986; Straus 1996, 1997; Straus and McGrath 1994). A variety of things that come for free in FTF are either difficult to support or outright missing in CMC (Kiesler and Cummings 2002). Backchannel communication, which is important for modulating conversation, is either weak or nonexistent in CMC, although it has become common to keep an instant messaging (IM) chat going during audio or video conferences (e.g., Kellogg et al. 2006). Paralinguistic cues that can soften communication are often missing. Participants in CMC tend to have an informational focus, which means there is usually less socializing, less small talk. Over time, this can lead to poorer social integration and organizational effectiveness (Nohria and Eccles 1992).

CMC often introduces delay. This is well known to be very disruptive to communication (Egido 1988; Krauss and Bricker 1966; O'Conaill, Whittaker, and Wilbur 1993; Ruhleder and Jordan 2001; Tang and Isaacs 1993). Participants will communicate less information, be more frustrated with the communication, and actually terminate communication sessions sooner. Delay can be managed, but it takes special care among the participants and turn-taking widgets in the interface of the tools being used. For instance, if there is delay, then full-duplex open communication will not work, since participants will step all over each other's communication. Either the participants must use a social protocol (e.g., like that used in radio communications with spacecraft), or they must employ a mike-passing procedure with interface indications of who wants to talk next.

Although it might seem desirable to always have the maximum communication and tool support possible, it is not always possible or even necessary to do so. Research shows that effective real-time collaboration can take place under a number of different arrangements, depending on the task, the characteristics of the participants, the specific geographical dispersion of the participants, and the processes employed to manage the interactions. There are also organizational effects, especially when the real-time collaborations are embedded in ongoing activities, as they almost always are.

For instance, early work (Williams 1977) showed that, in referential communication tasks, full-duplex audio is just as effective as FTF. Subsequent research comparing audio and video conferencing (see summaries in Finn, Sellen, and Wilbur [1997]; Cadiz et al. [2000] found similar results for a tutored video-instruction task) showed that for many tasks audio is sufficient and that video adds nothing to task effectiveness, though participants usually report they are more satisfied with video. There are important exceptions, however. Negotiation tasks are more effective with video (Short, Williams, and Christie 1976). This is probably because the more subtle visual cues to the participants' intentions are important in this kind of task. Further, Veinott et al. (1999) found that when participants have less common ground, video helps. In their case, participants were nonnative speakers of English who were doing the task in English. For native speakers, video was no better than audio, but nonnative speakers did better when they had video. Again, visual cues to comprehension and meaning likely played an important role. Recently, an experimental study by Daly-Jones, Monk, and Watts (1998) showed that high-quality video resulted in greater conversational fluency over just high-quality audio, especially as group size increased. There was also a higher rated sense of presence in the video conditions.

An important lesson to draw from this literature is that there are two broad classes by which we might assess whether video is important in real-time collaboration. On the one hand, except for tasks like negotiation or achieving common ground, groups are able to get their work done effectively with high-quality audio. However, for things like satisfaction, conversational fluency, and a sense of presence, video adds value. These kinds of factors might be very important for long-term organizational consequences like employee satisfaction. As of yet, no long-term studies have been done to examine this conjecture.

Audio quality is critical. Ever since early literature review (Egido 1988), it has been reported over and over again that if the audio is of poor quality participants will develop a workaround. For instance, if the audio in a video conferencing system or in a web conferencing system is poor quality, participants will turn to a phone conference.

The social ergonomics of audio and video are also keys to their success. Many of the failures of audio conferencing, especially over the Internet, result from poor-quality microphones, poor microphone placement, poor speakers, and interfering noises like air conditioning. Getting these details right is essential. Similarly, for video, camera placement can matter a lot. For instance, Huang, Olson, and Olson (2002) found that a camera angle that makes a person seem tall (as opposed to actually being tall) affects how influential a person is in a negotiation task. Apparent height matters a lot. Other aspects of camera placement or arrangement of video displays make a big difference as well but are not well known.

An exception is eye contact or gaze awareness, where studies of FTF communication show that these are key linguistic and social mediators of communication (Argyle and Cook 1976; Kendon 1967). It is very difficult to achieve eye contact in CMC systems. Many attempts have been made (Gale and Monk 2000; Grayson and Monk 2003; Monk and Gale 2002; Okada et al. 1994; Vertegaal 1999; Vertegaal et al. 2001), and at least the subjective reports are that these can be effective. But these all require special equipment or setups. And they do not scale very well to multiparty sessions. A recent study by Nguyen and Canny (2007) showed that a relatively simple and inexpensive setup that supports gaze awareness (being able to tell who is looking at whom) had a clear effect on a task that assessed the formation of interpersonal trust.

While for most situations having at least high-quality audio is essential, there are some special cases where a text-based channel, like chat or instant messaging, can work fine. For instance, in the Upper Atmospheric Research Collaboratory (UARC, later known as the "Space Physics and Aeronomy Research Collaboratory" or SPARC), a chat system worked very well for carrying out geographically distributed observational campaigns, since the flow of events in these campaigns were relatively slow (campaigns went on for several days, key events would take many minutes to unfold). McDaniel, Olson, and Magee (1996) compared chat logs with earlier FTF conversations at a remote site and found many elements of them very similar, including informal socializing. But this kind of ongoing scientific campaign is very unlike the interactions that take place in a typical meeting.

Instant messaging is a new communication modality that is making substantial inroads into organizations. Muller et al. (2003) found in a survey study of three organizations that the introduction of instant messaging led to significantly less use of such communication channels as e-mail, voice-mail, telephone, teleconference, pager, and FTF. They also found that instant messaging was used for "substantive business purposes." Furthermore, in one of the organizations where they surveyed users after 24 months of usage they found that the substantive reasons for using IM increased. In a study of IM logs in an organization, Isaacs et al. (2002) found that a large proportion of IM conversations involved "complex work discussions." They found that IM users seldom switched to another communication channel once they were engaged in

IM. Nardi, Whittaker, and Bradner (2000) observed in a field study that workers used IM for a variety of purposes, not just for information exchange. Such matters as quick questions, scheduling, organizing social interactions, and keeping in touch with others were common uses of IM. Thus, IM has emerged as a significant communication medium in the workplace and is used even when other, richer communication channels were available.

Although IM is a relatively new phenomenon in the workplace, it is clearly established as a useful and widely used tool outside the workplace. This will undoubtedly assist in the development of more sophisticated versions of the tool, as well as its integration into on-line conferencing systems. There is clearly much promise here. We have noticed, for example, that during online conferences IM or chat serves as a backchannel for side conversations or debugging, an extremely useful adjunct to the core audio or video communication taking place in such conferences.

The other key feature of successful remote meetings is the ability to share the objects they are talking about, such as the agenda, the to-do list, the latest draft of a proposal, a view of an object to be repaired, and so on. Many researchers (Fussell, Kraut, and Siegel 2000; Karsenty 1999; Kraut, Fussell, and Siegel 2003; Kraut et al. 2002; Luff et al. 2003; Nardi et al. 1993; Whittaker, Geelhoed, and Robinson 1993) have provided experimental evidence of the value of a shared workspace for synchronous audio-supported collaboration. More traditional video conferencing technologies often offer an "object camera," onto which the participants can put a paper agenda, Powerpoint slides, or a manufactured part. More generally, any form of video can also be used to share work objects (Fussell, Kraut, and Siegel 2000; Nardi et al. 1993). For digital objects, there are now a number of products that will allow meeting participants to share the screen or, in some cases, the remote operation of an application. Some companies are using electronic whiteboards, both in a collocated meeting and in remote meetings to mimic the choreography of people using a physical whiteboard. In some "collaboratories," scientists can even operate remote physical instruments from a distance and jointly discuss the results.

There are a growing number of studies that have looked at cultural issues in CMC. For example, Setlock, Fussell, and Neuwirth (2004) studied the differences in conversational content between Chinese and American pairs while engaged in a decision-making task, either in a FTF situation or using instant messaging, and found a series of differences in how they conversed. On the basis of analyses of agreement and efficiency, along with some specific text analyses, they characterized pairs of Americans as viewing the task as one of working out a mutually acceptable joint rating, whereas the Chinese pairs worked to reach agreement on the relative worth of the specific items to be rated. Fussell and her colleagues have carried out a series of studies comparing CMC behaviors across Asian and American cultures (e.g., Diamant, Fussell, and Lo 2009; Wang, Fussell, and Setlock 2009). A recent review of work on multicultural teams is by Connaughton and Shuffler (2007). The emergence of a new conference series on Intercultural Collaboration (e.g., International Conference on Intercultural Collaboration or ICIC 2010) provides a focused venue for work like this.

24.3.4 Blogs

Weblogs, or more commonly called "blogs," have burst upon the Internet scene in recent years. Blogging software that makes it easy to put up multimedia content has led people to set up sites for all manner of purposes. A site can contain text, pictures, movies, and audio clips. A common social purpose is to keep an on-line diary. Another is to provide commentary on a topic of interest. For instance, blogs played a major role in the 2004 election (Adamic and Glance 2005). Nardi et al. (2004) studied why people blog, as it is sometimes puzzling that people would essentially share personal or private information about themselves through the web. Blogging has emerged as a major research topic in this area, and the literature is growing apace.

A special topic related to blogging is the emergence of microblogging, best instantiated by Twitter. Twitter limits contributions to 140 characters, so of necessity "tweets," as they are called, are concise. Yet Twitter has emerged as a major social phenomenon, and of course is also receiving significant scholarly attention. A couple of recent examples of such studies include Huberman, Romero, and Wu (2009) and Zhao and Rosson (2009).

24.3.5 Disaster Response

Within the past decade the kinds of CMC tools we have been reviewing have emerged as major resources for dealing with disasters. There are now a number of studies of these phenomena. For example, Vieweg et al. (2010) studied the use of Twitter in two natural emergencies, the 2009 grass fires in Oklahoma and the 2009 flooding of the Red River. They found that the use of Twitter made major contributions to situational awareness in both cases. Palen et al. (2009) studied the role of CMC in the 2007 mass shooting at Virginia Tech. Mark, Al-Ani, and Semaan (2009) looked at the role of CMC in maintaining resilience in a war zone, particularly Iraq. Schafer, Ganoe, and Carroll (2007) looked at emergency management planning in a community, focusing on what kind of software architecture would support the kinds of needs faced there. These examples are just the tip of the iceberg of recent work in the area, all of which is showing that the wide variety of collaboration technologies now available can have a substantial impact on the handling of emergencies.

24.4 COORDINATION SUPPORT

24.4.1 Meeting Support

An early and popular topic in CSCW was the support of FTF meetings. A number of systems were developed and tested. While of late the focus has shifted to the support of geographically distributed meetings, the early work on meeting support led to some important and useful conclusions.

Some meeting-support software imposed structure on the process of the meeting, embodying various brainstorming and voting procedures. Group decision-support systems (GDSSs) arose from a number of business schools, focusing on large meetings of stakeholders' intent on going through a set series of decisions, such as prioritizing projects for future funding (Nunamaker et al. 1991). With the help of a facilitator and some technical support, the group was led through a series of stages: brainstorming without evaluating, evaluating alternatives from a variety of positions, prioritizing alternatives, and so on. These meetings were held in specialized rooms in which individual computers were embedded in the tables, networked to central services, and summary displays shown "center stage." A typical scenario involved individuals silently entering ideas into a central repository, and after a certain amount of time, they were shown ideas one at a time from others and asked to respond with a new idea triggered by that one. Later, these same ideas were presented to the individuals who were then asked to rank or rate them according to some fixed criterion, like cost. Aggregates of individuals' opinions were computed, discussed further and presented for vote. The system applied computational power (for voting and rating mechanisms), and networking control (for parallel input) to support typically weak aspects of meetings. These systems were intended to gather more ideas from participants, since one did not have to wait for another to stop speaking in order to get a turn. And, anonymous voting and rating was intended to insure equal participation, not dominated by those in power.

Evaluations of these GDSSs have been reviewed producing some generalizations about their value (McLeod 1992; Kraemer and Pinsoneault 1990; Hollingshead, McGrath, and O'Connor 1993). The systems indeed fulfill their intentions of producing more ideas in brainstorming and having more evaluative comments because of anonymity. Decisions are rated as higher in quality, but the meetings take longer and the participants are less satisfied than those in traditional meetings.

A second class of technologies to support real-time meetings is less structured, more similar to individual workstation support. In these systems, groups are allowed access to a single document or drawing, and can enter and edit into them simultaneously at will. Different systems enforce different "locking" mechanisms (e.g., paragraph or selection locking) so that one person does not enter while another deletes the same thing (Ellis, Gibbs, and Rein 1991). Some also allow parallel individual work, where participants view and edit different parts of the same document, but can also view and discuss the same part as well. This kind of unstructured shared editor has been shown to be very effective for certain kinds of free-flowing meetings, like design or requirements meetings (Olson et al. 1993). The rated quality of the meeting products (e.g., a requirements document or plan) was higher when using these technologies than with traditional whiteboard or paper-and-pencil support, but like working in GDSSs, people were slightly less satisfied. The lower satisfaction here and with GDSSs may reflect the newness of the technologies; people may not have yet learned how to persuade, negotiate, or influence each other in comfortable ways, to harness the powers inherent in the new technologies.

These new technologies did indeed change the way in which people worked. They talked less and wrote more, building on each other's ideas instead of generating far-reaching other ideas. The tool seemed to focus the groups on the core ideas, and keep them from going off on tangents. Many participants reported really liking doing work in the meetings rather than spending time only talking about the work (Olson et al. 1993).

A third class of meeting room support appears in electronic whiteboards. For example, the LiveBoard (Elrod et al. 1992), SoftBoard and SmartBoard are rear projection surfaces that allow pen input, much the way a whiteboard or flip chart does. People at Xerox PARC (Palo Alto Research Center Incorporated) and Boeing have evaluated the use of these boards in meetings in extended case studies. In both cases, the board was highly valued because of its computational power and the fact that all could see the changes as they were made. At both sites, successful use required a facilitator who was familiar with the applications running to support the meeting. At Xerox, suggestions made in the meeting about additional functionality were built into the system so that it eventually was finely tuned support for their particular needs (Moran et al. 1996). For example, they did a lot of list making of freehand text items. Eventually, the board software recognized the nature of a list and an outline, with simple gestures changing things sensibly. For example, if a freehand text item was moved higher in a list, the other items adjusted their positions to make room for it. The end product was not only a set of useful meeting tools, but also a toolkit to allow people to build new meeting widgets to support their particular tasks.

As technological developments have enabled the creation of large, affordable displays, research has picked up on the utility of large displays for small team collaboration. An obvious application of large displays is for complex, high-resolution data, such as maps, medical images, and a variety of complex scientific visualizations. There are of course interesting issues in dealing with such large displays, such as how to navigate them when they are extraordinarily rich in detailed information (Ball, North, and Bowman 2007), how to distribute control among users (e.g., single selection device vs. one per person; see Birnholtz et al. [2007]), and how to deal with sensitive or private information, as in the context of shift changes in a hospital (Wilson, Galliers, and Fone 2006). Robertson et al. (2005) have a good discussion of the many usability issues that arise with large displays. There is a large and growing literature on this topic.

Tabletop displays constitute another way of presenting lots of information for collaborators. This too is a rapidly growing area of research that we do not have space to cover in any detail. But some recent, representative studies that would help one get into the literature include Isenberg et al. (2010), Morris, Lombardo, and Wigdor (2010), Hartmann et al. (2009) and Tang et al. (2006).

Meetings are important, though often despised, organizational activities. Research of the kind just reviewed has shown quite clearly that well-designed tools can improve both work outcomes and participant satisfaction. However, meetings in organizations seldom use such tools. Inexpensive mobile computing and projection equipment combined with many commercial products mean that such tools are within reach of most organizations. But not having these elements readily available in an integrated way probably inhibits their widespread adoption.

While traditional meetings are often viewed as wasteful and frustrating, there can be huge benefits to working together in collocated environments. Kiesler and Cummings (2002) reviewed a number of the characteristics of physical collocation that can benefit performance. In a detailed study of one such situation, Teasley et al. (2002) found that "radical collocation," in which software development teams worked together in a dedicated project room for many weeks, dramatically improved their productivity. Reasons for this included the constant awareness of each other's work status, the associated ability to instantly work on an impasse as a group, and the availability of rich shared artifacts generated by the project.

24.4.2 Workflow

Workflow systems lend technology support to coordinated asynchronous (usually sequential) steps of activities among team members working on a particular task. For example, a workflow system might route a travel reimbursement voucher from the traveler to the approving party to the accounts payable to the bank. The electronic form would be edited and sent to the various parties, their individual to-do-lists updated as they received and/or completed the tasks, and permissions and approval granted automatically as appropriate (e.g., allowing small charges to an account if the charges had been budgeted previously or simply if there was enough money in the account). Not only is the transaction flow supported, but also records are often kept about who did what and when they did it. It is this later feature that has potentially large consequences for the people involved, discussed in the last paragraph in this section.

These workflow systems were often the result of work reengineering efforts, focusing on making the task take less time and to eliminate the work that could be automated. Not only do workflow systems therefore have a bad reputation in that they often are part of workforce reduction plans, but also for those left, their work is able to be monitored much more closely. The systems are often very rigid, requiring, for example, all of a form to be filled in before it can be handed off to the next in the chain. They often require a great deal of rework because of this inflexibility. It is because of the inflexibility and the potential monitoring that the systems fall into disuse (e.g., Abbott and Sarin 1994). However, Grinter (2000) examined several cases of successful deployment of workflow systems, and drew some helpful conclusions about what is required for these to work. Klein, Dellarocas, and Bernstein (2000) introduced a special double issue of *Computer Supported Cooperative Work* on adaptive workflow systems that deal with some of the exception-handling that can be such an important feature for success.

The fact that workflow can be monitored is a major source of user resistance. In Europe, such monitoring is illegal, and powerful groups of organized workers have made sure that such capabilities are not in workflow systems (Prinz and Kovenbach 1996). In the United States, it is not illegal, but many employees complain about its inappropriate use. For example, in one software engineering team where workflow had just been introduced to track bug reports and fixes, people in the chain were sloppy about noting who they had handed a piece of work off to. When it was discovered that the manager had been monitoring the timing of the handoffs to assign praise or blame, the team members were justifiably upset (Olson and Teasley 1996). In general, managerial monitoring is a feature that is not well received by people being monitored (Markus 1983). If such monitoring is mandated, workers' behavior will conform to the specifics of what is being monitored (e.g., time to pass an item off to the next in the chain) rather than perhaps to what the real goal is (e.g., quality as well as timely completion of the whole process).

24.4.3 Group Calendars

A number of organizations have now adopted online calendars, mainly in order to view people's schedules to arrange meetings. The calendars also allow a form of awareness, allowing people to see if a person who is not present is expected back soon. Individuals benefit only insofar as they offload scheduling meetings to others, like to an administrative assistant, who can write as well as read the calendar. And, in some systems the individual can schedule private time, blocking the time but not revealing to others his or her whereabouts. By this description, on-line calendaring is a classic case of what Grudin (1988) warned against, a misalignment of costs and benefits; the individual puts in the effort to record his/her appointments so that another, in this case a manager or coworker, can benefit from ease of scheduling. However, since the early introduction of electronic calendaring systems, many organizations have found successful adoption (Mosier and Tammaro 1997; Grudin and Palen 1995; Palen and Grudin 2002). Apparently such success requires a culture of sharing and accessibility, something that exists in some organizations and not others (Lange 1992; Ehrlich 1987). But today group calendars are a common piece of infrastructure in many settings (Miller 2009).

24.4.4 Awareness

In normal work, there are numerous occasions in which people find out casually whether others are in and, in some cases, what they are doing. A simple walk down the hall to a printer offers numerous glances into people's offices, noting where their coats are, whether others are talking, whether there is intense work at a computer, and so on. This kind of awareness is unavailable to workers who are remote. Some researchers have offered various technology solutions; some have allowed one to visually walk down the hall at the remote location, taking a 5-second glance into each passing office (Bellotti and Dourish 1997; Fish et al. 1993). Another similar system, called “Portholes,” provides periodic snapshots instead of full-motion video (Dourish and Bly 1992). Because of privacy implications, these systems have had mixed success. The places in which this succeeds are those in which the individuals seem to have a reciprocal need to be aware of each other’s presence, and a sense of cooperation and coordination. A contrasting case is the IM system in which the user has control as to what state they wish to advertise to their partners about their availability. The video systems are much more lightweight to the user but more intrusive; the IM ones give the user more control but require intention in action. Another approach investigated by Ackerman et al. (1997) looked at shared audio as an awareness tool, though this too has privacy implications.

As mentioned earlier, instant messaging systems provide an awareness capability. Most systems display a list of “buddies” and whether they are currently on-line or not. Nardi, Whittaker, and Bradner (2000) found that people liked this aspect of IM (see also Muller et al. [2003]; Isaacs et al. [2002]). And, since wireless has allowed constant connectivity of mobile devices like PDAs, this use of tracking others is likely to grow. But again, there are issues of monitoring for useful or insidious purposes, and the issues of trust and privacy loom large (see Godefroid et al. [2000]).

Another approach to signaling what one is doing occurs at the more micro level. And again, one captures what is easy to capture. When people are closely aligned in their work, there are applications that allow each to see exactly where in the shared document the other is working and what they are doing (Gutwin and Greenberg 1999). If one is working nearby the other, this signals perhaps a need to converse about the directions each is taking. Empirical evaluations have shown that such workspace awareness can facilitate task performance (Gutwin and Greenberg 1999).

Studies of attempts to carry out difficult intellectual work within geographically distributed organizations show that one of the larger costs of geographical distribution is the lack of awareness of what others are doing or whether they are even around (Herbsleb et al. 2000). Thus, useful and usable awareness tools that mesh well with trust and privacy concerns could be of enormous organizational importance. This is a rich research area for CSCW.

An important body of material on this topic appeared in a special issue of *Computer Supported Cooperative Work* in 2002. We do not have the space to engage the nine important articles published in this special issue, but anyone wanting to delve more deeply into this topic of necessity needs to digest this special issue. Schmidt’s (2002) article exploring the very concept of awareness itself certainly deserves attention.

A related problem that has recently received much attention is the matter of interruptions. Interruptions have the property that there is an asymmetry between the interrupter and the interrupted, in that the former seemingly has more control over the occasions of interruptions than the latter (Nardi and Whittaker 2002).* These issues become even more acute in distributed work, especially with weak awareness support. Given this, several investigators have explored with some success whether techniques drawn from statistical decision theory or machine learning could be used to figure out from sensor data whether a person is interruptible (e.g., Horvitz and Apacible 2003; Fogerty et al. 2005).

24.5 INFORMATION REPOSITORIES

24.5.1 Repositories of Shared Knowledge

In addition to sharing information generally on the web, in both public and intranet settings, there are applications that are explicitly built for knowledge sharing. The goal in most systems is to capture knowledge that can be reused by others, like instruction manuals, office procedures, training, and “boilerplates,” or templates of commonly constructed genres, like proposals or bids. Experience shows, however, that these systems are not easy wins. Again, similar to the case of the on-line calendaring systems described in Section 24.4.3, the person entering information into the system is not necessarily the one benefiting from it. In a large consulting firm, where consultants were quite competitive in their bid for advancement, there was indeed negative incentive for giving away one’s best secrets and insights (Orlikowski and Gash 1994).

Sometimes subtle design features are at work in the incentive structure. In another adoption of Lotus Notes, in this case to track open issues in software engineering, the engineers slowly lost interest in the system because they assumed that their manager was not paying attention to their contributions and use of the system. The system design, unfortunately, made the manager’s actual use invisible to the team. Had they known that he was reading daily what they wrote (though he never wrote anything himself), they would likely have continued to use the system (Olson and Teasley 1996). A simple design change that would make the manager’s reading activity visible to the team would likely have significantly altered their adoption.

The web of course provides marvelous infrastructure for the creation and sharing of information repositories. A variety of tools are appearing to support this. Of particular interest are open source tools that allow for a wider, more flexible infrastructure for supporting information sharing (see www.sakai.org). The major types of collaboratory (see Section 24.7.3) are those that provide shared data repositories for a community of scientists. The topic of “knowledge management” has received extensive treatment over the past decade or more and is far beyond the scope of what we can review here.†

* Though one interesting finding is that in the normal course of activity, many interruptions are self-administered (Mark, Gonzalez, and Harris 2005).

† A Google search in August 2010 under “knowledge management” yielded over 70 million hits!

24.5.2 Wikis

A wiki is a shared web space that can be edited by anyone who has access to it. They were first introduced by Ward Cunningham in 1995, but have recently become very popular. These can be used in a variety of ways, both for work and for fun. The most famous wiki is Wikipedia (www.wikipedia.org), an online encyclopedia where anyone can generate and edit content. It has grown to have millions of entries, and has versions in at least ten languages. A recent study carried out by *Nature* found that for science articles Wikipedia and the Encyclopedia Britannica were about equally accurate (Giles 2005). Bryant, Forte, and Bruckman (2005) studied the contributors to Wikipedia, and suggested that a new publishing paradigm was emerging. Viegas, Wattenberg, and Dave (2004) developed imaginative visualizations of Wikipedia authoring and editing behavior over time. While an extensive literature on Wikipedia has developed in recent years, an interesting paper by Kittur and Kraut (2010) studies nearly 7000 other wikis, noting both similarities and differences with the findings that have emerged from studies of Wikipedia. For instance, coordination mechanisms across a wide range of wikis tended to be similar to Wikipedia. But a wide range of policies, procedures, and other mechanisms for managing a wiki appeared in the larger sample.

24.5.3 Capture and Replay

Tools that support collaborative activity can create traces of that activity that later can be replayed and reflected upon. The UARC explored the replay of earlier scientific campaign sessions (Olson et al. 2001), so that scientists could reflect upon their reactions to real-time observations of earlier phenomena. Using a video cassette recording metaphor, they could pause where needed, and fast forward past uninteresting parts. This reflective activity could also engage new players who had not been part of the original session. Abowd (1999) has explored such capture phenomena in an educational experiment called Classroom 2000. Initial experiments focused on reusing educational sessions during the term in college courses. Lipford and Abowd (2008) report on the long-term deployment of such a system, noting a number of challenges in making such systems effective. We do net yet fully understand the impact of such promising ideas.

24.6 SOCIAL COMPUTING

24.6.1 Social Filtering, Recommender Systems

We often find the information we want by contacting others. Social networks embody rich repositories of useful information on a variety of topics. A number of investigators have looked at whether the process of finding information through others can be automated. The kinds of recommender systems that we find on websites like Amazon.com are examples of the result of such research. The basic principle of such systems is that an individual will tend to like or prefer the kinds of things (e.g., movies and books) that someone who is similar to him/her likes. They find similar people by matching their previous choices. Such systems use a variety of algorithms to match preferences with those of others, and then recommend new items. Resnick and Varian (1997) edited a special issue of the *Communication of the ACM* on recommender systems that included a representative set of examples. Herlocker, Konstan, and Riedl (2000) used empirical methods to explicate the factors that led users to accept the advice of recommender systems. In short, providing access to explanations for why items were recommended seems to be the key. Cosley et al. (2005) studied factors that influence people to contribute data to recommender systems. Recommender systems are emerging as a key element of e-commerce (Schafer, Konstan, and Riedl 2001). Accepting the output of recommender systems is an example of how people come to trust technical systems. This is a complex topic, and relates to issues like security that we briefly described in Section 24.3.

24.6.2 Trust of People via the Technology

It has been said that “trust needs touch,” and indeed in survey studies, coworkers report that they trust those who are collocated more than those who are remote (Rocco et al. 2000). Interestingly, those who spend the most time on the phone chatting about non-work-related topics with their remote coworkers show higher trust than those they communicate with using only fax and e-mail. But lab studies show that telephone interaction is not as good as FTF. People using just the telephone behave in more self-serving, less-trusting ways than they do when they meet face to face (Drolet and Morris 2000).

What can be done to counteract the mistrust that comes from the impoverished media? Rocco (1998) had people meet and do a team-building exercise the day before they engaged in the social dilemma game with only e-mail to communicate with. These people, happily, showed as much cooperation and trust as those who discussed things face to face during the game. This is important. It suggests that if remote teams can do some FTF teambuilding before launching on their project, they will act in a trusting/trustworthy manner.

Since it is not always possible to have everyone on a project meet face to face before they launch into the work, what else will work? Researchers have tried some options, but with mixed success. Zheng et al. (2001) found that using chat for socializing and sharing pictures of each other also led to trustful relations. Merely sharing a resume did not. When the text is translated into voice, it has no effect on trust, and when it is translated into voice and presented in a moving human-like face, it is even worse than text-chat. (Jensen et al. 2000; Kiesler, Sproull, and Waters 1996). However, Bos et al. (2001) found that interactions over video and audio led to trust, albeit of a seemingly more fragile form.

If we can find a way to establish trust without expensive travel, we are likely to see important productivity gains. Clearly the story is not over. However, we must not be too optimistic. In other tasks, video does not produce “being there.” There is an overhead to the conversation through video; it requires more effort than working face to face

(Olson, Olson, and Meader 1995). And, today's videos over the Internet are both delayed and choppy, producing cues that people often associate with lying. One does not trust someone who appears to be lying. Trust is a delicate emotion; today's video might not just do it in a robust enough fashion, though the Nguyen and Canny (2007) study mentioned in Section 24.3.3 presented some encouraging results.

24.7 INTEGRATED SYSTEMS

24.7.1 Media Spaces

As an extension of video conferencing and awareness systems, some people have experimented with open, continuous audio and video connections between remote locations. In a number of cases, these experiments have been called "Media Spaces," and these were very popular experiments in industry in the late 1980s and early 1990s. For example, at Xerox, two labs were linked with an open video link between two commons areas (Olson and Bly 1991), the two locations being Palo Alto, California, and Portland, Oregon. Evaluation of these experiments showed that maintaining organizational cohesiveness at a distance was much more difficult than when members are collocated (Finn, Sellen, and Wilbur 1997). However, some connectedness was maintained. Where many of these early systems were plagued with technical difficulties, human factors limitations, or very large communication costs, in today's situation it might actually be possible to overcome these difficulties, making media a possibility for connecting global organizations. A new round of experimental deployments with new tools is needed.

24.7.2 Collaborative Virtual Environments

Collaborative virtual environments are 3D embodiments of multiuser domains (MUDs). The space in which people interact is an analog of physical space, with dimensions, directions, rooms, and objects of various kinds. People are represented as avatars—simplified, geometric, digital representations of people, who move about in the 3D space (Singhal and Zyda 1999). Similar to MUDs, the users in a meeting situation might interact over some object that is digitally represented, like a mock up of a real thing (e.g., an automobile engine, an airplane hinge, a piece of industrial equipment) or with visualizations of abstract data (e.g., a 3D visualization of atmospheric data). In these spaces, one can have a sense as to where others are and what they are doing, similar to the simplified awareness systems described earlier. In use, it is difficult to establish mutual awareness or orientation in such spaces (Hindmarsh et al. 1998; Park, Kapoor, and Leigh 2000; Yang and Olson 2002). There have even been some attempts to merge collaborative virtual environments with real ones, though with limited success so far (Benford et al. 1998).

The emergence of multiplayer games with rich virtual environments has literally exploded in the past decade. There is a growing literature on the characteristics of play and collaboration in these games. Ducheneaut and Moore (2005) described the learning of social skills in such games. Brown and Thomas (2006) speculated that achieving mastery in such collaborative games might become an important entry on a resume. Bainbridge (2007) discussed the scientific research potential of such worlds. Nardi (2010) summarized her extensive experience in playing World of Warcraft. This is just the briefest sample of what is available.

Another recent development is the emergence of virtual environments like Second Life. These are not game environments, but a platform in which a wide range of social phenomena are supported in a virtual world. Participants have an avatar, whose visual appearance and clothing can be designed. People in Second Life engage in commerce, buying and selling real estate, making things like clothing or furniture, and a variety of other imports from real life (or RL as it is known in Second Life). Many colleges and universities have a presence in Second Life, and have experimented with offering classes and discussion forums. A number of corporations have a presence in Second Life, and have engaged in creative activities such as prototyping future places (e.g., hotel designs) or software. The first author of this chapter recently participated in a usability evaluation of software developed by IBM Research.

24.7.3 Collaboratories

A collaboratory is a laboratory without walls (Finholt and Olson 1997). From a National Research Council report, a collaboratory is supposed to allow "the nation's researchers [to] perform their research without regard to geographical location—interacting with colleagues, accessing instrumentation, sharing data and computational resources [and] accessing information in digital libraries" (National Research Council 1993, p. 7). Starting in the early 1990s, these capabilities have been configured into support packages for a number of specific sciences (see Finholt [2002]). The Science of Collaboratories project (www.science of collaboratories.org) has identified more than 200 existing collaboratories and has drawn lessons about why some succeed and others do not (Olson, Zimmerman, and Bos 2008).

A number of companies have also experimented with similar concepts, calling them "virtual collocation." The goal there is to support geographically dispersed teams as they carry out product design, software engineering, financial reporting, and almost any business function. In these cases, suites of off-the-shelf groupware tools have been particularly important and have been used to support round-the-clock software development among overlapping teams of engineers in time zones around the world. (Carmel 1999). There have been a number of such efforts, and it is still unclear as to their success or what features make their success more likely, though Olson et al. (2008) have summarized a rich variety of possible factors.

24.8 CONCLUSIONS

Many of the functions we have described in this chapter are becoming ordinary elements of infrastructure in networked computing systems. Prognosticators looking at the emergence of collaborative technologies and the convergence of computing and communication media have forecast that distance will diminish as a factor in human interactions (e.g., Cairncross 1997). However, to paraphrase Mark Twain, the reports of distance's death are greatly exaggerated. Even with all our emerging information and communications technologies, distance and its associated attributes of culture, time zones, geography, and language will continue to affect how humans interact with each other. Emerging distance technologies will allow greater flexibility for those whose work must be done at a distance, but we believe (see Olson and Olson [2000]) that distance will continue to be a factor in understanding these work relationships.

ACKNOWLEDGMENTS

Preparation of this chapter was facilitated by several grants from the National Science Foundation (research grants IIS-9320543, IIS-9977923, ATM-9873025, IIS-0085951 and cooperative agreement IRI-9216848) and a grant from the Army Research Institute (W91WAW-07-C-0060). We are also grateful to several anonymous reviewers for helpful comments on earlier drafts.

25 Human–Computer Interaction and the Web

Helen Ashman, Declan Dagger, Tim Brailsford, James Goulding, Declan O'Sullivan, Jan-Felix Schmakeit, and Vincent Wade

CONTENTS

25.1 INTRODUCTION

As successful as the web is for delivering information globally and rapidly, many problems remain which make it a challenging or unproductive experience for some users, or even impossible for other users.

Pioneering research work in the early 1980s introduced and defined the concept of usability as critical to the success of interactive products and systems (Eason 1984). From the 1990s, there has been a developing relationship between usability and the web, such that for many people, the two terms are inextricably linked. Specifically, not only does the web demand good usability, it can be argued that usability necessitates the web. There are five key reasons why usability and the web have become so closely associated with each other:

1. *Web use is approaching ubiquity.* For many countries, the people who access the web are approaching the population as a whole. For some countries (e.g., Australia and New Zealand), it has been estimated that around 80% of the population are using the web, while the entire North American region has more than 76% of the population using the web.* It seems reasonable to predict that in the future, Internet use will be as near-ubiquitous as telephone use. Such diversity raises many issues related to interdependent variables such as age, gender, culture, disability, language abilities, computer skills and knowledge, domain skills and knowledge, and so on. In particular, considerable ongoing research considers the accessibility of the web, that is, how can websites be designed to account for the needs of as many people as possible (e.g., those with visual impairments) (Abascal and Nicolle 2001; Goble, Harper, and Stevens 2000).
2. *Web users are largely discretionary users.* Apart from the specific case of the work context and company intranets, web users generally do not have to use a particular site (or even the web at all) to achieve their goals. They have alternatives available to them (e.g., another website, making a phone call, visiting a shop), and if they experience usability problems, they do not necessarily have to struggle on or adapt to the poor interface. They are empowered to explore the existing options.
3. *Web usability problems have a clear relationship with sales* (Moss 2010; Nielsen 2008). For websites aiming to sell products or services, poor usability directly impacts on sales. If a user cannot find the product or relevant information, they are unlikely to continue in the transaction. In this case, it has been noted that usability is affecting the experience of a product before purchase (Nielson 2000). Consequently, the website information space must consider many of the issues (e.g., navigation, layout of items, labeling) relevant to the traditional design of physical space for shops.
4. *The web is evolving at a rapid pace.* Technical characteristics are continually changing in response to new application/task areas, facilitated by computer processing power and communication speeds, but also by recent advances in interaction mode. This has an immediate impact on the functionality available to web users (e.g., animations, videos), developments in user-interface design (e.g., clickable items, mouse-over navigation), as well as tools (e.g., cookies, plug-ins). More recently, there have been radical shifts in the capabilities of mobile devices such as smartphones. These changes have firstly seen web applications becoming situation-aware, knowing their geographic location and communicating with other devices (such as other smartphones, other devices,† or radio frequency identification [RFID]), with varying levels of autonomy. Second, we also have seen significant changes in the usual input methods, with touch-sensitive devices creating interfaces that users find attractive, although these come with their own usability issues (Nielsen 2010b). In contrast, users' skills, knowledge, and expectations are often slower to evolve, leading to an inevitable gulf between users (particularly infrequent users) and the web. This is particularly notable when viewing the web on mobile devices (Nielsen 2010a).
5. *Website technical development is easy.* It is simple to have a presence on the web when compared with the resources necessary for traditional product-development processes. To generate a website requires few technical skills, and one can do so with no programming or usability experience, although clearly the basic capabilities do not necessarily make for a useable website. This has contributed to the vast number of websites, ultimately adding to the complications of navigation, while emphasizing the importance of usability as a differentiating factor.

In this chapter, we first consider what it is that makes the web hard to use. We look specifically at browsing and linking, finding things with search-and-query perhaps aided by semantic web classification, increasing the relevance of things we find with personalization and portals, communities and social networks, and finally the mobile web.

25.2 WHAT MAKES THE WEB HARD TO USE?

Much of the difficulty in using the web lies in the vast quantity of information available—browsing and searching becomes increasingly difficult to do and imprecise in its results. Results can be ambiguous, or quite general, and

* Figures for 2009 from www.internetworldstats.com.

† Even toys such as the AR drone (see http://ardrone.parrot.com/) interact with smartphones and have a programmable interface, which could make them largely autonomous of human drivers.

frequently there can be many millions of them. Then having located what one wants, technical flaws, such as broken links or browser incompatibilities often render the information unreachable or unreadable. Most importantly, web pages or the browser interface itself can give a poor presentation, and for some classes of users, make the information inaccessible.

In this section, we look at some of the problems with using the web. In subsequent sections, we look at the further developments in the web that address these issues.

25.2.1 Browsing and Linking: "What's Wrong with the World Wide Web" Revisited

Around 15 years ago, the difficulties in using the web were explored in depth, and presented a vision of "fourth-generation hypermedia" (Bieber et al. 1997). In particular, the importance of hypermedia in the structuring of information was described:

> Hypermedia provides contextual, navigational access for viewing information and … represents knowledge in a form relatively close to the cognitive organizational structures that people use. Thus hypermedia supports understanding.

The authors went on to define a table of desired hypermedia features (Bieber et al. 1997). Of particular relevance to human–computer interaction (HCI) and the web are the personalization of links, both by annotation and computation, and overviews.

Many of these desired features are still missing from the mainstream web applications. In particular, the generally applicable personalization of links and content is still largely unachievable without specialist tools. In fact, some backsliding on this is evident, as the mid-1990s Mosaic browser supported the creation of annotations at both personal and group level and, more importantly, offered this service by default in a standard browser.* Mosaic development, however, was discontinued when Netscape became widespread. W3C's Annotea project† offered the same essential functionality but not within a standard browser and not without setting up effort from a technically-literate user—annotations are by no means a standard or easily accessible web service.

Creating personalized annotations is challenging enough, but the creation of one's own links over third-party data sources is essentially unknown. This is not because of any shortcomings in the technology, as in fact many solutions have been available within the research community for some time (see Section 25.3). The earliest plans for web browsers, dating back to 1991 (Cailliau and Ashman 1999), anticipated a "writeable web" where personalized links and annotations would be easily supported, yet this has not become mainstream web technology.

Another key aspect of personalized links which is often overlooked is that personal links are private links. If one creates a web page, complete with links, then those links are necessarily as available as the content. This is not always desirable, especially if links record one's private associations and thoughts, and the intellectual property represented by those associations has value. The technology for personalized links gives the user private links, over public documents, in much the same way that users' bookmarks are private. For privacy reasons alone, the technology for personalized links should be requisite for all mainstream browsers.

Other desired hypermedia features such as local overviews are provided not as a standard web service but as a site-specific courtesy page optionally supplied by site managers. Global overviews seem an increasingly distant feature, as the vast complexity of the web makes the usual, graph-based representations completely unworkable, both computationally and visually. The earlier paper noted that,

> Web browsers have no inherent way of presenting the structure and interrelationships of data of any sort. For example, there is no way to visualize even the simple interrelationships of web documents, such as "Where can I go from here?" or "Which documents point to this document?" The reader has no idea of the position of a given document within the corpora unless an author explicitly embeds such details. (Bieber et al. 1997)

So why is it that so little has seemingly been done to address these outstanding problems? It could be because the technology is too inaccessible to the nonspecialist user and that the obvious upfront costs of assimilating the technology outweigh the perceived benefits. It still seems to be true that,

> the use of Web technology is in part determined by its capabilities. Readers learn to make do with the available tools instead of demanding better tools, perhaps because they are not aware of how better tools might help them. (Bieber et al. 1997)

Only when we make the web more usable to the nonspecialist user will the use of all but the most basic tools become commonplace, resulting in higher productivity and better assimilation of information in the user.

25.2.2 Finding Things on the Web

25.2.2.1 Search and Query on the Web

One recent estimate has placed the size of the World Wide Web at around 24 billion pages.‡ With this wealth of information, the web would be untenable without mechanisms to assist navigation and file location. The most common web tool in use today is the search engine. To use a search engine, the user must submit a series of terms known as a query. This query in some way formulates and embodies what the user of the search system would like to retrieve information about. The usual output produced by the search engine is a small set of links to a selection of web documents extracted from the billions available. These web pages represent the search engine's response

* In 1994, the Mosaic browser was the "killer application" for the Internet, being the first major web browser, freely available from the National Center for Supercomputing Applications (NCSA). Its developers later spun off the Netscape company.

† http://www.w3.org/2001/Annotea/.

‡ http://www.worldwidewebsize.com/

to the user's information need, each document having been determined by the system as probably relevant to the query.

Presented with a set of results, the user selects a web page. If the document fails to meet the user's requirement, they return to the search engine for another result, or modify the query in light of previous results. This continues until the user's need is satisfied or the user's commitment to the search wanes (Harman 1992a).

From the perspective of a typical user, this has two main problem areas:

1. The confusion and uncertainty surrounding query formulation
2. The impenetrability of seemingly endless results

In Section 25.4, we discuss these obstacles and review a range of solutions.

25.2.2.2 Relevance

Although browsing and search-and-query are excellent tools for finding information on the web, they remain generic functions whose behavior is the same, regardless of the context. What remains to be considered now is how to further filter the mass of information on the web according to its relevance, not to a query, but to the individual user or to a community of users.

Information systems are often designed for a hypothetical "average" user. This "one-size-fits-all" approach ignores diversity in cultural and educational backgrounds, abilities, objectives, and aspirations. An information system with a single-user interface for all users is conceptually the same as a car manufacturer selling a car in only a single color—"any color so long as it's black."*

One solution is to build personalizable information systems, delivering content specific to requirements of different users. Without such systems, effective universal accessibility to information cannot be achieved. With it, every computer user and special-interest group will have personally tailored access to information sources. Personalization can take many forms, and it can involve the tailoring of hypertext links, the tailoring of presentation (often an accessibility issue), and the tailoring of content.

Content personalization has many benefits, for not only users, either as individuals or within a community, but also for the providers of information. For individuals, the tailoring of content can reflect a wide variety of requirements, but is always aimed at providing information most pertinent to that user in their current context. In e-Learning applications, for example, more challenging lessons are not served to the user until mastery of prerequisite material is achieved. In e-Commerce, a simple form of user consensus underlies a recommender system that personalizes suggestions for further purchases based on the current users' purchasing history similarity to that of other users.

For groups, personalization of content could help create communities of common interest among otherwise disparate users. Personalization can also support existing communities or social networks of users, by creating portals for accessing materials which are "personalized" to the interests of the group or community, either with a recommender systems approach or by sharing of explicit personal recommendations.

Personalization of information can also improve the whole computer use experience for the two major groups of under-represented users: (1) non-American/English cultural and language groups, and (2) people with special information needs. The web may have been "invented" by Europeans (Cailliau and Ashman 1999), but its subsequent development from 1993 was based on United States and has a distinctly American culture, including a predominance of the English language, linguistic form and alphabets.† However, there are now programs of research aiming to "localize" content, both in information systems and in the web, so that content can be delivered according to cultural, linguistic, and location-specific needs.‡ There are also devices which are now able to seek out location-specific information, as described in Section 25.8.

For information providers and publishers, personalization could create a delivery of information as suitable as possible to each individual user or special-interest group. In the normal publishing model, it is not economically feasible for publishers or information owners to publish information in a multitude of different forms, but with personalization and adaptation (see Section 25.6), it would be possible to do the personalization "on the fly" at no additional cost to the publishers, bringing enormous economic advantage to publishers using the technology.

This is essentially the same principle encountered in teaching—lectures present the information in a fairly general fashion, whereas tutorials or other small-group teaching give the students a chance to specify exactly what they need to know and to be given examples most helpful to them. In fact, the pressure on teaching resources has partly motivated adaptation and personalization in e-learning, and similarly it is the lack of resources preventing publishers from delivering their materials tailored to special-interest groups and to the individual. With e-learning, adaptation and personalization have arisen because teachers must offer personalized tutoring but are increasingly short of resources. With e-commerce, multicultural groups and special needs groups, adaptation and personalization can also be applied to offer an equally valuable specialization of information that is just not otherwise available.

25.2.3 User Interface Issues

Context played an important part in the personalization of content and links. However, context also needs to be

* Henry Ford is credited with saying "You can paint it any color, so long as it's black," but the Model T eventually appeared in many colors. Customer demand can motivate personalization.

† The American culture and set of assumptions is reflected in not only issues such as inadvertently rendering Arabic script backwards (left to right) because browsers render left to right by default, but also in American spelling of HTML tags, such as "color" and "gray."

‡ See, for example, http://www.cngl.ie/research.html.

considered in any environment, not just for personalization purposes.

25.2.3.1 Context of Use

When investigating the usability of web user interfaces, one must first consider the overriding issue of context. Context of use is seen as a critical constituent of usability, defined by ISO (1998) to "consist of the users, tasks and equipment (hardware, software and materials) and the physical and social environments in which a product is used." With respect to the web, the user, task, and environment issues are constantly evolving, leading to new challenges for HCI researchers and practitioners. For instance, the traditional environment for web users would have been the workplace, but statistics show that this is no longer the single situation for web use. Eighty-eight percent of U.K. web users access the Internet primarily from home.* Also, an increasing number of people now access the Internet through mobile devices (e.g., laptops, phones, personal digital assistants). In these situations, designers must consider a much wider range of physical environment factors, for instance, varying lighting, noise and thermal conditions, as well as other tasks that users may simultaneously carry out.

For example, there are widespread concerns regarding the use of Internet services within road-based vehicles (Lai et al. 2002; Burnett, Summerskill, and Porter 2004). Access to the web while driving may provide a range of tangible benefits to drivers, some driving related (e.g., prebooking a parking space, accessing real-time traffic information), and others oriented toward productivity or entertainment needs (e.g., viewing the latest information on stocks, downloading MP3 files). Traditional access to the web through desktop computers has utilized user-interface paradigms that are both highly visual and manual (e.g., scanning a page for a link and then using a mouse to point and then click on the link). Such activities are in clear conflict with the safety/time-critical task of driving which places heavy demands on the visual modality, while requiring continuous manual responses (e.g., turning the steering wheel). Clearly, designers need to establish fundamentally new interaction styles for use in a driving context of use (e.g., speech recognition, voice output, haptic interfaces). As part of this process, designers of interfaces for in-car Internet services must consider whether drivers should be given access to functionality while the vehicle is in motion. There is considerable ongoing research to provide guidance as to what constitutes an overly distracting interface (Lai et al. 2002).

25.2.3.2 Navigation Issues

At one time, it was asserted that the two biggest difficulties facing web users are download times and navigation (Nielson 2000; McCracken and Wolfe 2004). Download times are largely governed by the technical capabilities of Internet connections (which continue to increase as demand increase), together with clear design variables (e.g., the size of individual website pages). Navigation issues are considerably more complex. According to one diary-based study (Lazar et al. 2003), between one-third and one-half of time spent using a computer is unproductive, a situation predominately attributed to problems in web navigation.

In analyzing the navigation problem, we must first consider what is meant by the navigation task. A CHI workshop on this topic from 1997 (Jul and Furnas 1997) commented that a difficulty with research in the area was that authors tended to define navigation in varying ways. A broad view (adapted from the CHI workshop) is taken here, in which navigation can be said to involve the following:

- Planning "routes": When people navigate through space (whether real or virtual), they must first consider their overall strategy, that is, what methods will be appropriate in the current situation. For the web, a range of methods exist which aim to assist the user when deciding how to navigate across the web (e.g., search engines, directories, URLs) and/or within specific sites (e.g., site maps, navigation menus, links). Many people find it difficult to generate a suitable plan, for a range of reasons, either concerning basic cognitive limitations (such as remembering URLs), a lack of knowledge (choosing appropriate search terms, misunderstanding Boolean logic), or because methods are poorly implemented (e.g., confusing layouts for site maps).
- Following "routes": Once a high-level plan exists, people need to execute the subsequent point-by-point decisions, necessitating a virtual form of locomotion through the information space. In this stage, typical problems facing the web user often relate to the design of linking mechanisms between pages, for example, ambiguous link labeling, unclear graphics or icons, relevant information appearing offscreen, the need to visually scan large numbers of links, and so on.
- Orienting within the "space": The "where am I?" problem of the web is perhaps the one most discussed and researched (Otter and Johnson 2000). For optimum navigation performance and confidence, people need to have a sense of their current location in relation to their surroundings (e.g., their final destination, their start point, other key "landmarks," such as a home page). Orientation difficulties are often compounded on the web because users are "dropped" into a specific location that may not be the site designers' intended start point, through the use of search engines and bookmarks.
- Learning the "space": Repeated exposure to any large-scale environment (whether it be real or virtual) will lead to a deepening knowledge of objects within the space (e.g., particular pages), as well as an understanding of the various relationships between the objects (e.g., how pages follow each other, the overall structure of a site). These specific cases of

* Figures for July 2005 from www.statistics.gov.uk.

mental models are commonly known as cognitive maps, and facilitate fast and accurate navigation performance. Websites with poor differentiation (e.g., all pages appearing to be similar), low visual access (e.g., difficult to see where one can go next) and high path complexity (e.g., many links on a page) will all contribute to a poorly formed cognitive map (Kim and Hurtle 1995).

25.2.4 Summary

In the subsequent sections, we turn to some solutions for the problems outlined here, looking first at browsing and linking (Section 25.3), and then turning to searching and querying (Section 25.4), semantic web technologies (Section 25.5), personalizing the user experience (Section 25.6), communities and social web (Section 25.7), and the mobile web (Section 25.8).

25.3 BROWSING AND LINKING

The fundamental mechanism for viewing information on the web is by browsing implemented by hypermedia links.* However, this core capability still encounters technical problems which interrupt the user's browsing, such as difficulties in finding relevant material and limitations in the way relevant materials can be presented.

In this section, we look at some solutions, including automatic management of broken links, the easy personalization of links and how links can enable different perspectives on the same data.

25.3.1 Broken and Misdirected Links

Broken links, generally the well-known "error 404," remain an irritation for users of the web (Nielsen 1998). They are perceived to be "disruptive to the user experience" and a sign of an "unprofessional" website (Wikipedia 2010). However, broken links have frustrated users not only of the web but of earlier hypertext systems, and some of the first work on link integrity motivated the open hypermedia systems' principle of externalizing links, rather than embedding them into the data (Davis 1995).

Externalizing links implies that links are stored separately from the data being linked, so that reconciliation of the link to its referent was required, usually immediately before use, as a "late binding" of links (Brailsford 1999). However, any changes in the data meant that links could be either displaced, pointing to the wrong place in a document (part-of-file error, Davis 1998), or completely invalidated, with no document now known for the link to apply to (a whole-file error, Davis 1998).

HyperText Markup Language (HTML) links suffer from a similar problem, despite being embedded in the data because it is not only the source of the link (the "from" part of it) that must be reconciled to its referent, but also the destination (the "to" part). It is in the latter that HTML links are frequently wrong, with an estimated 23% of web links being broken within a year (Lawrence et al. 2001).

The solutions to broken links can be characterized as being *preventative* (creating infrastructure or procedures that avoid broken links), *corrective* (correcting broken links where they are discovered) or *adaptive* (never storing actual links, only instructions for making them as required) (Ashman 2000).

From the user's point of view, it might initially seem that preventative solutions are ideal because the irritation of broken or misdirected links will never happen. However, many of the preventative measures can only guarantee accurate links within a limited scope, and changes outside that scope (such as an entire domain name change) can still result in broken links. Also, they can be functionally limited; for example, it may be impossible to guarantee link integrity into information that is not part of the same preventative scheme.

Corrective solutions tend to be more robust, as they assume breakage will occur and have procedures in place to correct links, where possible, or to otherwise deal with them. These procedures are sometimes computations which aim to discover the new location for the linked document. These often function as mass correction procedures, taking place at intervals, which detect broken links and attempt to correct them, discard them, or at least to notify the page owner of the problem. From the everyday user's point of view, this is a reasonable form of solution, requiring little or no effort on their part, with breakages often not encountered by the user. However, it is still possible that the user will discover a broken link, increasingly so if it is some time since the most recent correction.

Also, the corrective approach may discard unfixable links that the user has previously required. This leaves the user with the knowledge that a link that was once present is now gone and seemingly unrecoverable. Perhaps a more user-friendly solution to irretrievably broken links are the so-called soft 404s (Bar-Yossef et al. 2004)—when pages go missing, those pages are replaced by human-readable error messages which essentially assume the identity of the missing page. They frequently offer the user the option of a search of the site, or perhaps redirect the user to a new location. It is estimated that 25% or more of all dead links are these soft 404s (Bar-Yossef et al. 2004).

The correction of links is very much a research problem still, with much effort expended into double-guessing what were the original link creator's intentions in making the link. However, if the link was originally created by a computation, then the correction often amounts to nothing more than executing the computation again. If for example, the link computation was to "link every instance of a person's name to their home page," then if the name is moved within various pages, or appears or disappears, the links can easily be reinstated to their correct positions.

* The very names of the two most important elements of the Web infrastructure, *hypertext* transfer protocol (http) and HTML indicate this clearly. The PageRank algorithm is based on link analysis, showing that links are an essential component in search engine indices as well.

The adaptive approach assumes that all data is subject to change, as do the corrective solutions. Instead of having procedures for correction in place, it guarantees correct links by never having links in storage. The instructions to create links are stored, and links are created as required from them. This dynamic approach was trialed in experimental systems, which created links either on user demand (Davis, Knight, and Hall 1994) or as a background process (Verbyla and Ashman 1994).

The adaptive approach is now evident in everyday web usage, for example, with the use of scripts to create and serve web pages dynamically, often as a result of a database query, where links are calculated and inserted at the time of serving. However, it cannot assist with links created and maintained by other users, and neither can the preventative or corrective approaches.

In the end, the major obstacle to link integrity in the web is its anarchic nature. There is no central authority which can impose robust linking practice on the mass of users, indeed the failure of the error-tolerant naming solutions such as uniform resource names (URNs) to capture the imagination shows that it is not even possible to tempt users into good linking practices, let alone force them.* Even a direct plea from one of the joint creators of the web has been unable to achieve link robustness (Berners-Lee 1998). As long as users continue to create links without troubling to maintain them, other users will eventually encounter them as broken links. There are however numerous solutions that, combined, will help keep the problem at bay, so that users may experience almost 404-free browsing.

25.3.2 Personalizing Links

Many users at some stage want to create their own links or annotations, generally to record their own associations between data, or to ease everyday information access. In fact, easing information access is an obvious but frequently overlooked purpose for links—links function as a form of "user pull" of information, hiding the information while still making its presence known, but providing that information on request with the minimum of user effort.

Users have different needs, and an author of web pages cannot anticipate all such requirements, let alone provide them. Even if all the potentially useful links were provided, not only would users disagree on the value of the links, but the interface and performance of the browser would suffer. For example, not every user wants a dictionary link, which could give a basic definition of any word selected by the users. However, non-native speakers of a language could find such a link invaluable. Glossary links are essential to a reader not familiar with technical terms, but become intrusive to seasoned readers. In each case, the users want to be able to "switch on or off" links to reflect their own needs.

This is easy with current research technology. Even as far back as 1992 (Davis et al. 1992), the technology to provide links over data not owned by the user was available. It was even quite simple to create a form of computed link, for example to link every occurrence of a name with a bibliography. Within a short time, it even became feasible not just to exploit link computation to automatically create one's own links, but to even create one's own link computation specifications, so that exactly the right computation, pointing into the right data collections, could be easily linked at the user's wish (Verbyla and Ashman 1994)—an early precursor of the web services principle so widespread today.

The technology that supports personalization of links has not yet propagated into mainstream web browsers. Yet the different solutions have been trialed in a web context; for example, the Distributed Link Service enabled individuals to make their own private link sets or to contribute to their group's collective link sets (Carr et al. 1995). Even the creation of one's own link computation specifications was trialed in a web environment (Cawley et al. 1995).

It is possible that a growing awareness for the need for privacy in online actions may yet motivate users to demand an easy-to-use personalized link facility. Even personalized annotations are a minority facility, only feasible for the reasonably technically literate user. Being able to record one's personalized links enables a user to record his or her private associations and collections, often representing original intellectual ideas or commercially valuable information, without advertising it to all and sundry. As more and more of each user's online interactions and transactions are exposed to outside scrutiny, authorized or otherwise, the provision of a feature with the fortunate side-effect of offering private means for recording ideas ought to become a priority for future web browser development.

We discuss further in Section 25.6 on how the personalization of links is increasingly feasible in the adaptive web.

25.3.3 Transclusion

Transclusion has always been a key component of the vision of hypermedia, ever since its earliest days (Nelson 1965). The term was originally used to denote the inclusion, by referential addressing, of part of one document within another; although its usage has now expanded to encompass the presentation of data in a context other than the one originally intended. With one important exception, transclusion was not until relatively recently widely implemented on the web. That exception is the HTML <IMG> tag—which transcludes an image into the context of the document. The image itself is neither embedded within the document nor copied—it is transcluded. However, in recent years, this concept has generated a great deal of interest, and features in a number of areas of web technology, including data interchange (Wilde and Lowe 2002), online publishing (Krottmaier 2002), multimedia (Kolbitsch 2005), and education (Moore, Stepp, and Diday 2001). Most importantly, it is now implemented in Media Wiki, and as such is an integral part of Wikipedia.†

* As evidenced by the lack of recent activity on URNs at the World Wide Web Consortium's *Naming and Addressing* page at http://www.w3.org/Addressing/.

† http://en.wikipedia.org/wiki/Wikipedia:Transclusion.

Although transclusion is a seemingly simple idea, it has been pointed out by Goulding, Brailsford, and Ashman (2010) that there are actually two quite distinct aspects to transclusion, called *instance transclusion* and *identity transclusion*, which are used for very different purposes. Identity transclusion is used to represent a unique entity, such as an image, in multiple contexts. Therefore, a single image may be transcluded onto many different web pages. Instance transclusion is closer to the concept of instantiation that is familiar to object-oriented programmers—in that different instances of an entity may be represented in different contexts. For example, in a system that models the actors that have played "James Bond," each transclusion represents the same fictional secret agent, but each instance is completely distinct from the others: Sean Connery's Bond is very much a different individual to Roger Moore's, even though they are both based on the creation of "Ian Fleming," a property they both inherit from the original entity. There is a distinction between the two uses of the word transclusion—an instance transclusion does not share all its relations across all of its contexts, whereas an identity transclusion does because for the latter, only one entity is being modeled. This is important, and a lack of appreciation of this has in the past led to confusion among the designers of different transclusion implementations.

25.4 SEARCHING AND QUERYING

Browsing, enabled by hypermedia links, was the first technology for accessing information on the web. However, the enormous success of the web and its rapid uptake by millions of users rapidly rendered browsing alone a manifestly inadequate tool for information access. Searching has now become a major, perhaps *the* major, means of locating information on the web.*

However, accessing information using search engines presents difficulties. First, the user faces the problem of creating an accurate description of his or her requirement. Second, the user must make sense of the results that the search engine produces. Solutions to these difficulties are discussed in this section.

25.4.1 Query Formulation

It is accepted that the typical user will experience difficulties when attempting to formulate an effective query. Three significant factors stand out:

1. *Low user commitment.* Users are reluctant to provide information beyond the bare minimum. In fact, what emerges is that search engine use is characterized by short queries and limited interaction coupled with unreasonably high expectations (Jansen, Spink, and Saracevic 2000; Rolker and Kramer 1999; Kobayashi and Takeda 2000):

> Real people in the real world, doing real information seeking and in a hurry, use Web search engines and give 2-word queries to be run against billions of Web pages. We expect, and get, sub-second response time and we complain when there are no relevant Web pages in the top 10 presented to us. (Browne and Smeaton 2004)

   Users, it would appear, are chary of commitment. They expect very-high quality results from each and every search instance rather than subscribing to the notion of search as an iterative process.

2. *Uncertain information needs.* Users often have an incomplete understanding of their information need, and their initial need will frequently mature during, and in direct response to, the process of searching (Lancaster 1968):

> Searchers normally start out with an unrefined or vague information need which becomes more sharply focused as their search continues and exposure to information changes their information need. (Browne and Smeaton 2004)

   This initial lack of clarity with regard to the object of the search readily translates into imprecise query terms, which in turn begets irrelevant and disappointing results. Some users quit the searching process at a very early stage, confounded by this apparent "failure."

3. *Difficulties in expressing their need.* Users may not know the correct syntax to frame their queries, or the commands to interact with the search engine. They may know in general terms what web pages they wish to retrieve, but struggle to find the query terms most likely to identify them:

> Except in special circumstances, it is difficult for a user to ask an information retrieval system for what they want, because the user does not, in general, know what is available and does not know from what it has to be differentiated. (Card, Robertson, and Mackinlay 1991)

   This is not surprising, as the formulation of a "successful" query requires some awareness of information retrieval theory, relatively uncommon among typical users. Some of this theory can be guessed by observant users (who might notice, for instance, that query terms which frequently occur in web pages produce poor results), but the remaining users must persevere with an environment in which much remains unsaid or unknown, never knowing why their search failed, or indeed why it succeeded.

To counter some of the problems mentioned above, researchers working with search engines have developed

* Four of the top 10 websites globally are search engines; see http://www.alexa.com/topsites.

strategies designed to improve the quality of a submitted query. One of these strategies is relevance feedback (RF):

1. The user submits an initial query and the search engine serves results.
2. The user then identifies relevant and non-relevant web pages using associated checkboxes, clickable links, radio buttons, and so on. This action supplies the search engine with feedback.
3. The search engine then automatically modifies the original query in response to the feedback. This may involve adding search terms to the query, known as query expansion. It may also involve reweighting of the query, where information in the relevant and non-relevant set of documents is used to modify the importance of various query terms.
4. The modified query is run by the search engine and a new set of search results is shown to the user.
5. This process continues until the user's information need is satisfied.

This technique is particularly successful, and it has been repeatedly demonstrated that RF can improve the performance of a search engine at comparatively little cost to the user or the system (Ruthven and Lalmas 2003; Harman 1992b; although see Spink, Jansen, and Ozmultu (2000), for contrast). For example, Koenemann (1996) noted that the

> … availability and use of relevance feedback increased retrieval effectiveness; and increased opportunity for user interaction with and control of relevance feedback made the interactions more efficient and usable while maintaining or increasing effectiveness.

However, it has also been found that in order for RF to be effective, the user must be offered a meaningful dialog for participation. Ruthven conducted a series of experiments examining the performance of user-supplied feedback measured against an automated equivalent. Commenting on the relatively low performance of the users, he identified a failure in the infrastructure supporting the user's search:

> … simple term presentation interfaces are not sufficient in providing sufficient support and context to allow good query expansion decisions. Interfaces must support the identification of relationships between relevant material and suggested expansion terms and should support the development of good expansion strategies by the searcher. (Ruthven 2003)

In summary, many search engine users find the formulation of an effective query difficult. RF offers an effective solution, providing

- The users are willing to commit to several search iterations.
- A suitable and useable feedback interface is implemented.

25.4.2 Results List

The results generated by a web search engine will frequently not satisfy the user. Sometimes, this negative result will occur because the search engine cannot find any documents that match the user's information need. However, it is much more likely to happen because the user has submitted a very broad query, resulting in too many documents. This difficulty has been identified as the "abundance problem," occurring when "the number of pages that could reasonably be returned as relevant is far too large for a human user to digest" (Kleinberg 1999).

Many solutions to this challenge have been suggested, but three interesting approaches are as follows: (1) community-based ranking algorithms; (2) improved visual interfaces; and (3) document clustering. We now examine each approach in turn.

25.4.2.1 Community-Based Ranking Algorithms

A search engine aims to rank a set of web pages in order of the likelihood that they will be relevant to the user's information need, with the document most likely to be relevant appearing first. This likelihood of relevance is usually calculated using a statistical measure related to the occurrence of the query terms in the documents concerned. Known as term frequency, this measurement is traditionally normalized with respect to document length and multiplied by a measure reflecting the specificity of each term within the document collection (Sparck Jones 1972; Aizawa 2003; Salton, Yang, and Yu 1975).

Document rankings dependent upon term frequency represent a purely arithmetical evaluation of the web pages concerned. This evaluation can (and does) provide a useful approximation of the likelihood of relevance to the user, but is by no means an authoritative measure. The underlying assumption—that term frequency translates directly into relevance—is exactly that: an assumption. There is no guarantee that a web page that contains a high frequency of the query terms will be any more relevant than a second page containing a lower frequency of those same terms. The latter may have fewer of the important keywords, but might be far superior in other, less quantifiable respects (e.g., it may be more concise, better illustrated, superior in style, easier to read, more complete in its references, etc.).

One solution to this problem has been to supplement the rudimentary rankings that can be constructed through statistical observations with more sophisticated sources of information. This has led to the development of a general class of ranking algorithms which implement citation-based metrics for relevance scoring (Garfield 1972; Pinski and Narin 1976). In these algorithms, the relative importance of each web page is a function of the number of other web pages that link to it (Brin and Page 1998). As Kleinberg (1999) observed, these "in-links … encode a considerable amount of latent human judgment." Accordingly, a web page that is referenced by a good proportion of its peers is a natural candidate for high ranking.

25.4.2.2 Improved Visual Interfaces

Hearst (1997) has observed that "long lists littered with unwanted irrelevant material" represent an unwieldy and nonintuitive method for delivering search results to the user.

Rather than expending resources developing more sophisticated ranking algorithms, Hearst asserted that the answer to this problem lay in shifting

> … the user's mental load from slower, thought intensive processes such as reading to faster, perceptual processes such as pattern recognition. It is easier, for example, to compare bars in a graph than numbers in a list. Color is very useful for helping people quickly select one particular word or object from a sea of others.

She went on to speculate that in the near future, advanced search interfaces may abandon the 2D page metaphor altogether, adopting "alternatives that allow users to see information on the Web from several perspectives simultaneously." A software implementation based on this very idea, known as the information visualizer (Card, Robertson, and Mackinlay 1991), has proved surprisingly powerful—in one experiment an organizational hierarchy requiring 80 printed pages was displayed on just one 3D screen (Robertson, Mackinlay, and Card 1991). It seems clear that a visual tool for searching the web which helps the user to "see" a set of search results rather than just "read" them would have considerable utility.

25.4.2.3 Document Clustering and Click Data as Relevance Feedback

Another way of simplifying a set of search results is to generalize. The process of generalizing a set of results begins with identifying particular commonalities shared by some members of that set (e.g., use or nonuse of certain terms, subject matter, file type, etc.). Web pages determined to be "similar" in some way are then grouped together under a single category or heading, and the user is subsequently presented with several coherent clusters of web pages rather than the traditional list. Provided the number of clusters is relatively low, this technique quickly reduces the cognitive load of studying the results, allowing a user to "skim" rather than to read.

There are numerous clustering algorithms for aggregating like documents in this way. While search engines require a function that indicates the relevance of documents to the search term, clustering algorithms generally require a similarity function that indicate the mutual relevance of documents to each other.

The in-links of a web page might be used recognized by Brin and Page (1998) and recognized by Kleinberg (1999) as indicators of latent document human judgment, but there is another, more dynamic and far more populous dataset of implicit human judgment. This alternative form of implicit human judgment is clickthrough data, and the subset of clickthrough data which makes up coselection data.

Clickthrough data (or just click data) is the implicit RF provided by users when they select a result from the results list of a search. Click data implies a measure of perceived relevance of selected URL to the search term. Coselection occurs where the user makes two or more clicks from a set of search results, implying in addition that the selected URLS are mutually relevant, so that coselections are a form of RF from URL to URL. This means that coselection data can be used as a similarity function for clustering URLs.

Click data has been considered as a form of relevance ranking, and while some research show they are not entirely reliable, at least over traditional, text-based search, other research show that they improve the relevance of results from image searches (Ashman et al. 2009). Furthermore, coselection data can further improve search results by being able to cluster search results into sense-singular aggregations; that is, it can be used to disambiguate a search term.

An example of coselection use was applied to the problem of ambiguity in query-based search (Truran, Goulding, and Ashman 2005). Lexical ambiguity causes considerable problems, complicating the already difficult task of establishing what a user is actually looking for, especially with the tendency to use few words in any query. An analysis of the query log of a very-large online encyclopedia recently found that 1 in 20 queries were largely wasted simply because a user chooses ambiguous query terms (Wen, Nie, and Zhang 2001). Truran, Goulding, and Ashman (2005) showed that clustering with coselections as a similarity function was capable of autocategorizing a set of search results into believable sense categories without any semantic analysis of the web pages concerned. Neither was an external knowledge source, such as a dictionary or expert system used. Instead, sense discrimination was the quiet background product of user consensus—the system studied and learned from its clientele, utilizing what Fitzpatrick and Dent (1997) termed the "information consuming habits" of its users to create a human-intuitive overview of the distinguishable semantics of the query, like documents grouped with like (Michalski, Stepp, and Diday 1983).

25.4.3 Summary

Users of a search engine often become impatient with the number of results returned when a query is submitted, and rarely proceed beyond the first page of suggestions (Harman 1992a). To ensure the most relevant documents appear on the first page, more sophisticated ranking algorithms have been developed which exploit the inherently self-referential nature of the web.

However, even with these improvements, search engines are still serving large chunks of unrefined information to their users. This seems likely to change soon. Search engines will almost certainly begin to abstract categories and significant groupings from any given set of results automatically, and visual interfaces that simplify the user's task seem probable.

25.5 SEMANTIC WEB

The rapid rise in the usage and sophistication of web content and services has led to the desire to make such content and services more discoverable and usable by applications at runtime. A key problem in meeting this desire is how to expose the semantics (meaning) of the web content or web service interfaces in a manner that is widely interpretable by applications. Significant progress has been made in addressing this problem over the last number of years, with proposals to express the semantics of information and web service interfaces using languages based on the eXtensible Markup Language (XML). This section briefly introduces the opportunity that the vision encapsulates, the reality and progress that has been made with the underlying technologies, and argues that to achieve the vision, more focus is required with respect to human interaction issues.

25.5.1 Vision and Opportunity

In their seminal article in 2001, Berners-Lee, Hendler, and Lassila (2001) captured the vision of the semantic web and exposed to a wider audience the research that had been ongoing into semantic-based technologies over the previous years, a momentum which has continued over the past decade. The case study in the article involved the setting up by a pair of working children of a series of therapist appointments for an elderly parent at times that would suit the children's calendars. It envisioned how this would be achieved with little interaction and fuss through a combination of intelligent applications working in conjunction with semantically exposed web content and services.

At the core of the approach is the exposition of metadata related to a web resource or web service that refers to a semantic model that can be processed by an intelligent application to find out more about the metadata and how it relates to other concepts or models. For the semantic model, although several alternatives have been proffered (e.g., Web Service Modeling Ontology, XML Topic Maps [XTM 2001]), by far the most researched, advocated, and used is the Resource Description Framework (RDF)-based family of standards (Resource Description Framework [RDF], RDF Schema [RDFS], Web Ontology Language [OWL] [W3C Semantic Web Standards 2010]) that represent graphs of semantic information as triples. Progressively more formal semantics are attached to the nodes and associations within the graphs as one moves from the RDF representation, through RDFS, to OWL. So, for example, an association between two nodes can be typed as a "subclass" within all representations, but OWL gives the ability to declare an association as "symmetric." These semantic model representations are accompanied by a range of reasoners, which have been designed to support applications in interpreting the represented models consistently, independently of who produced the model or the type of reasoner used. A reasoner is defined as a system that allows one to infer implicitly represented knowledge from the knowledge that is explicitly expressed (Baader et al. 2007). So, for example, if in a model we might declare the association "friend_of" as symmetric, and we explicitly associate Bob as "friend_of" Alice, then a reasoner will infer that Alice is a "friend_of" Bob implicitly, even if not explicitly declared. There are a wide range of OWL reasoners that have been developed. Examples include KAON2 (Hustadt, Motik, and Sattler 2004), Pellet (Sirin et al. 2007), F-OWL (Zhou et al. 2004), and OWLPrime (Wu et al. 2008). Each implementation has its own functional and nonfunctional tradeoffs, including semantic expressiveness, computational complexity, memory footprint, and processor load. Although applications can embed these reasoners directly and manipulate the semantic models using XML technologies, typically manipulation of the semantic models and access to reasoner capabilities by applications has been facilitated through an API such as Jena (Carroll et al. 2004).

There is no shortage of case studies and use cases that describe the opportunity and breadth of the application of semantic technologies (W3C Examples 2010), but broadly they fall into three categories: (1) applications that enable better search/information retrieval; (2) those that enable better personalization; and (3) those that enable easier information integration.

25.5.2 Reality and Progress

Despite promising results from the various case studies and use cases, the semantic web and related technologies has yet to become mainstream. In their 2006 article, Shadbolt, Berners-Lee, and Hall (2006) examined the status of the semantic web and proposed some reasons for the lack of viral uptake of the approach. Their conclusion was that despite clear evidence of maturity and utility of the approach and technologies, the semantic web will not become widespread unless a point is reached where "serendipitous reuse of data, your own and others', becomes possible." To this end, they advocated the widespread publication of data using RDF, and promotion of the use of emerging "lightweight" semantic models.

Today there is evidence that progress is being made in these directions. The "linked open data" initiative was launched in 2007 by W3C, with the intention of publishing a wide range of publically accessible information as RDF triples, and interlinking them (W3C Linked Data 2010). According to the W3C in April 2010, "collectively, the data sets consist of over 13.1 billion RDF triples, which are interlinked by around 142 million RDF links." Data on the linked open data cloud spans a diverse range of topics, data sets exist which relate to music, statistical data, movies, and much more. As for lightweight semantic models usage, there have been some successes in popular usage of a number of these. For example, the friend of a friend vocabulary describing persons, their activities, and their relations to other people and objects has become popular. Another example is the Semantically-Interlinked Online Communities vocabulary, which is increasingly popular for interconnecting social media such as blogs, forums, and mailing lists to each other.

Most significant however, is the momentum that is gaining behind the embedding of RDF in eXtensible HyperText Markup Language (XHTML) documents, through "RDF—in—attributes (RDFa)." RDFa is a W3C Recommendation (W3C RDFa) that adds a set of attribute level extensions to XHTML for embedding RDF-based metadata within web documents. Support for this standard has already been announced by Yahoo, Google, Facebook, and most recently Drupal. Opening up the option of referencing RDF models in existing web pages will naturally help in the mainstreaming of semantic technologies within the existing web community.

25.5.3 Human Interaction

Although the momentum is encouraging, it is clear that the mainstreaming of the semantic web approach will falter unless more focus is placed on how to widen beyond knowledge engineers, the creation, maintenance, and mapping of the underlying semantic models and their referencing. Typically tools for working with semantic models have either taken an approach where the semantic model is presented in a tree-like structure (e.g., Protégé 2010) or as a graph, either using simple visualization (e.g., OntoViz 2010) or more sophisticated presentations (e.g., OntoSphere [Bosca, Bomino, and Pellegrino 2005]). Although both types of tools have been useful for knowledge engineers, up until a few years ago very few user trials had been undertaken, or very little consideration had been given to usability issues (Jameson 2006). A notable exception to this is the cognitive support underpinning and the usability evaluations undertaken as part of the development of the CogZ tool for knowledge engineers (Falconer and Storey 2007). However, over the last number of years, the research community has started to focus on the challenges involved in semantic model creation and management by people who are not knowledge engineers. Natural language interfaces have been developed to enable domain experts to get involved in the development of a semantic model (Dimitrova et al. 2008). Techniques have been developed to monitor and analyze a user's interaction with files on his or her computer and the user's interaction on the web, and allow the user to develop and maintain a semantic model of personal interests based on the information gathered, with a view to supporting more relevant and personalized information retrieval (Groza et al. 2007). Gaming approaches have been experimented with in order to engage ordinary users in semantic model creation and maintenance (Siopaes and Hepp 2008). An add-on to the Firefox web browser is being evaluated to see if ordinary web users will periodically engage in the mapping between semantic models, in this case a model representing RSS feeds mapping to a model representing the user's personal interests (Conroy et al. 2009).

Although such research initiatives are laudable, it is clear that significant effort is still required in tackling the challenges of human interaction by ordinary web users with semantic models, coupled with the continued progress in mainstream web community and tool support for RDF usage, before the promise of the semantic web vision will be fully realized.

25.6 PERSONALIZING THE USER EXPERIENCE

Web users regularly have difficulty finding exactly appropriate content for their needs. Yet, when one considers that users' searches (on Google or Bing), on average, only contain two or three keywords in their queries, the level of success of these search engines is relatively impressive. So what improvements can we make to both enhance the retrieval of content so that it is more suited to the user-intended task and circumstances? How can we enhance the presentation of the web content so that it can be more easily comprehended?

From the other perspective, content providers have traditionally adopted a "one-size-fits-all," which attempts to provide a "generalized view" of the content subject. Unfortunately, this can result in content which is not particularly suited to any one user group. Thus, how can we maximize the usefulness of the content provider's information so that it can be presented to the user in the most effective and relevant manner? How can we help content providers maintain content, which is intended for users with differing interests, prior knowledge, and goals? In this section, we will examine approaches of personalization, and community support that are becoming widely used to address these issues.

Web personalization attempts to dynamically present the web information in a form most easily utilized by a particular user (either based on prior knowledge of that user or explicit information provided by that user). Personalization empowers users by organizing or presenting content in ways which are more suited to that user's particular needs or circumstances. Personalization enables content (web) providers to focus on individual users' needs while maximizing the reuse of existing content.

Although personalization and general web portals have quite distinct approaches to web design, they are all aimed at producing an end user experience that is apparently uniquely appropriate for each individual. This is what might be called "my web." Personalization is where the contents of websites are presented (either transparently, or under user control), so that the material is appropriate for the needs and requirements of the individual. Personalization can be embedded within a website interface or offered through a web portal. Personalization can be achieved with a broad range of techniques of varying degrees of sophistication, from something as simple as a user-selectable color scheme through to an adaptive content management system based on a comprehensive user model. Examples of simple forms of personalization are commonly used for e-commerce websites; for example, recommending certain content or products, suggesting "more appropriate" products or services based on a user's location or origin.

Personalization can also be seen in web search portals or services. Web search services, which know a user's previous searches and identify that user's location/context, can dynamically (and transparently) influence the results retrieved so that more relevant content, sensitive to the context of that particular user, are presented. Search engines such as Google adopt some of these practices.

More sophisticated personalization is increasingly being seen in web application portals such as e-learning portals, tourist advisory portals, and information sites. This personalization can be at the level of individuals, communities, or organizations. Where personalization is operating at the level of community, there is an opportunity for the adapted experience to be shared by a community. The "community-based personalization" is becoming more important as the growth in user collaboration and instances of web communities become more prevalent.

Another way of understanding personalization is to think of it as involving three logical steps: (1) *adaptive retrieval* where the querying of the content is enhanced by knowing more about the users intention, goal, needs, or context; (2) *intelligent content reasoning* where the association of ideas/concepts in the subject area can be reasoned about and the related or relevant content identified; and (3) *adaptive content composition* where the content is actually assembled using smaller units of content to generate a webpage or a website where aspects of contents navigation, presentation, and interaction are all modified for the benefit of that particular user.

25.6.1 Personalization

Modern websites frequently consist of content dynamically drawn from back end databases and information sources. Thus the content displayed by a website is often dynamically retrieved and displayed. The question arises then, why retrieve the exact same information, composed the same way, for all users when we know users differ enormously? Using personalization, a website can prove to be more "motivating" to use and more "encouraging" for users to revisit.

Personalization began with simple forms of adaptation of web pages; for example, by displaying the actual user's name on the top of the web page and welcoming him or her back, or by providing a panel of suggested content in the home page which was potentially of specific interest to that user based on previous history using the web page. One of the longest established examples of this is http://www.amazon.com, which stores information about the customer's interests, gleaned from various sources, to generate a personalized home page and suggest items that are likely to be of interest. Adaptive hypermedia, now typically referred to as adaptive web, is an academic discipline that is dedicated to bringing personalization to the web (Brusilovsky 2007). The principal application areas of Adaptive Web systems have traditionally been in information kiosk-style systems, educational systems, and tourism. However, personalization is now emerging in areas as diverse as news access and publishing (Billsus and Pazzani 2007) to healthcare (Cawsey Grasso, and Paris 2007) and even within museum information systems (Brusilovsky and Maybury 2002).

Educational web-based systems in particular have progressed the use of personalization mainly because their aims were focused on making it easy for the users/learners to comprehend the content and be as contextually relevant as possible to the user (Conlan and Wade 2002). For example, traditional (face to face) education is naturally very adaptive. A student who does not understand a question will ask the teacher for an explanation. If the student does not understand the answer, then the teacher explains it in different terms—maybe simplifying, maybe using a more appropriate example, maybe using different modalities (e.g., pictures, video, etc.). Exactly how the teacher explains it depends on the needs and competences of the student, so the teacher adapts the content (in this case the explanation) to the individual student. The ultimate goal of adaptive educational systems is to provide this capability to web-based learning. So far, most such systems are mainly experimental, but they are important because the majority of adaptive web research has been applied in this area.

25.6.1.2 Adaptive to the User's Need or Adaptable by the User

A web system is said to be *adaptive* if it can perceive the needs of a particular user, and hence is usually transparent to the user (i.e., a user may not be aware of the personalization that is actually happening on her or his behalf). An *adaptable* web system relies on the user explicitly giving the system personal information and requires explicit intervention by the user to initiate the adaptation. Adaptive web systems base their content delivery on what the system perceives to be a user's need. Adaptable systems, however, use information obtained directly from the user—which in most cases will represent that user's desire. Because need and desire are not necessarily the same thing, there is potential for a conflict of interests. When considering adaptive systems, the underlying assumption is that the system knows better than the user what is most appropriate. Although this sounds disempowering (and if implemented badly it can be), there are many circumstances where this view is justified—particularly if the user does not understand the ramifications of a particular choice at a decision point.

For example, in educational systems learners may not always have all of the facts or the pedagogic background necessary to take control of their own teaching regime. In "real-life" education, this is why we have teachers rather than just resources. Implementing this "system knows best" paradigm without due care creates the potential for serious problems in an adaptive system. It is quite likely to result in frustration or anger if a user realizes that the system is going against his or her desires, or if the system's assumption of need is incorrect—particularly a problem with a poorly thought out or in appropriate user model. Well-designed adaptive systems do not take control away from the user, rather they provide suggestions (albeit sometimes strong ones) as to the most appropriate path. This is then a user interface issue, and it may take the form of reordering content or suggesting what content is considered most appropriate (e.g., a common mechanism is to change link color).

When we consider that many users query the web to perform different kinds of "informal learning," for example, to find out a fact or detail, to get an explanation of a concept or process, to inform themselves of information valuable to them, we can realize that personalization of both the retrieval and presentation of web information can greatly benefit the user.

25.6.1.3 Adaptive Web—Architectures and Models of Adaptation

The first generation of adaptive web systems tended to be monolithic systems in which the actual adaptation/adaptive behavior was embedded in the actual content itself (typically as HTML, scripted rules or some form of intelligent reasoning). Such adaptive systems tended to work for specific content as the rules were embedded in and written for that content. Developing another adaptive website usually entailed developing an entirely new adaptive system (and embedding new rules in the new content). Thus the effort of development was similar each time, with only the "know-how" being used across different developments. Authors of such adaptive websites needed to be proficient programmers and the adaptive websites tended to be very application-specific, such as AHA (version 1), ELM-ART, and Interbook.

The second-generation adaptive web architectures made a deliberate separation between the reasoning needed to decide the adaptive behavior/presentation and the actual content. This recognizes that there needed to be multiple information sources to decide the appropriate adaptive behavior and rendering, also that web content needed associated metadata which described the subject of the content, the form of the content, and so on. The rules about how this information could be used to generate a navigation or rendering of the content needed contained in other models. This approach was called the "multimodel approach" as it typically entailed a minimum of three models: (1) a user model capable of representing instantiations of different users; (2) a content model which was a metadata description of the content pages that were to be adaptively navigated or rendered; and (3) a narrative model which contained the rules that when executed generated new "navigations" over different subjects (which the content entailed) and different renderings (Conlan and Wade 2002). The narrative was somewhat independent of the content in that it reasoned about the subject or kind of content to be adaptively navigated rather than reasoning directly about the instances of those subjects (i.e., about the specific pages themselves). Thus the narrative generated a "navigation" across subjects which was then mapped down to specific web pages to be retrieved. The part of the adaptive system (typically called an adaptive engine or adaptive player) used this navigation across the subject(s) to choose appropriate web page instances and renderings. This enabled the adaptive engine to be independent of the actual content and so greatly reduced the cost of development of new adaptive websites or portals. Moreover, authoring an adaptive website or portal, only required the authoring of the user model, metadata models, and narrative models. Thus a programmer was no longer required to author new sites. Examples of such adaptive systems include APeLS (Conlan and Wade 2002) and AHA (De Bra, Smits, and Stash 2006).

The current generation of adaptive web systems has expanded further on the multimodel approach and includes the runtime reconciliation of multiple kinds of models, such as user models, context models, narrative models, environment models, and web service models to generate unique navigations and renderings of webpages. They are typically portal-based and examples include GRAPPLE (De Bra, Smits, and Stash 2006), Knowledge Sea (Ahn, Farzan, and Brusilovsky 2006), and AE (O'Keeffe and Wade 2009). Authoring tools for such systems are intended for subject experts rather than technical programmers (i.e., users who know about the subject area of the website and can graphically author the models). Such authoring systems hide the complexity of the inference rule specification by offering graphical ways in which to indicate where adaptation should take place and what kind of information should be used to determine that adaptation. We call such adaptive systems "multidimensional" in that they can reconcile multiple dimensions of a user or context on which to base the adaptation. Examples of different dimensions that adaptive systems can adapt upon include content descriptions, subject areas, service descriptions, context (of use), delivery environment, and intended user process or activity. It is not the case that models for each of these dimensions is required for each adaptive system, but rather for different adaptive systems or systems which are intended to deliver adaptation for particular purposes or situations, tend to draw on at least three or more of these dimensions (Wade 2009).

25.6.1.4 Means of Adapting Content and the User Experience

The two most common approaches to implementing adaptation on the web is at the level of either content (i.e., adaptive presentation) or linking (i.e., adaptive navigation support). Within each of these, there are a number of techniques used that are described briefly in this section but are reviewed in detail elsewhere (Brusilovsky 1996).

The majority of adaptive presentation operates on text, although in principle any media type may be adapted. Adaptation of modality is where the adaptation operates at the level of choices between different media types (e.g., text, speech, animation, etc.). Although this is likely to become more important in the future, multimedia adaptation is currently relatively rarely implemented (one example is Fagerjord 2005). However, this is likely to increase in web applications supporting disability access or "hands busy/eyes busy" web applications.

There are a number of ways in which the adaptive presentation of text has been implemented—usually by manipulating fragments of predefined text. Some systems add fragments to a standard minimum body of text; others remove fragments that the system deems inappropriate. When fragments are removed they may be completely hidden, or they may be merely dimmed. Another variant of fragment removal is to use "stretchtext" (a body of text is hidden behind a single word or phrase and expanded on request). Some systems instead of adding or removing fragments of text simply reorder the fragments. A major problem with all forms of adaptive text presentation is the impact that it has upon narrative flow. Different users will necessarily have different narratives, which is not a problem per se other than the fact that it is possible (or even likely) that a web page will no longer form a coherent whole if its text is manipulated. This problem may be ameliorated by writing text in the form of conceptually discrete "atoms," but that causes quite serious problems with authoring (most people find it difficult to write following this sort of constraint) and makes legacy content difficult to adapt.

Adaptive navigation support has fewer problems with narrative flow because links are (usually) less fundamental to the sense of a page than is text. Adaptive linking has been divided into five main categories (Brusilovsky 1996): direct guidance, link sorting, link hiding, link annotation, and map adaptation. Direct guidance is where the system makes a recommendation as to the next node to visit, based on the adaptation criteria. This is often used for "guided tour" type of direction for novice users (i.e., it is tantamount to a linear sequence of "Next" buttons). Link sorting is where the ordering of links is changed—so that the most appropriate one is at the head of the list, or in a particularly prominent place. Link hiding is where inappropriate links are not displayed. This, of course, can make parts of the system inaccessible to some users, which may or may not be acceptable. A variant of link hiding is link dimming, where it is still possible to follow the link but is less prominent in the user interface than links that are deemed more relevant. In a link annotation system, visual clues are attached to links to give the user some idea of their status with respect to the system—for example, font sizes or colors can be used to provide a gradation of relevance. Lastly, in map adaptation systems a navigational map is generated according to the adaptation rules.

25.6.1.5 User Modeling

In order to be able to do any adaptation, adaptive systems need to know something about the person who is using them. This information is stored in a "user profile" either on the local (end user) machine or, far more commonly, in a centralized database (accessible by the adaptive system). In the user profile, as well as personal information (name, ID, etc.), the criteria that the system will use for adaptation are stored and these criteria constitute the user model. Although a detailed discussion of user modeling is beyond the scope of this chapter, the basic principles are very simple. A user model is simply a set of values that adaptive systems use to make decisions about relevance. One approach to user modeling is that of stereotype models (Kaplan, Fenwick, and Chen 1993). With these, users are grouped together with other like-minded individuals. For example, "2nd year Chemistry undergraduates" or "people who like cats" are both stereotypes and as such it is possible to make reasonable assumptions about members of those groups (e.g., "will know the structure of butane" or "will appreciate photos of cute kittens," respectively). The other main user modeling methodology is that of the overlay model (Fischer et al. 1990), where the individual's knowledge, background, and any other relevant data are overlaid onto the sum of all knowledge in the system. More frequently adaptive hypermedia systems adopt hybrids of these two approaches so that any given user is initially stereotyped, and as the system learns more about them, it uses an overlay model to record their progress (Zakaria and Brailsford 2002).

User modeling is critical for a usable adaptive system. If the user model is in some way flawed (i.e., if the information stored does not match the reality of users' background and behavior), then content is likely to be maladapted for a user, and the system is often extremely difficult to comprehend. This is compounded by the fact that there are no standards for user modeling, and most adaptive systems use their own proprietary user model. User Models in general should be "scrutable," meaning that the user can find out what information is being stored about him or her and why it is needed (Kay 2006). A growing concern is the privacy issues around eliciting and storing such user model information (Ashman et al. 2009).

25.6.1.6 Authoring

With third-generation adaptive systems, developing new adaptive information portals or experiences principally requires authoring of the adaptive models (e.g., user model, content model, narrative model, etc.) and ensuring relevant content is available. However, up until the relatively recently mature authoring systems for personalized, web systems were not available. However, some have begun to be used. Typically, these authoring tools are specific to a particular adaptive engine and application type. For example, the adaptive course construction tool was an e-learning authoring tool that enabled teachers to graphically represent the learning activities and concepts and to apply personalization based on different aspects of the learners, for example, competencies, learning goals, and so on (Dagger, Wade, and Conlan 2005). Other web-based adaptive e-learning authoring tools included My Online Teacher (Hendrix and Cristea 2007) and WHURLE (Meccawy et al. 2008).

However, there are a number of potentially difficult issues that need to be considered when attempting to design authoring interfaces for adaptive web-based systems (Cristea, Carro, and Garzotto 2005). First, there is a need for a new design paradigm, together with associated metaphors because personalization breaks the fundamental design paradigm of the web—that of the "page." When authoring a conventional web page, the author concentrates on content and can reasonably assume that users will see the page as it is created. Hence most authoring systems for static web pages use a fairly conventional WYSIWYG paradigm—quite similar to that of a word processor. In the case of adaptive systems, however, the authoring process requires a separation of content authoring from the authoring of the parameters for adaptation. Depending on the adaptation model that is used, what the author sees might be somewhat or completely different from what any given end user sees. Current authoring tools allow the author to graphically specify some potential "navigational" paths through the subjects, which the web content presents. The tools allow the author to indicate personalization criteria, for example, user interest, user prior knowledge that the authoring systems convert to adaptation rules. Thus the author need not write the rules themselves, but such rules are generated as a consequence of the author's identification of adaptive situations and the (user or context) information to be used in the adaptation.

Recently, there has been a move to ensure the authoring tools can create adaptive applications executable by different adaptive engines. A most recent attempt has been GRAPPLE project,* which has addressed this issue.

25.6.2 Recommenders

Another branch of personalization on the web has been the development of "Web Recommenders." These are similar in some ways to adaptive web systems, but specifically they suggest or recommend resources or web content to users. Simple examples are now quite common on the web, for example, Amazon's recommendations are based on previous book sales. There are typically three main categories of recommender systems: content-based, collaborative, and hybrid recommendation approaches (Adomavicius and Tuzhilin 2005). Content-based recommenders make recommendations based on the descriptions of the content and a profile of the user's interests. Collaborative (filtering)-based recommenders use the opinions of other users to filter or evaluate items and deduce their relevance to a user. Hybrid recommenders are recommenders which have combined the first two techniques along with other optimizations (Burke 2007). Recommender systems typically do not influence the actual composition or presentation of the recommended web resources and are therefore considered more as an enhanced web retrieval approach.

25.7 COMMUNITIES AND SOCIAL WEB

25.7.1 Communities

While an in-depth discussion of online communities is outside the scope of this section,† they can be described as "cyberspace[s] supported by computer-based information technology, centered upon communication and interaction of participants to generate member-driven content, resulting in a relationship being built" (Lee et al. 2003). From this definition, the makeup of an online community can be characterized as part technology, part sociology, and part psychology. This section will focus on the technologies. The idea of the Internet has always been rooted in communities, groups of people sharing common interests, goals, objectives, ownership and locale, and in creating links and bridging geographic, cultural, or temporal barriers. Part of the original vision of computer pioneers, such as Nelson (1982) was that people could easily share, edit, and comment on as well as read publicly available materials. Technological advances on the web are providing affordances to produce and share content and to network and interact at unprecedented rates. Web logs (more commonly referred to as blogs), of which there are more than 200 million,‡ allow a user to post material online which can be cited, rated, commented upon, and redistributed throughout the Internet. These blogs require no special knowledge of authoring or technical expertise and are usually accessed with a standard web browser.

Another technology that is important in the development of communities on the web is Wikis, which are community websites designed to facilitate collaborative authoring and knowledge sharing. The most spectacular example of this is the Wikipedia project—a vast encyclopedia written collaboratively by volunteers using a Wiki.§ The system provides facilities to discuss changes made to articles, and authors may vote on controversial issues—the editorial policy being the assumption that the exposure of material to many users will result in the addition of depth and elimination of errors. Wikipedia was founded in 2001, and by 2009, it contained more than 13 million articles, 78% of which were non-English.¶ However, these statistics change literally every minute.** While Blogs and Wikis, as relatively new community-enabling technologies, provide impressive statistics, the oldest and probably still largest community activity supporting technology is e-mail with an estimated 247 billion messages per day sent in 2009.††

However, as stated above, technology constitutes a very small part of an online community. The HCI design challenges lie in supporting the fabric, the governance and evolution of that community, and how the locus of control can be disseminated effectively among its users. For example, while central policy can be established to place boundaries on the types of interaction allowed (e.g., Wikipedia five pillars‡‡), the task of moderation should be driven by the ethics of the community members and their personally acceptable rules of interaction. These soft skills/interpersonal communication skills are a fundamental contributor to the longevity of online communities. The technologies chosen and the HCI principles applied should be driven by the lifecycle stage (inception, creation, growth, maturity, and death) of the online community (Iriberri and Leroy 2009).

25.7.2 Social Web

The term "Social Web" can be used to describe how people interact with people, how people interact with content, and how content interacts with content across the World Wide Web. These interactions can range from socializing and sharing information with friends, to playing games against peers, to planning and organizing events, to professional networking in your industry, to dating and relationship building, to seeking advice from others, to shopping, to traveling, and so forth.

While social networking sites to date largely focus interactions within their own silo (e.g., using Facebook, you can only primarily connect with other Facebook users), the Social Web looks in part to proliferate the interaction and connection affordances of social networking across the greater web. Similar to how first-generation web protocols enabled a user to jump between hypertext documents on the web, the Social

Web is a move to enable the seamless transition, aggregation, and merging of social interactions online from many different sources, applications, and networks.

Many social network providers are moving toward this by lowering the barriers to interaction through "social plug-ins" or functional widgets that can be placed on any website to leverage some of the functionality of the source network (e.g., Twitter @anywhere and Facebook Like Button applications). Although their primary purpose is to drive more traffic to those networks, the spread of social interaction affordances across the web is gaining real traction (more than 1 million websites integrate with the Facebook platform*). Movements like the Federated Social Web† are addressing the technical and architectural challenges of a Social Web infrastructure by focusing on technologies to support and promote online identity and security, exchangeable and configurable profiles, definition, declaration and management of relationships, sharing of media and activity streams, messaging, indexing and searching, functional interoperability, and data portability. These enabling technologies will inevitably lead to a series of complex design challenges when building applications to leverage the capabilities and affordances of the Social Web.

The Social Web is bringing HCI online design practices to the forefront of web development. Design is no longer primarily focused on the user as a consumer. The user as a producer and a curator at both individual and community levels now takes center stage in the design process. Services like Facebook have set the bar so high for user interaction (usability or the behavior of a system in response to its users) and user experience (a subjective feeling of satisfaction with learning and using a system) that web users expect high levels of technical sophistication at the click of a button or the swipe of a finger. The Social Web is not seen as a virtual place where people congregate but as a ubiquitous medium that is becoming intertwined with our everyday, physical lives. People are accessing and producing social media on the go at exponentially growing rates‡ with increasing levels of associated context and augmented social experiences thanks to services like Foursquare and Scvngr.

The proliferation of social media production and sharing is sometimes referred to as the "Real-Time Web." As events happen around the world, whether big international events such as the World Cup or personal events such as "I met an old friend at the cinema last night," details of the event quickly make their way onto and across the Social Web through tweets, status updates, or some form of social media sharing. The more popular the event, the more network resonance (how the news of the event propagates across the Social Web) it creates. However, this ubiquity of information creates design problems of its own. Most importantly, how can we filter out all the noise that exists within the Social Web to get to the information that we want, when we want it? The "Right-Time Web" aims to leverage the methods of personalization described previously to adapt and tailor the information streams of the Social Web "just for me."

25.8 MOBILE WEB

25.8.1 Touch and Speech as Interaction Mechanisms

Touch-sensitive screen technology has been available since the late 1960s, and the ability to directly touch and manipulate information on a device is undoubtedly appealing to many users. Early touch screens were of very low resolution and could only sense a single touch, which made their applications quite crude—generally this involved pressing large hot spots or buttons. The ability for a touch screen to respond to multiple touches simultaneously, however, provides the possibility for control of interfaces by multifingered gestures (Wellner 1991), and such devices allow interactions that had previously used peripherals such as keyboards and mice to be easily accomplished by a single, highly space-efficient device (Westerman, Elias, and Hedge 2001). The phrase "multi-touch sensing" was coined by Han (2005) when he prototyped the technology that was later popularized by the Apple iPhone, and is now widespread in a large variety of smartphones, tablet computers, and other consumer devices. For some of these, such as the iPhone, the multitouch interface is the only means of interaction, although others (such as many Google Android devices) also contain a small physical keyboard.

The gestures used to interact with modern smartphones provide users with a rich new means of accessing web content, such as using finger-spreading movements to zoom and sliding movements to pan. This provides user interface designers with a toolset that goes a long way toward ameliorating the problems of displaying complex hypermedia content on small screens. However, the success and extremely rapid uptake of this technology has itself led to a number of design problems. Designers of different applications have quite frequently adopted their own nonstandard conventions and methods of interaction design. For example, a leftward swipe of a single finger might pan across an image or it might return to a previous web page. In both cases, this gesture represents a pan, but in the former example it is spatial, whereas in the latter, it is temporal (Wigdor, Fletcher, and Morrison 2009).

There are two major technologies that are used for touch screens, capacitive screens can only be operated by fingers and require a very light touch. Resistive screens may be operated by fingers, fingernails, or stylus and require a higher force threshold. Styluses enable more precise interaction than fingers alone, but they are inconvenient and easily lost. For text entry, some capacitive devices, such as iPhones, compensate for the loss of accuracy by the use of automated error correction. Physical feedback (i.e., sound or vibrations) helps to increase the usability of capacitive touch screens, and then for simple interactions, the user performance is similar, or even slightly superior to that of physical keys (Lee and Zhai 2009).

Speech recognition is now quite accurate, and in recent years, the technology has become reliable and cheap enough

[‡] http://mashable.com/2010/03/03/comscore-mobile-stats/.

to incorporate into a wide range of devices, and it is thus, technically at least, now a viable means of interaction. However, outside of specialized applications (mostly among blind or motor-impaired users), it has yet to become widely adopted. Part of the reason for this is undoubtedly simply the disruption that is caused by people speaking simultaneously in public places, and the fatigue that is caused by continuous speaking. However, Shneiderman (2000) has also pointed out some more fundamental problems with voice interfaces. Human–human voice interaction uses subtle variations of speed, intonation, and volume to convey a rich emotional subtext. Not only is this difficult to model in human–computer voice interaction systems, but it can actually disrupt the interaction. Moreover, the problem-solving parts of the brain also support verbal communication, so tasks requiring concentration are generally best carried out in silence—whereas physical tasks are handled by a different part of the brain. This means that most people find it easy to manipulate a touch or keyboard interface while thinking, but much harder to issue accurate voice commands. However, despite these problems, speech input is undoubtedly important for accessibility of smartphones. It is also possible that hybrid voice/touch interfaces might become important in the near future. An interesting experimental system of this type is the "earPod" developed by Zhao et al. (2007). This is an eyes-free menu system, which uses a touch interface for input and a speech system for output. Although the user performance was initially slower than with more conventional systems, after as little as 30 minutes practice, most users became very proficient with the system and could consistently outperform other user interfaces.

25.8.2 Situation-Aware Web-Enabled Devices

25.8.2.1 Context-Aware Devices

In recent years, mobile web devices, such as PDAs, smartphones and tablet computers, have led to the emergence of the mobile web as a direct extension of the "traditional" Internet. These devices, because of their increasingly smaller form-factor and intuitive touch-screen interface have opened a new way of accessing the web right from our fingertips. Users are no longer bound to a stationary computer or laptop to access the web; it is now available from an always-online, small device that fits into our pockets and allows access to the web at any time from any place. Services and applications are now becoming location-aware, using the physical location of the web device, and the context in which it is used, as an input to improve our interaction with these services (Virrantaus et al. 2006). This has led to many new opportunities in the area of mobile commerce (Rao and Minakakis 2003), mobile advertising, informational services, entertainment, education, or business processes (Varshney 2001). Although the first location-aware systems were developed in the 1990s, they still face many challenges today (Patterson, Muntz, and Pancake. 2003).

Various means of locating a mobile device have been developed and implemented, such as the first, true location-aware system based on radio transmitters and badges (Want et al. 1992). Work in related areas, such as augmented and virtual reality has also helped in refining location and position tracking in mobile devices. Optical sensors, based on infrared technology for example, were used by Ward et al. (1992). Schmalstieg and Wagner (2007) show the use of visual markers to provide orientation information on handheld devices. As Bluetooth technology has become available in mainstream mobile devices, it too has been utilized as a source of locality information (Aalto et al. 2004). RFID tags, based on low-powered radio-transmitters have also been used successfully, and Rashid et al. (2006), for example, created a real-world Pac-Man game, based on positioning information retrieved from RFID sensors.

However, global positioning system (GPS), a technology that relies on geostationary satellites to determine the location, is now used as the predominant means of locating a mobile device in the physical world today. It has been extended to the implementations found in modern devices, which rely on external processing to enhance positioning accuracy (Djuknic and Richton 2001), and have been used successfully in wide, open areas, but are inaccurate in indoor settings or areas without a clear view of the sky, a limitation of the consumer-grade GPS receivers included in such devices (Wing, Eklund, and Kellogg 2005). Benford et al. (2006) implemented an urban mixed-reality game, and Thomas et al. (2000) created an augmented reality version of the game Quake. These implementations show, however, that this technology can be used for many different applications.

The fundamental goal of location-awareness is fully context-aware systems (Harter et al. 2002) that adapt dynamically to the context in which they are used. The context of a system relates to its usage environment and is derived from sensory input (Hong, Suh, and Kim 2009), such as its physical location, its orientation, the current weather, time and date, and the status of the device. Services can then utilize this context to provide appropriate information, communication, or computation to its user. Ultimately, context-aware computing will pave the way for ubiquitous computing by fully integrating mobile systems into our everyday life.

25.8.2.2 Location-Aware Applications for Mobile Devices Today

Today, smartphones, such as the Apple iPhone or Android platform devices, include magnetic sensors for orientation information, and assisted GPS to provide location information. These devices are widely popular today, leading to the emergence of new applications and uses, such as location-awareness, to the general public.

However, even before the release and wide availability of mobile phones with positioning technology, Rao and Minakakis (2003) identified location-based services as a major step in the evolution of mobile commerce. The ability to pin-point a user's exact location has long been the dream of commercial users, for example, for mobile advertising, product or shopping information, entertainment, education, or the inclusion in business processes (Varshney 2001). End-users have also realized the opportunities location-aware devices could bring, as Kaasinen (2003) found in a user study, concluding that personalized, location-aware services can be beneficial and are accepted by users if they contribute positively to the overall experience.

Today, any application developed for the iPhone or Android platform can utilize location and orientation features. Google, for example, is utilizing the physical location of a device to supplement search results, while mapping and routing applications allow users to easily navigate the real world. Some other examples include Yelp,* providing location-aware crowdsourced reviews and recommendations, social networking (such as Google Latitude,† Foursquare,‡ and Gowalla§), crowdsourced traffic information, navigation and maps through Waze¶ as well as location-aware information services for weather and news.

The ever-increasing popularity of location-aware smartphones and applications have led to the emergence of urban computing, the integration of computing technology into our everyday life and daily activities (Kindberg, Chalmers, and Paulos 2007). This includes pedestrian navigation systems (Arikawa, Konomi, and Ohnishi 2007) and an adaption of Social Web applications to physical locations, utilizing 2D-barcodes, GPS, and blogs (Hansen and Grønbæk 2008).

25.8.2.3 New Interface to the Web: Augmented Reality

With the availability of orientation and positioning information in everyday devices, such as smartphones, augmented reality has become accessible to the general public.

Augmented reality refers to the "supplementation of the real world with virtual objects" (Azuma et al. 2001). Traditionally, mobile augmented reality systems have been developed based on specialized hardware and portable computers, military-grade GPS receivers for accurate location information and often required the user to wear a head-mounted display to provide an immersive environment (Hollerer et al. 1999; Thomas et al. 2000). However, as evaluated by Schmalstieg and Wagner (2008), utilizing small mobile devices, such as mobile phones, requires a different approach to the design of virtual environments. The "magic lens" style view has been developed for handheld devices, using the screen of the handset as a lens and augmenting the limited view available.

Papagiannakis, Singh, and Magnenat-Thalmann (2008) highlight the impact recent technological advancements of smartphones and availability of wireless wide area networks and 3G networks has had on the development of mobile augmented reality systems. Specialized hardware, weighing many kilograms, is not required anymore, as powerful smartphones can be used for this purpose instead.

Augmented reality systems require accurate location and sensor information to mesh the real-world view with additional, generated information. Implementations on smartphones and mobile handsets today rely on GPS location information, as well as gyroscopic sensory information to create augmented views. However, sensors available in smartphones are notoriously inaccurate and inconsistent, tainting the overall augmented reality experience (Wagner and Schmalstieg 2009). Further challenges include the social acceptance of systems, low-bandwidth wireless network infrastructure and limited graphical capabilities and memory of mobile devices. Inaccurate sensory information has been identified as a key problem in the augmented reality community, with work being currently underway to overcome these problems through the development of filtering and prediction algorithms, such as Gotow et al. (2010).

A number of specialized systems have already been developed that take advantage of this evolution of smartphones, such as Studierstube (Schmalstieg and Wagner 2008), as well as a new generation of mobile augmented reality games (Broll et al. 2008).

A number of applications are already available for the iPhone and Android platforms, such as Layar,** an augmented reality browser allowing users access to 3D informational overlays, and Wikitude,†† an augmented reality overlay for Wikipedia.

25.9 CONCLUSIONS

In this chapter, we have considered HCI in a specific web context, looking at the issues impeding smooth user interaction with web tools and documents. Although some problems remain unsolved, generally the usability of the web has improved greatly since its early days. We have also seen in the past few years an enormous expansion in the capacity of mobile devices, greatly broadening the reach of the web, as well as challenges posed by popular new input methods on context-aware devices.

26 Human-Centered Design of Decision-Support Systems

Philip J. Smith, Roger Beatty, Caroline C. Hayes, Adam Larson, Norman D. Geddes, and Michael C. Dorneich

CONTENTS

26.1 OVERVIEW

Computers can assist decision makers in a variety of different ways. They can, for instance, support users with improved access to information, with more informative displays of this information, or with more effective forms of communication. They can also use algorithms to actively monitor situations and to generate inferences in order to assist with tasks such as planning, diagnosis and process control. This chapter focuses on interaction design issues (Preece, Rogers, and Sharp 2002; Scott, Roth, and Deutsch 2005) associated with this latter role, in which the software uses numerical computations and/or symbolic reasoning to serve as an active decision-support system (DSS) (Turban, Aronson, and Liang 2004).

An underlying assumption in design of human-centered systems is that the characteristics of the user population, the tasks they perform, and the context and environment in which they perform them are all inherently intertwined. DSS designers need to understand all three in order to understand what support a DSS should provide to help users to be more effective in a specific task and context. This chapter aims to provide DSS designers with approaches for understanding of all three, and their integration.

The chapter begins with a focus on design methods. We emphasize the value of an iterative design process with multiple cycles of design and testing with users, in increasingly realistic contexts. This process is strongly aided by the use of concrete scenarios and use cases to define the design problem, and the use of cognitive task analyses (CTAs) and work domain analyses to guide both the development of the underlying functions in the DSS, and the design of the interface that mediates the interactions of the user with these functions (Bittner 2002; Cockburn 2000; Kulak and Guiney 2003).

The chapter then proceeds to discuss aspects of human performance relevant to the design of DSSs. This includes a discussion of factors that limit human performance, as these factors suggest opportunities for improving performance through the introduction of a DSS. This discussion also includes consideration of the influence of a DSS on the user's cognitive processes, emphasizing the need to think in terms of the resultant joint cognitive system that is not a simple combination of the capabilities of the two agents (user and DSS) alone (Hoc 2001; Hollnagel and Woods 2005; Jones and Jacobs 2000).

The discussion further emphasizes the need to consider more than just the surface interactions of the user with the interface to the DSS, and to consider the impact of the broader task context on performance (Amalberti 1999; Miller, Pelican, and Goldman 2000; Parasuraman 2000; Rasmussen, Pejtersen, and Goldstein 1994). This latter emphasis suggests that the design of a DSS needs to be viewed from the perspective of cooperative problem solving, where the computer and the person interact with and influence each other (Beach and Connally 2005; Hoc 2000; Jones and Mitchell 1995; Larsen and Hayes 2005; Larson 2010; Mital and Pennathur 2004; Parasuraman, Sheridan, and Wickens 2000; Smith, McCoy, and Layton 1997). From this viewpoint, the underlying functionality is just as important as the surface level representation or interface, as it is the overall interaction that determines ultimate performance.

The chapter also frames the design and use of a DSS as a form of cooperative work between several individuals (Bowers, Salas, and Jentsch 2006; Grabowski and Sanborn 2003; Hutchins 1990; Orasanu and Salas 1991; Rasmussen, Brehner, and Leplat 1991; Hutchins 1995; Olson and Olson 1997; Smith et al. 2000), with the computer as the medium through which they cooperate. This teamwork may involve system users who are physically or temporally distributed. In addition, the discussion further suggests that it is useful to think of the design team as working cooperatively with the users, trying to communicate with them and extend or augment their capabilities, and doing so through the software and other artifacts (such as paper documents) that they have developed. This perspective is useful as a reminder that we need to consider the psychology of the designers as well as the psychology of the users of systems, applying that understanding to help us take advantage of the strengths of both groups as they work cooperatively.

Thus, this chapter approaches the design of DSSs from four perspectives. The first is to emphasize the need to identify effective approaches to support human-centered design process, including the application of use cases, CTAs and work domain analyses as a part of an iterative design process. The second is to provide a discussion of the human factors considerations relevant to the design of a DSS (Helander, Landauer, and Prabhu 1997; Meister and Enderwick 2002; Wickens et al. 2004). The third is to provide very practical lists of questions that need to be asked as part of the design process. The fourth is to use case studies to provide concrete, detailed illustrations of how these considerations can be addressed in specific application contexts.

26.2 APPROACHES TO DESIGN

A number of complementary and overlapping approaches have been articulated to help ensure adequate consideration of user needs, preferences and capabilities during the design process, and to gain insights into possible functionality to incorporate in a DSS. These include the use of participatory design (Bodker, Kensing, and Simonsen 2004; Schuler and Namioka 1993), scenario-based design (Carroll 1995), and the completion of various forms of needs assessments (Tobey 2005; Witkin and Altshuld 1995), CTAs and cognitive walkthroughs (Crandall, Klein, and Hoffman 2006; Jonassen, Tessmer, and Hannum 1999; Kirwan and Ainsworth 1992; Rubin, Jones, and Mitchell 1988; Schragen et al. 2000). It also includes various forms of domain analyses aimed at identifying the critical features and constraints that characterize the domain of interest.

There are many approaches to design, all of which are useful and important ways of obtaining the human perspective. One or many of them may be used over the course of a single design project. Some may be most useful in the early stages of the design process, and others as the design becomes more mature. Chapters 48 and 49 discussed the use of participatory and scenario-based design as approaches to the design process. The focus of this section will therefore be on other approaches including various forms of cognitive task and domain analyses. However, it should be noted that the development of, and results from, a CTA can in general be very useful in helping to support participatory design, as can the development and use of scenarios. As Mack (1995, p. 368) notes:

> Developing and sharing a set of touchstone stories is an important cohesive element in any social system. … Gathering, discussing, and sharing these stories as a group can be an effective means to team building.

All the design approaches and techniques discussed can be applied as a part of a larger overall, iterative human-centered design process, so we will start by briefly describing this larger context.

26.2.1 Iterative Human-Centered Design Processes

26.2.1.1 What Makes a Design Process "Human Centered?"

There are many types of design processes, but not all of them are human centered. A *human-centered* design process is one that involves human feedback at all stages of the design process starting from the identification of the need for a DSS and the gathering of user requirements, all the way though testing and evaluation of the final products. Human-centered design processes take into account human skills, needs and limitations. Perhaps the two defining properties of human-centered design processes are that their central goal is to create a result that people find not only usable but highly effective, and the input of potential users is incorporated from conception until launch of the product.

The students of one of the authors once asked, "If we e-mail the customer once a week to let her know what we are doing, does that make it human-centered?" The answer was, "It's a good start, but it's not enough." First of all, the customer is not always one of the potential users. For example, a manager in the Veteran's Administration may ask for a DSS as part of a telemedicine tool to help medical personnel conduct follow up visits across distance. The manager is technically the customer, but not the user in this case. The patients and care providers will be the users. Second, users need to be more actively involved than simply getting a status report each week. The user does not necessarily need to be a member of the design team, as in participatory design, but it is essential to frequently seek user input, review and testing of the design with real or realistic problems.

The advantages of following a human-centered design process are a greater likelihood that users will accept and use the resulting DSS, and that it will provide better support, with greater effectiveness, fewer errors, and increased safety. One may ask, when should one adopt a human-centered versus a nonhuman-centered design approach? We would argue that since all DSSs must interact with people, all DSS should be developed through a human-centered design process. In fact we would further argue that all products, processes and systems interact with humans in some way, and thus all design processes should be human centered.

26.2.1.2 Needs Analysis

Before designing a DSS, one first needs to assess whether a DSS is really needed, and if so what that DSS should do. For example, suppose a manager from a product design and manufacturing company approaches a designer and says, "Many of the product designs my engineers create result in serious manufacturing problems that result in many scrapped products. I want a DSS that will review product designs and give advice on whether or not they are manufacturable." However, what the customer believes will solve the problem may not always be the best solution. The DSS designer must start the design process by gathering information on the overall context using a variety of techniques, including interviews, focus groups, plant walkthroughs, and ethnographic studies of people doing their work. In the situation described above the appropriate approach may be to first interview a variety of engineers (the intended users), and manufacturers to see what they perceive the problem and solution to be, as well as to visit the offices of the designers and manufacturers, and where possible to measure the scope of the problem. How many parts must be scrapped? What were the reasons they had to be scrapped? What is the cost? One may find that a DSS is exactly what is needed or, alternatively that a DSS would be less cost-effective than increasing the training for the engineers on the rapidly evolving manufacturing processes. It is always important to first get a handle on the larger context so as to better understand the underlying problem and goals, and whether a DSS is really the best way to solve the problem.

If the DSS designer finds that a DSS is, indeed, an appropriate solution, then he or she must identify the likely user groups and observe them in their current work environment where possible, and understand the tasks they must do. As a second example, suppose the goal is to design a better scheduling system for receptionists in a medical clinic. To inform design of the DSS, it is useful to sit in an unobtrusive corner of the office as the receptionists are doing their normal work and observe what they do, and where the current problems lie. In one scenario observed by one of the authors, the receptionists had to do multiple conflicting tasks. They had to schedule patients for follow-up appointments at the request of the doctors. These requests were made through the computer. They had to discuss scheduling needs with care providers who would stop into their office. They had to answer telephones, address patient questions, schedule telephone requests for appointments from patients, determine who needed emergency treatment and who could wait based on self-reported pain levels, check in patients as they arrived, and sooth the disgruntled ones. They were often interrupted in the middle of interruptions of other tasks, placing great demands on their short-term memory. Some tasks simply did not get done. The receptionists were extremely stressed, and turnover for the job was high. While it was clear that more was needed than a DSS to really address the scope of the challenge, it was also clear that much could be done to improve the situation through a DSS that helped them to manage multiple scheduling tasks by providing visual interfaces that reduced the burden on their working memories, and assisted with management of simultaneous tasks.

Information from such observations provides critical guidance for the design process, as well as the work domain and CTAs that will be described in Sections 26.2.3 and 26.2.2.1.

26.2.1.3 Design as a Process of Iterative Improvement

Human-centered design processes are typically iterative, with multiple design cycles in which some version of the DSS is created, and potential users are then asked to comment on or test a version of the DSS. Alternatively, a simulation of human behavior can sometimes be used to test or estimate time required for completing a task using the DSS (see Sections 26.2.2.1 and 26.2.2.2). However, since human behavior is very complex, unpredictable and therefore hard to model, in many cases it is simplest and most effective to use human testers.

With each successive design cycle, the prototype of the DSS should become more detailed and realistic, and the testing done with people closer to the real users, with problems in the real contexts in which they will be used. Early versions of the DSS design may be little more than a graph on paper showing the steps in the process that a user would take using the DSS (see the discussions of Sections 26.2.3 and 26.2.2.1). Assessment may involve asking a potential user to review the diagrams by "walking through" the steps for a specific problem and offering feedback (see Section 26.2.2.3). As the design progresses through successive cycles, the design should become progressively more detailed. Later designs might include sketches on paper showing how the visual interface of the software will look, and yet more mature designs may be partially working software prototypes of the DSS. In the final version of the DSS, it should be tested with real users, solving real problems, in the real context. That said, it is often hard to get access to users with special expertise or to recreate the real contexts safely, for example, if the DSS is to be used by military commanders on the battlefield, or by rescue personnel during hurricane relief. However, much can be learned by testing the DSSs with people who have related expertise, such as officers in training, or off-duty or retired coast guard personnel, in situations where people role play to create a "mock" battle or disaster scenario.

There are many prototyping and evaluation techniques which one can apply at various iterations of the design process described throughout this volume. We will focus on cognitive task and work domain analyses as approaches for understanding and modeling the users' work domain, and the cognitive tasks they perform in that domain. These models are critical for informing a DSS design.

26.2.2 Cognitive Task Analyses and Cognitive Walkthroughs

Cognitive task analyses and cognitive walkthroughs are methods for understanding how a task is performed in a specific environment, and assessing DSS designs, sometimes before they are even implemented. A CTA models the components of a task and the thought processes used to carry it out. In some cases, computational versions of cognitive task models, called *cognitive architectures*, are used to predict task performance for a given DSS design. In contrast, a *cognitive walkthrough* uses a potential user, rather than a computational model, to "walk through" the steps in a task as they would be performed using the DSS design. Each provides a different type of useful feedback to the DSS designer. A cognitive architecture may be used to estimate the time required to perform a task given for a proposed DSS. The person performing the cognitive walkthrough may provide more qualitative feedback about whether the design makes sense, and whether there are other functions which the DSS should provide to properly support the task.

26.2.2.1 Cognitive Task Analyses

Scenarios and use cases are also important in providing the framing for specific CTAs. The starting point for a specific

CTA is the high-level context provided by a scenario or use case. As Kutti (1995, p. 19) notes:

> An important feature of a scenario is that it depicts activities in a full context, describing the social settings, resources, and goals of users.

Thus, to begin a CTA, one must specify the person for whom the product is to be designed (a persona), the goal which that person is trying to achieve, and the immediate and broader contexts in which that goal will be pursued.

Many methods for conducting CTAs (Gordon and Gill 1997; Hollnagel 2003) have their roots in hierarchical task analysis techniques, which involve decomposing a high-level goal or task into a hierarchy of subgoals or subtasks (Annett et al. 1971; Annett and Stanton 2000; Diaper and Stanton 2004; Miller, Galanter, and Pribram 1960; Preece et al. 1994). This approach originally focused only on the decomposition of the task without concern with the underlying cognitive processes. However, hierarchical task analysis has been extended to capture not only goal-subgoal relationships, but that also associated cognitive processes.

An influential example of this evolution is GOMS (Goals, Operators, Methods and Selection rules) (Card, Moran, and Newell 1983; Kieras 2004; St. Amant et al. 2005; Williams 2005). GOMS makes use of hierarchical decomposition, but also provides a control structure that introduces operators and rules for selecting which operator to apply in a given goal-driven context. As Preece et al. (1994, pp. 419–420) note:

> A GOMS analysis of human–system interaction can be applied at various levels of abstraction in much the same way that the hierarchical task analysis splits tasks into subtasks. … Three broad levels of granularity determine the GOMS family of models:
>
> - The GOMS model, which describes the general methods for accomplishing a set of tasks.
> - The unit task level, which breaks users' tasks into unit tasks, and then estimates the time that it takes for the user to perform these.
> - The keystroke level, which describes and predicts the time it takes to perform a task by specifying the keystrokes needed.

26.2.2.2 Cognitive Architectures

This move toward explicit computational representation of internal cognitive processes has been extended to the extent that broad, task-independent cognitive architectures have been developed that can be used to model performance in a given task/system context and generate performance predictions (Byrne and Kirlik 2005). Three such systems are Adaptive Control of Thought—Rational (ACT-R) (Anderson 1993; Anderson et al. 2004), State, Operator and Result (SOAR) (Laird, Newell, and Rosenbloom 1987; Nason, Laird, and Schunn 2005), and Executive-Process Interactive Control (EPIC) (Kieras and Meyer 1997; St. Amant et al. 2005). All three incorporate procedural knowledge that must operate within the constraints of certain constructs such as working memory (Baddeley 1998, 1999; Cary and Carlson 2001; Radvansky 2005; Seamon 2005) that are used to model human capabilities and limitations (Myers 2004; Wickens et al. 2004).

26.2.2.3 Cognitive Walkthroughs

This work on the development of computational models to describe or predict task performance is complemented by more qualitative, judgment-based approaches using expert reviews that are similarly rooted in the hierarchical decomposition of a task based on goal-subgoal relationships. These latter techniques are motivated by the assumption that expert judgments about the adequacy of a design will be more accurate and complete if they are made while explicitly considering the context that the user will be dealing with (the user's current goal and subgoal and the display the user is viewing while trying to achieve that goal).

There are a number of variations on how to conduct such qualitative cognitive walkthroughs or predictive CTAs (Annett and Stanton 2000; Bisantz, Roth, and Brickman 2003; Diaper and Stanton 2004; Gordon and Gill 1997; Hollnagel 2003; Jonasson et al. 1999; Kirwan and Ainsworth 1992; Klein 2000; Schraagen, Chipman, and Shalin 2000; Shepherd 2000; Vicente 1999). As an example, one such method is outlined by Lewis and Wharton (1997) as follows:

Step 1. Select the context for a use case to be used for an evaluation. Each such use case specifies three primary considerations:

- *User*. What are the characteristics of the user of the product that might affect its use? (the persona in the use case)
- *Context*. What is the broader physical, organizational, social and legal context in which the product will be used?
- *Task*. What is the high-level task or goal for which the product is being used?

Note that this specification is solution independent. It essentially defines the design problem for this use case.

Step 2. Specify the normative (correct) paths for completing the goal of this use case (represented as a goal hierarchy) using the current product design, indicating the alternative sequences of steps that the user could take to *successfully* achieve the specified goal. Note that there could be more than one correct path for completing a given task.

Step 3. Identify the state of the product and the associated "world" at each node in the goal hierarchy. In the case of a software product, the state of the product would be the current appearance of the interface and any associated internal states (such as the queue of recently completed actions that would be used should an undo function be applied). The state of the "world" applies if the product or the user actually changes something in the world as part of an action, such as changing the temperature of a glass manufacturing system through a process control interface.

Step 4. Generate predictions. For each correct action (node in hierarchy) attempt to

- Predict all the relevant success stories
- Predict all the relevant failure stories
- Record the reasons and assumptions made in generating these stories
- Identify potential fixes to avoid or assist in recovery from failure stories

This final step involves walking through the hierarchy along each path that leads to success, and playing psychologist, generating predicted behaviors at each node (for each associated screen display or product state). This walkthrough could be done by an expert in human–computer interaction (HCI) or by a domain expert. Because of the differences in their backgrounds relevant to the design and the domain of interest, individuals from each group are likely to generate somewhat different predictions.

Lewis and Wharton (1997) suggest asking four questions to help guide this prediction process:

- Will the user be trying to achieve the right effect?
- Will the user notice that the correct action is available?
- Will the user associate the correct action with the desired effect?
- If the correct action is performed, will the user see that progress is being made?

Smith, Stone, and Spencer (2006) suggest some additional, more detailed questions that can be asked to help the analyst consider how different cognitive processes influence performance (Card, Moran, and Newell 1983; Wickens et al. 2004):

- Selective attention: What are the determinants of attention? What is most salient in the display? Where will the user's focus of attention be drawn? (Bennett and Flach 1992; Eckstein 2004; Johnston and Dark 1986; Lowe 2003; Pashler, Johnston, and Ruthruff 2001; Yantis 1998.)
- Automaticity and controlled attentional processes: Does the design support skill-based performance for routine scenarios and controlled, knowledge-based processes for novel situations? (Logan 2005; Rasmussen 1983; Rasmussen, Pejtersen, and Goldstein 1994.)
- Perception: How will perceptual processes influence the user's interpretation? How, for instance, will the proximity of various items on the screen influence judgments of "relatedness" as predicted by the Gestalt Law of Proximity? (Bennett and Flach 1992; Kohler 1992; Tufte 1983, 1990, 1997; Vicente 2002; Watzman 2003.)
- Learning and memory: How will the user's prior knowledge influence selective attention and interpretation? Does the knowledge necessary to perform tasks reside in the world or in the user's mind? (Baddeley 1998, 1999; Grondin 2005; Hester and Garavan 2005; Hutchins 1995; Norman 2002; Ormrod 2003; Radvansky 2005; Scaife and Rogers 1996; Seamon 2005.)
- Information processing, mental models, and situation awareness: What inferences/assumptions will the user make? What internal representations will support such processing? (Endsley 2003; Endsley and Garland 2000; Gentner and Stevens 1983; Johnson et al. 1981; Plous 1993; Schaeken 2005.)
- Design-induced error: How could the product design and the context of use influence performance and induce errors? (Bainbridge 1983; Beach and Connally 2005; Johnson et al. 1981; Larsen and Hayes 2005; Parasuraman and Riley 1997; Reason 1990, 1997; Roth, Bennett, and Woods 1987; Sheridan 2002; Skirka et al. 1999; Smith and Geddes 2003; Smith et al. 1997.)
- Motor performance: Can the controls be used efficiently and without error? (Jagacinski and Flach 2003.)
- Group dynamics: How will the system influence patterns of interaction among people? (Baecker et al. 1995; Brehm, Kassin, and Fein 1999; Forsyth 1998; Levi 2001; Olson and Olson 2003.)

Thus, Steps 1–3 as described earlier involve describing how a product (such as a DSS) can be used to achieve a specific goal. Step 4 involves predicting how people might perform when using this product, either successfully or unsuccessfully, as they try to achieve this goal. Thus, the "cognitive" part of this analysis is embedded only in Step 4. Note also that the goal-subgoal hierarchy does not attempt to represent the further sequences of actions that could arise once the user starts down a failure path. This helps to keep the size of the hierarchy smaller, keeping the analysis task more manageable. (For some applications, it may be desirable to actually expand the goal-subgoal hierarchy to represent the complete path of a failure story.)

Finally, going beyond just the use of hierarchical decomposition techniques, Gordon and Gill (1997, pp. 133–134) note that

> CTA [Cognitive Task Analysis] methodologies differ along several dimensions. These include the type of knowledge *representation* or formalism used to encode the information obtained from the analysis, the *methods* used for eliciting or identifying expert (or novice) knowledge, and the *type of task and materials* used in the analysis. Typical representation formats include lists and outlines, matrices and cross-tabulation tables, networks, flowcharts, and problem spaces with alternative correct solution paths.

Thus, although the use of hierarchical goal-subgoal representations is one of the more popular approaches, there are a variety of other complementary approaches that are labeled as CTAs (Crandall, Klein, and Hoffman 2006). These alternatives include the use of concept maps and conceptual graph analyses (Gordon and Gill 1992) and different approaches to extracting and representing the knowledge of experts about critical incidents (Crandall, Klein, and Hoffman 2006; Klein, Caulderwood, and MacGregor 1989). The ultimate goal of all of these approaches, however, is to better represent and predict how users' knowledge and control processes or cognitive processes will be applied in a given task environment. This task environment could be the existing world (a descriptive analysis) that is being studied in order to design improved support tools, or an envisioned world that incorporates some specific design proposal intended to improve performance (a predictive analysis).

26.2.3 Work Domain Analyses

Cognitive task analyses tend to focus on how to support performance for an already identified task or goal. However, in many cases DSSs are designed to support performance in very complex environments (Bar-Yam 2003, 2005) where it is unlikely that all of the possible scenarios that could arise will be predicted during the design process. Thus, there is also a need for design methodologies that support the development of robust designs that will be effective even when novel situations arise (Vicente 1999).

To deal with this need, a complementary set of design methodologies have been developed under the label of work domain analysis (Burns, Bizantz, and Roth 2004; Burns and Hajdukiewicz 2004; Burns and Vicente 2001; Reising and Sanderson 2002; Vicente 2002; Vicente and Rasmussen 1990; Vicente and Rasmussen 1992). In general terms, the emphasis is on understanding and modeling the work domain or application area rather than simply modeling the performance of people on a prespecified set of tasks within this domain. The argument is that the domain analysis can identify the critical parameters or constraints relevant to successful performance in that domain and thus serve as the basis for a design that can handle both routine and novel (unanticipated) situations.

To make this point more concrete, as a very simple but illustrative example, Vicente (2000) contrasts verbal directions on how to travel from one point to another versus the use of a map. In this analogy, the directions provide a very efficient but brittle description of how to accomplish the desired goal. The map requires more work (interpretation), but is more flexible in the face of obstacles that might render the directions unusable. Building on this analogy, Vicente (2000, p. 115) notes:

> This decrease in efficiency [of maps vs. directions] is compensated for by an increase in both flexibility and generality. Like maps, work domain representations are more flexible because they provide workers with the information they need to generate an appropriate response online in real time to events that have not been anticipated by designers. This is particularly useful when an unforeseen event occurs because task representations, by definition, cannot cope with the unanticipated.

The literature on work domain analyses discusses the use of abstraction (means-end) hierarchies and aggregation (part-whole) hierarchies to complete a domain analysis, and then using the results of this analysis to guide the design of the DSS for supporting operator performance (Burns and Hajdukiewicz 2004; Vicente 1999; Vicente and Rasmussen 1990). The basic logic of this approach is that, in order to design appropriate representations to assist an operator in completing tasks using some system, the complete and correct semantics of the domain must first be appropriately defined. Since such a design is concerned with supporting goal-oriented behaviors, one way to represent the semantics is with an abstraction (means-end) hierarchy that captures the "goal-relevant properties of the work domain" (Vicente and Rasmussen 1990, p. 210). In addition, because the domains of interest are often quite complex, aggregation hierarchies may be useful to decompose the overall domain into a set of interrelated subparts.

26.2.4 Approaches to Design—Summary

Much of the work on methods for completing CTAs and work domain analyses has been stimulated by the challenges of developing DSSs to support performance on complex tasks. The description above provides a sense of the range of techniques that have been developed, and emphasizes the need to understand both the constraints of the application context and the nature of the agent(s) (person or people) involved. The insights provided by such analyses can be used to guide the design of the underlying functionality embedded within a DSS, and to guide the design of the interaction between a DSS and its user.

26.3 HUMAN PERFORMANCE ON DECISION-MAKING TASKS

There are several reasons why an understanding of human performance is important to the designer of a DSS. The first is that the motivation for developing such systems is to increase efficiency (reduce production costs or time) and/or to improve the quality of performance. Thus, it is important for the design team to be able to efficiently and effectively complete the initial problem definition and knowledge engineering stages of a project, identifying areas where improvements are needed. An understanding of human performance makes it possible to, in part take a top-down approach to this, looking to see whether certain classic human performance phenomena (such as hypothesis fixation) are influencing outcomes in a particular application. A second motivation for understanding human performance is that a human-centered approach to the design of a DSS requires consideration and support of the user's skills (Garb 2005). To do this effectively, knowledge of human performance (perception, learning and memory, problem solving, decision making, etc.) is essential. A number of these aspects of human performance are covered in Chapters 1–5, so this chapter will just highlight some of the factors most relevant to the design of a DSS, and discuss how such factors are relevant to this design task.

26.3.1 Errors and Cognitive Biases

In very broad terms, human errors (Strauch 2004; Wiegmann and Shapell 2003) can be classified as slips and as mistakes (Norman 1981). Slips arise through a variety of cognitive processes, but are defined as behaviors where the person's actions do not match his intentions. Generally, this refers to cases where the person has the correct knowledge to achieve some goal but, due to some underlying perceptual, cognitive or motor process, fails to correctly apply this knowledge. As Norman (1988, p. 106) describes it: "Form an appropriate goal but mess up in the performance, and you've made a slip." Mistakes, on the other hand, refer to errors resulting from the accurate application of a person's knowledge to achieve some goal, but where that knowledge is incomplete or wrong.

DSSs are potentially useful for dealing with either of these sources of errors. If slips or mistakes can be predicted by the design team, then tools can be developed to either help prevent them, recover from them, or reduce their impacts.

26.3.1.1 Slips

Norman (2002) discusses six categories of slips. Knowing something about these different causes can help the designer to look for possible manifestations in a particular application area. These six categories as defined in Norman include the following:

- Capture errors, "in which a frequently done activity suddenly takes charge instead of (captures) the one intended" (p. 107).
- Description errors, where "the intended action has much in common with others that are possible" and "the internal description of the intention was not sufficient" often resulting in "performing the correct action on the wrong object" (pp. 107–108).
- Data-driven errors, where an automatic response is triggered by some external stimulus that triggers the behavior at an inappropriate time.
- Associative activation errors where, similar to a data-driven error, something triggers a behavior at an inappropriate time, but in this case the trigger is some internal thought or process.
- Loss-of-activation errors, or "forgetting to do something" (p. 109).
- Mode errors, or performing an action that would have been appropriate for one mode of operation for a system, but is inappropriate for the actual mode or state that the system is in.

26.3.1.2 Mistakes

As defined earlier, mistakes are due to incorrect knowledge (the rule, fact, or procedure that the person believes to be true is incorrect, resulting in an error) or incomplete (missing) knowledge.

26.3.1.3 Cognitive Biases

The literature on human error also provides other useful ways to classify errors in terms of surface level behavior or the underlying cognitive process. Many of these are discussed under the label of cognitive biases (Brachman and Levesque 2004; Bradfield and Wells 2005; Fraser, Smith, and Smith 1992; Gilovich, Griffin, and Kahneman 2002; Haselton, Nettle, and Andrews 2005; Kahneman and Tversky 2000; Plous 1993; Poulton 1989), including

- Gambler's fallacy (Croson and Sundali 2005). Concluding there is a pattern in a series of events that is in reality a random sequence. Gilovich, Vallone, and Tversky (1985) for instance, found that individuals believe they see streaks in basketball shooting even when the data show that the sequences are essentially random.
- Insensitivity to sample size (Bjork 1999). Failing to understand that the law of large numbers implies that the probability of observing an extreme result in an average decreases as the size of the sample increases. Tversky and Kahneman (1974), for example, found that subjects believed that "the probability of obtaining an average height greater than 6 feet was assigned the same value for samples of 1000, 100 and 10 men."
- Incorrect revision of probabilities. Failure to revise probabilities sufficiently when data are processed simultaneously, or conversely, revising probabilities too much when processing the data sequentially.
- Ignoring base rates. Failure to adequately consider prior probabilities when revising beliefs based on new data.
- Use of the availability heuristic (Blount and Larrick 2000). Tversky (1982) suggests that the probability of some type of event is in part judged based on the ability of the person to recall events of that type from memory, thus suggesting that factors like recency may incorrectly influence judgments of probability.
- Attribution errors. Jones and Nisbett (1971) describe this by noting that "there is a pervasive tendency for actors to attribute their actions to situational requirements, whereas observers tend to attribute the same actions to stable personal dispositions."
- Memory distortions due to the reconstructive nature of memory (Blank 1998; Handberg 1995). Loftus (1975) describes processes that distort memories based on the activation of a schema as part of the perception of an event, and the use of that schema to reconstruct the memory of the event based on what the schema indicates should have happened rather than what was actually perceived originally. Smith et al. (1986) and Pennington and Hastie (1992) provide descriptions of similar phenomena in decision-making tasks.

In recent years, there has been considerable controversy regarding the nature and validity of many of these explanations as "cognitive biases" (Fraser, Smith, and Smith 1992; Koehler 1996; Haselton, Nettle, and Andrews 2005), suggesting that it is important to carefully understand the specific context in order to generate predictions as to whether a particular behavior will be exhibited. Using the incorrect revision of probabilities as an illustration, Navon (1978) suggested that in many real-world settings the data are not independent, and that what appears to be conservatism in revising probabilities in a laboratory setting may be the result of the subjects applying a heuristic or cognitive process that is effective in real-world situations where the data are correlated.

A more detailed example is provided by the popular use of the label "hypothesis fixation." This behavior refers to some process that leads the person to form an incorrect hypothesis and to stick with that hypothesis, failing to collect critical data to assess its validity or to revise it in the face of conflicting data. A variety of cognitive processes have been hypothesized to cause this behavior. One example is called biased assimilation, where the person judges a new piece of data as supportive of his hypothesis (increasing the level of confidence in the hypothesis) based simply on the consideration of whether that outcome could have been produced under his hypothesis. This contrasts with inferential processes based on a normative model that suggest that beliefs should be revised based on the relative likelihood of an outcome under the possible competing hypotheses, and that would, in the same circumstance, lead to a reduction in the level of confidence in his hypothesis.

Another example of a cognitive process discussed in the literature as relevant to hypothesis fixation is the so-called "confirmation bias." This phenomenon, described in Wason (1960) and in Mynatt et al. (1978), is concerned with the person's data collection strategy. As an example, in a study asking subjects to discover the rules of particle motion in a simulated world, Mynatt et al. described performance by concluding that there was "almost no indication whatsoever that they intentionally sought disconfirmation." Later studies, however, have suggested that this "bias" is really an adaptive "positive test" strategy that is effective in many real-world settings, and that it is the unusual nature of the task selected by Mynatt et al. that makes it look like an undesirable bias (Klayman and Ha 1987). Smith et al. (1986) further suggest that, in real-world task settings where such a strategy might lead to confirmation of the wrong conclusion, experts often have domain-specific knowledge or rules that help them to avoid this strategy altogether, thus ensuring that they collect critical potentially disconfirming evidence.

26.3.1.4 Designer Error

Many of the error-producing processes discussed above appear to focus on system operators. It is important to recognize, however, that the introduction of a DSS into a system is a form of cooperative work between the users and the design and implementation team and that, like the users, the design team is susceptible to errors (Petroski 1994). These errors may be due to slips or mistakes. In the case of mistakes, it may be due to inadequate knowledge about the application area (the designers may fail to anticipate all of the important scenarios) or due to incorrect knowledge. It may also be due to a failure to adequately understand or predict how the users will actually apply the DSS, or how its introduction will influence their cognitive processes and performances. In addition, sources of errors associated with group dynamics may be introduced. Whether such errors are due to a lack of sufficient coordination, where one team member assumes that another is handling a particular issue, or due to the influence of group processes (Brehm, Kassin, and Fein 1999; Forsyth 1998; Janis 1982; Levi 2001; McCauley 1989; Tetlock et al. 1992; Tetlock 1998) on design decisions, the result can be some inadequacy in the design of the DSS, or in the way the user and the DSS work together. (Note that such group processes are also important potential sources of errors when system operators work together as part of teams, with or without technological support.)

26.3.1.5 Systems Approaches to Error

Reason (1991, 1997) and Wiegmann et al. (2004) caution designers against fixating on the immediately preceding "causes" of an accident when trying to prevent future occurrences. They remind us that, in many system failures, a number of conditions must coincide in order for the failure to occur. This presents a variety of leverage points for preventing future occurrences, many of which are preemptive and thus remote from the actual accident or system failure. Many of these changes focus on preventing the conditions that could precipitate the system failure, rather than improving performance once the hazardous situation has been encountered.

26.3.1.6 Errors and Cognitive Biases—Implications for Design

As described at the beginning of this section, the value of this literature to the designer is the guidance it provides in conducting the initial knowledge engineering studies that need to be completed in order to identify opportunities for improvement in some existing decision-making process that is to be supported by a new DSS. Familiarity with this literature is also critical to the designer to ensure that the introduction of the DSS does not result in new design-induced errors. This literature also serves to emphasize two additional considerations:

- The occurrence of errors are often due to the co-occurrence of a particular problem-solving strategy with a given task environment that is "unfriendly" to that strategy (i.e., situations where the strategy is not sufficiently robust). Strategies that were adaptive in one setting may no longer be adaptive in the newly designed environment. The potential for such a negative transfer of learning needs to be considered as part of the design.

- For routine situations, people tend to develop expertise that lets them employ knowledge rich problem-solving strategies (Crandall, Klein, and Hoffman 2006; Klein 1993; Kolodner 1993; Newell 1990) that avoid the errors that could be introduced by certain general problem-solving strategies. However, in many system designs, people are expected to act as the critical safety net during rare, idiosyncratic events that the design team has failed to anticipate. These are exactly the situations where people have to fall back on their general problem-solving strategies, and are thus susceptible to the potential errors associated with these weak problem-solving methods.

In addition, this review emphasizes the need to take a broad systems perspective, recognizing that the design and implementation team are a potential source of error, and understanding that, if the goal is to prevent or reduce the impact of errors, then the solution is not always to change performance at the immediate point where an error was made. It may be more effective to change other aspects of the system so that the potentially hazardous situation never even arises.

Finally, the emphasis on designer error implies that the design process for a DSS needs to be viewed as iterative and evolutionary. Just because a tool has been fielded, it is not safe to assume that no further changes will be needed. As Horton and Lewis (1991) discuss, this has organizational implications (ensuring adequate communications regarding the actual use of the DSS; budgeting resources to make future revisions), as well as architectural implications (developing a system architecture that enables revisions in a cost-effective manner).

26.3.2 Human Expertise

As discussed in Chapters 2–4, the nature of human information processing imposes a variety of constraints that influence how effectively a person processes certain kinds of information. These include memory, perceptual and information processing constraints. As a result, there are certain decision tasks where the computational complexity or knowledge requirements limit the effectiveness of unaided individual human performance.

From a design perspective, these information processing constraints offer an opportunity. If important aspects of the application are amenable to computational modeling, then a DSS may provide a significant enhancement of performance, either in terms of efficiency or the quality of the solution. (Note that even if development of an adequate computational model is not feasible, there may be other technological improvements, such as more effective communications environments, that could enhance performance. However, this chapter is focusing on DSSs that incorporate active information processing functions by the software.)

A good example of this is flight planning for commercial aircraft. Models of aircraft performance considering payload, winds, distance and aircraft performance characteristics (for the specific aircraft as well as the general type of aircraft) are sufficiently accurate to merit the application of DSSs that use optimization techniques to generate alternative routes and altitude profiles to meet different goals in terms of time and fuel consumption (Smith, McCoy, and Layton 1997). This example also provides a reminder, however, that it is not just human limitations that are relevant to design. It is equally important to consider human strengths, and to design systems that complement and are compatible with users' capabilities. In flight planning, for instance, this includes designing a system that allows the person to incorporate his judgments into the generation and evaluation of alternative flight plans, considering the implications of uncertainty in the weather, air traffic congestion and other factors that may not be incorporated into the model underlying the DSS.

This cooperative systems perspective has several implications. First, the designer needs to have some understanding of when and how the person should be involved in the alternative generation and selection processes. This requires insights into how the person makes decisions, in terms of problem-solving strategies as well as in terms of access to the relevant knowledge and data, and how the introduction of a DSS can influence these problem-solving processes. It also implies that the strengths underlying human perceptual processes need to be considered through display and representation aiding strategies (Burns and Hajdukiewicz 2004; Kleinmuntz and Schkade 1993; Jones and Schkade 1995; Tufte 1997) in order to enhance the person's contributions to the decision-making process by making important relationships more perspicuous or salient.

26.3.2.1 Descriptive Models

The literature on human problem solving and decision making provides some very useful general considerations for modeling human performance within a specific application. This literature, which is reviewed in more detail in Chapters 2–3, covers a variety of descriptive models of problem solving. This includes the use of heuristic search methods (Clancey 1985; Dasgupta, Chakrabarti, and Desarkar 2004; Michalewicz and Fogel 2004; Michie 1986; Rayward-Smith et al. 1996; Russell and Norvig 1995). This modeling approach (Newell and Simon 1972) conceptualizes problem solving as a search through a space of problem states and problem-solving operations to modify and evaluate the new states produced by applying these operations. The crucial insight from modeling problem solving as search is an emphasis on the enormous size of the search space resulting from the application of all possible operations in all possible orders. In complex problems, the size of the space precludes exhaustive search of the possibilities to select an optimal solution. Thus, some heuristic approach that satisfies, such as elimination by aspects (Tversky 1972), is needed to guide a selective search of this space, resulting in the identification of an acceptable (if not optimal) solution.

Another aspect of problem solving that Newell and Simon noted when they formulated the search paradigm was the importance of problem representation. Problem representation issues emphasize that a task environment is not inherently objectively meaningful, but requires interpretation for problem solving to proceed. Some interpretations or representations are more likely to lead to successful solutions than others (for certain agents). In fact, an important component of expertise is the set of features or the representation used to characterize a domain (Lesgold et al. 1988), sometimes referred to as domain ontology.

Task-specific problem spaces allow problem solvers to incorporate task- or environment-induced constraints, focusing attention on just the operations of relevance to preselected goals (Sewell and Geddes 1990). For such task-specific problem solving, domain-specific knowledge (represented in computational models as production rules, frames, or some other knowledge representation) may also be incorporated to increase search efficiency or effectiveness (Dechter 2003; Ghallib, Nau, and Traverso 2004; Laird, Newell, and Rosenbloom 1987; Shalin et al. 1997).

These models based on symbolic reasoning have been specialized in a number of powerful ways for specific generic tasks like diagnosis or planning (Chandrasekaran 1988; Ghallib, Nau, and Traverso 2004; Gordon 2004; Miller, Galanter, and Pribram 1960; Mumford, Schultz, and Van Doorn 2001; Nareyek, Fourer, and Freuder 2005). For example, computational models of planning focus on the use of abstraction hierarchies to improve search efficiency (Sacerdoti 1974), dealing with competing and complementary goals (Wilenski 1983) and mixed top-down/bottom-up processing (Hayes-Roth and Hayes-Roth 1979) to opportunistically take advantage of data as it becomes available. More recent developments have sought to deal with planning in stochastic environments (Madani, Condon, and Hanks 2003; Majercik and Littman 2003).

In contrast to such sequential search models, models based on case-based reasoning, recognition primed decision making or analogical reasoning (Crandall, Klein, and Hoffman 2006; Klein 1993; Kolodner 1993; Riesbeck and Schank 1989) focus on prestructured and indexed solutions based on previously experienced situations. These modeling approaches suggest that human experts in complex operational settings rarely describe their cognitions as sequential searches to construct alternative solution states, but rather as recognition processes that match features of the situation to prototypical, preformulated response plans (Zuboff 1988; Rasmussen 1983). In complex dynamic domains (Oliver and Roos 2005) like aviation or firefighting, these preformulated plans incorporate a great deal of implicit knowledge reflecting the constraints of the equipment, the environment, other participants in the work system, and previous experience. Over time, solutions sensitive to these constraints result in familiar, accepted methods which are then triggered by situational cues and modified in small ways as needed to deal with the specific scenario. However, it is important to recognize that such recognition-based processes can cause familiar task features to invoke only a single interpretation, resulting in hypothesis fixation or hindering creative departure from normal solutions. This limitation can be critical when the task environment contains a new, unexpected feature that requires a new approach.

26.3.2.2 Normative Optimal Models

In addition to these descriptive models, there is a large literature that characterizes human decision making relative to various normative models based on optimal processes, which help to emphasize important factors within the task and task environment that should be considered in making a decision in order to arrive at a better decision. These normative models are based on engineering models such as statistical decision and utility theory, information theory, and control theory (Jagacinski and Flach 2003; Rouse 1980; Sheridan and Ferrell 1974). By contrasting human performance with optimal performance on certain tasks and emphasizing the factors that should influence decision making in order to achieve a high level of performance, this literature helps the designer to look for areas where human performance may benefit from some type of DSS.

Finally, the literature on human expertise (Charness et al. 2006) emphasizes the ability of people to learn and adapt to novel situations, and to develop skeletal plans that guide initial decisions or plans, but that are open to adaptation as a situation unfolds (Geddes 1989; Suchman 1987; Wilenski 1983). The literature also emphasizes variability, both in terms of individual differences and in terms of the ability of a single individual to use a variety of decision-making strategies in some hybrid fashion in order to be responsive to the idiosyncratic features of a particular scenario.

26.3.2.3 Human Expertise—Implications for Design

An understanding of the literature on human expertise is of value to the designer in a number of different ways (Chi et al. 1998). First, in terms of the initial problem-definition and knowledge engineering stages, familiarity with models of human problem solving and decision making can help guide the designer in looking for important features that influence performance within that application. Second, in an effort to provide cognitive compatibility with the users, the design of many of the technologies underlying DSSs is guided by these same computational models of human performance. Third, even if the underlying technology is not in some sense similar to the methods used by human experts in the application, the designer needs to consider how the functioning of the DSS system should be integrated within the user's decision-making processes.

In terms of some specific emphases, the above discussion suggests the following:

- Do not fixate on active DSS technologies as the only way to improve system performance. Enhancing human performance through changes in procedures, improvements in passive communication tools, better external memory aids, and so on, may be more cost-effective in some cases. In addition, such changes may be needed to complement an active DSS in order to make its use more effective.

- Look for ways in which the direct perception of ecological constraints allows people to perform expertly (Flach et al. 1995). The ability to perceive these critical parameters or constraints directly may make what seems like a very difficult information processing task much less demanding.
- Related to the consideration of ecological constraints was the earlier suggestion that problem representation has a strong influence on how easily a problem solver can find a good solution. This issue of perspicuity (salience of the problem solution), however, is dependent not only on the characteristics of the task and task environment, but also on the nature of the problem solver. Thus, in order to enhance human performance as part of the decision-making process, it is important to consider alternative ways of representing the situation that will enable human perceptual and cognitive processes to work more effectively. In addition, problem representation can affect the performance of the designer. Consequently, alternative problem representations need to be generated as part of the design process to help the designer think more effectively.
- Consider the applicability of normative optimal models of performance for the task in order to focus attention on factors that should be influencing current performance, and to contrast optimal strategies with the strategies that people are actually using in response to these task-determined factors. Aspects of these normative models may also be appropriate for more direct inclusion in the DSS itself, even though the strategies used by people do not fully reflect the optimal processes highlighted by these normative models. In addition to considering the task structure highlighted by normative optimal models, use knowledge of the variety of different descriptive models of human problem solving and decision making to guide knowledge engineering efforts, making it easier and more efficient to understand how people are currently performing the tasks. Thus, all of these models of decision making represent conceptual tools that help the designer to more effectively and efficiently understand performance in the existing system, and to develop new tools and procedures to improve performance.
- Whether the DSS is designed to process information "like" the user at some level, or whether it uses some very different processing strategy, the user needs to have an appropriate and effective mental model of what the system is and is not doing (Kotovsky, Hayes, and Simon 1985; Lehner and Zirk 1987; Nickerson 1988; Zhang 1997; Zhang and Norman 1994). To help ensure such cognitive compatibility, the designer therefore needs to understand how people are performing the task.
- Consider design as a prediction task, trying to predict how users will interact with the DSS system, and how it will influence their cognitive processes and performances.

26.3.3 Additional Cognitive Engineering Considerations

Sections 26.3.1–26.3.2 focused on our understanding of human performance on decision-making tasks and the implications of that literature for design. Below, some additional considerations based on studies of the use of DSSs are presented.

26.3.3.1 Human Operator as Monitor

Numerous studies make it clear that, given the designs of DSSs for complex tasks must be assumed to be brittle, there is a problem with designs that assume that human expertise can be incorporated as a safety net by asking a person to simply monitor the output of the DSS, with the responsibility for overriding the software if a problem is detected. One problem with this role is that, in terms of maintaining a high level of attentiveness, people do not perform well on such sustained attention tasks (Meister and Enderwick 2002). As Bainbridge (1983, p. 776–7) notes: "We know from many 'vigilance' studies (Mackworth 1950) that it is impossible for even a highly motivated human being to maintain effective visual attention toward a source of information on which very little happens, for more than about half an hour. This means that it is humanly impossible to carry out the basic function of monitoring for unlikely abnormalities."

A related issue is the problem of loss of skill. As Bainbridge further notes, if the operator has been assigned a passive monitoring role, he "will not be able to take over if he has not been reviewing his relevant knowledge, or practicing a crucial manual skill." Thus, a major challenge for retaining human expertise within the system is "how to maintain the effectiveness of the human operator by supporting his skills and motivation."

26.3.3.2 Complacency and Overreliance

Studies reported by Parasuraman and Riley (1997) and Parasuraman (2000) introduce further concerns about assigning the person the role of critiquing the computer's recommendations before acting. These studies discuss how the introduction of a DSS system can lead to overreliance by the human user when the software is generating the initial recommendations (Metzger and Parasuraman 2005; Skitka, Mosier, and Burdick 1999).

26.3.3.3 Excessive Mental Workload

Designs that relegate the person to the role of passive monitor run the risk of a vigilance decrement due to insufficient engagement and mental workload. At the other extreme, designers must recognize that "clumsy automation" that leaves the person with responsibility for difficult parts of the task (such as coping with an emergency), but that adds additional workload (Kushleyeva et al. 2005) due to the awkward interactions now required to access information and functions embedded in the DSS (such as navigating through complex menus to view certain information), can actually impair performance because of the added mental workload of interacting with the DSS (Wiener and Nagel 1988). One line of research that is now getting increased attention is the potential to design adaptive systems that can monitor the human operator using neurophysiological measures that attempt to detect problems with alertness, mental workload or attention (Caggiano and Parasuraman 2004; Freeman, Mikulka, and Scerbo 2004; Grier, Warm, and Dember 2003; Mikulka, Scerbo, and Freeman 2002; Luo, Greenwood, and Parasuraman 2001). This work seeks to "determine whether a biocybernetic, adaptive system could enhance vigilance performance," with the goal of improving "monitoring performance on critical activities such as air traffic control and radar and sonar operation" (Mikulka, Scerbo, and Freeman 2002, p. 654), or offloading work to software or other people when the computer detects that excessive attentional demands are being placed on an individual.

26.3.3.4 Lack of Awareness or Understanding

Even if the person is sufficiently engaged with the DSS and the underlying task, designers need to consider how to ensure that the user has an accurate mental model of the situation, and of the functioning and state of the DSS (Billings 1997; Larkin and Simon 1987; Mitchell and Miller 1986; Roth, Bennett, and Woods 1987; Sarter and Woods 1993). If the person does not have such an understanding, then it may be difficult for him to intervene at appropriate times or to integrate the computer's inputs into his own thinking appropriately (Geddes 1997b). This concern has implications for selection of the underlying technology and conceptual model for a system, as well as for the design of the visual or verbal displays intended to represent the state of the world and the state of the software for the user, including explanations of how the DSS has arrived at its recommendations (Clancey 1983; Hasling, Clancey, and Rennels 1984; Nakatsu and Benbasat 2003).

26.3.3.5 Lack of Trust and User Acceptance

As outlined earlier, overreliance can be a problem with certain assignments of roles to the person and the computer. At the other extreme, lack of trust or acceptance of the technology can eliminate or reduce its value (Clarke et al. 2006; Muir 1987). This lack of acceptance can result in outright rejection of the DSS (in which case it either is not purchased or not used), or in a tendency to underutilize it for certain functions. It is important to note that this lack of acceptance can be due to resistance to change (Cartwright and Zander 1960; Forsyth 1998; Levi 2001) even if there is no intrinsic weakness in the DSS, due to general beliefs held by the operators (rightly or wrongly) about how the software will influence their lives, or due to beliefs about how well such a DSS can be expected to perform (Andes and Rouse 1992; Lee and See 2004; Marsh and Dibben 2003; Muir and Moray 1996; Riegelsberger, Sasse, and McCarthy 2005).

26.3.3.6 Active Biasing of the User's Cognitive Processes

Complacency is one way in which a DSS can influence the person's cognitive processing. Studies have also shown, however, that the use of a DSS can also actively alter the user's cognitive processes (Beach and Connally 2005; Larsen and Hayes 2005; Smith, McCoy, and Layton 1997). The displays and recommendations presented by the software have the potential to induce powerful cognitive biases, including biased situation assessment and failures by the user to activate and apply his expertise because normally available cues in the environment are no longer present. The net result is that the person fails to exhibit the expertise that he would normally contribute to the decision-making task if working independently, not because he lacks that expertise, but because the computer has influenced his cognitive processes in such a way that this knowledge is never appropriately activated. Studies have shown that these biasing effects can induce practitioners to be 31% more likely to arrive at an incorrect diagnosis on a medical decision-making task (Guerlain et al. 1996) and 31% more likely to select a very poor plan on a flight planning task (Smith, McCoy, and Layton 1997).

26.3.3.7 Distributed Work and Alternative Roles

Much of the literature focuses on the interactions between a single user and the DSS. Increasingly, however, researchers and system developers are recognizing that one approach to effective performance enhancement is to think in terms of a distributed work paradigm (Schroeder and Axelsson 2005; Smith, McCoy, and Orasanu 2001), where the software may be one "agent" in this distributed system (Geddes and Lizza 1999), or where the software may be viewed primarily as a mediator to support human–human interactions within virtual or distributed teams (Baecker et al. 1995; Bowers, Salas, and Jentsch 2006; Caldwell 2005; Carroll et al. 2003; Handy 1995; Hertel, Geister, and Konradt 2005; Hinds and Kiesler 2002; Hinds and Mortensen 2005; Hutchins 1990, 1995; Katz et al. 2004; Lurey and Raisinghani 2001; Olson and Olson 1997, 2003; Orasanu and Salas 1993; Rasmussen, Brehner, and Leplat 1991; Salas, Bowers, and Edens 2001; Salas and Fiore 2004; Smith et al. 1997). Such distributed systems can now be found in the military, in medicine, in aviation and a variety of other application areas.

Sycara and Lewis (2004) suggest that

> There are three possible functions that software agents might have within human teams:
>
> 1. Support the individual team members in completion of their own tasks
> 2. Assume the role of a (more or less) equal team member by performing the reasoning and tasks of a human teammate
> 3. Support the team as a whole (p. 204), and that "teams could be aided along four general dimensions: accessing information, communicating, monitoring, and planning" (p. 227).

In considering the design and use of DSSs for such applications, all of the more traditional factors must be considered. In addition, questions regarding the impact of the technology on team situation awareness (Endsley 2003), rapport, trust, and communication become paramount. It is also important to think of a broader set of design parameters, as distributed approaches to work open up the potential to use a variety of different architectures for distributing the work in terms of the locus of control or responsibility and the distribution of knowledge, data, and information processing capabilities (Griffith, Sawyer, and Neale 2003; Sheridan 1997; Sheridan 2002; Smith et al. 1997; Smith McCoy, and Orasanu 2000; Smith et al. 2003). Furthermore, DSSs may be necessary to make effective certain architectures for distributing the work.

26.3.3.8 Organizational Failures

The discussions above focus on design-induced errors made by the system operators. It is equally important for the design team to recognize that part of the design process is ensuring that the management of the organization into which the DSS is introduced will provide an effective safety net. This means that the design team needs to ensure that the organization has established effective procedures to detect significant problems associated with the introduction and use of the DSS, and that such problems are communicated to the levels of management where responsibility can and will be taken to respond effectively to these problems (Horton and Lewis 1991).

26.3.3.9 Social Responses to Computers

An accumulating body of research indicates that people respond to computers with strong social responses even when they consciously claim to think of computers as machines (Nass, Steuer, and Tauber 1994; Wang et al. 2005; Hayes and Miller 2010). For example, Johnson found that when the computer tutor, Adele, corrected learners with the same wording multiple times, they commented that Adele had a stern personality and low regard for their work (Johnson et al. 2003). As a second example, when computer agents are given human voices or faces, users often apply the same prejudices to the computer agents which they apply to different races or genders (Nass, Moon, and Green 1997; Gong 2008).

However, people have social responses to computers, regardless of whether the computers have anthropomorphic forms, faces, or voices (Nass, Steuer, and Tauber 1994), although the effect may be stronger when they are anthropomorphic. It is important for DSS designers to understand this, because users frequently react to computer applications as if they were social beings rather than simply "dumb" machines. Conversely, they may expect computer applications to interact with them according to culturally accepted norms for politeness (Hayes and Miller 2010). Software that does not follow these norms, for example by interrupting at inappropriate times, often irritates users and may lead to disuse of that application. Consider "help" applications that pop-up on the screen on their own, interrupting one's flow of thought, and requiring action to get rid of them. Such "helpful" programs are often turned off. However, following these norms may increase users' willingness to accept and use an application while increasing that application's effectiveness. For example, students may learn more from Adele if they feel respected and supported by her; users may be more motivated to continue and maintain exercise programs if their computer exercise advisor follows conventions for conversations (opening with small talk), and shows appropriate expressions (Bickmore 2010). The challenge in programming DSSs and other computer applications to follow culturally accepted norms for interaction is that many of these norms are implicit. We use them often without consciously being aware of what they are.

There are numerous applications where the utility of a DSS is enhanced if the user develops a certain appropriate level of trust in the DSS, and/or a long-term "relationship" with it. For example, "smart" medicine dispensers that remind patient's when they have skipped a dose (Wu et al. 2010); medical robots which monitor patient health, bring meals or medication, or assist patients in walking (Zhang, Zhu, and Kaber 2010); message managers used by dismounted soldiers (Dorneich et al. 2010); computer tutors (Johnson and Wang 2010); and exercise coaches whose success depends on their ability to engage the patient and keep them motivated over periods of months or years to continue an exercise program (Bickmore 2010). Norms for social interaction in a computer agent with a face, such as a computer tutor, health coach, or medical robot may extend to more than just what they do and say, but also to facial expressions. For example, the computer agent should not smile or laugh when the patient is explaining his or her frustration with his or her inability to manage pain.

In such applications, it has been demonstrated experimentally that a DSS can help soldiers to manage critical information more effectively under stress if the DSS follows rules of social interaction such as when to interrupt or not (Dorneich et al. 2010). Additionally, students have better learning outcomes when their computer tutor understand the rules of social engagement and politeness (Johnson et al. 2003), and soldiers are more likely to comply in a timely manner to a request made by a DSS when it exhibits an appropriate level of politeness and deference to rank in the phrasing of that request. Likewise, the goal in making polite medication reminder systems, medical robots, and computer health coaches is better patient compliance, and greater long-term adherence to health care and exercise programs.

26.4 CASE STUDIES

Below, case studies are presented focusing on the designs of several quite different DSSs. Within these case studies, a number of the issues raised earlier are discussed in more detail within the context of real-world applications, along with presentations of design solutions that provide concrete illustrations of how to deal with those issues.

26.4.1 Case Study A: Distributed Work in the National Airspace System—Ground Delay Programs

Earlier in this chapter, we indicated that a distributed work system can be characterized in terms of the assignment of control or decision-making authority in relationship to the distribution of knowledge and data. The Federal Aviation Administration's (FAA's) Enhanced Ground Delay Program (GDP) provides a very informative example for illustrating the significance of these parameters when designing a distributed system.

26.4.1.1 Application Area

The FAA's Enhanced GDP has been in operation since 1998. Its goal is to help match the arrival demand at an airport with the available capacity, where demand could exceed capacity because of a weather constraint at that airport, a closed runway, and so on.

The strategy underlying the use of GDPs is to delay departures to the constrained airport, holding these departures on the ground when that airport's arrivals are predicted to exceed capacity. Such a strategy has potential benefits for the FAA in terms of reducing air traffic controller workload (reducing the need for the use of airborne holding or some other air traffic control tactic). It also has potential benefits for the National Airspace System (NAS) Users, as it can be more economical to delay departures, holding these flights on the ground (reducing fuel consumption due to airborne holding as well as reducing the potential for diversions).

26.4.1.2 Original Approach to Distributing Work in a GDP

In principle, there are a variety of different ways to implement GDPs. Prior to 1998, the FAA used GDPs, but did so using an approach that was much less effective than the currently used procedure. Under this original paradigm, traffic managers at the FAA's Air Traffic Control Systems Command Center (ATCSCC) would set the airport arrival rate (AAR) for an airport, and then a DSS would automatically assign an arrival slot to each specific flight, which would then be held on the ground until it was time to depart to make its assigned arrival slot. NAS Users had one opportunity to swap flights in a batch mode (i.e., requesting all of the swaps at one time). This limited their ability to monitor the development of the situation over time and adapt as new information became available. In addition, although NAS Users were asked to cooperate in order to make this program work, there was actually a disincentive for them to provide the FAA with information about cancellations or potential delays. If the cancellation of a flight was reported to the FAA, the NAS User lost its assigned arrival slot; and if it was reported that a flight was going to miss its departure time (because of a mechanical problem, for instance), that flight could be assigned an even greater delay. As a result, NAS Users often chose to withhold this information from the FAA, resulting in unused arrival slots (wasted capacity).

26.4.1.3 Alternative Approach to the Design of GDPs

Given these limitations, a joint industry FAA program evolved to identify and implement a different approach to GDPs. This Collaborative Decision-Making (CDM) program explored methods for still achieving the FAA's primary goal (matching arrival rates to airport capacity), while giving NAS Users the flexibility to better achieve their business goals.

One approach would have been to have NAS Users provide the FAA with all of the knowledge and data about their business concerns relevant to decisions about which flights to assign to which arrival slots. In principle, the FAA traffic managers could have then determined "good" slot allocations for each NAS User, and assigned flights to slots accordingly. Such a decision would have had to somehow take into consideration the competitive nature of this situation and through some decision process determine an "equitable" solution.

It was decided that such an approach would produce unrealistic demands in terms of cognitive complexity and mental workload for these traffic managers, as they would have had to master the relevant expertise of the dispatchers working for each NAS User and to somehow use that knowledge to generate equitable slot assignments. (Dispatchers work for airlines and other general aviation operations that are required to, or choose to, abide by Part 121 regulations of the U.S. Federal Air Regulations, sharing responsibility for each flight with the pilots. They complete the preflight planning for a flight—determining its route, departure time, fuel load, and so on—and are also responsible for following that flight while it is airborne.)

26.4.1.3.1 Strategy for Distributing Work

Instead, the CDM program developed a new architecture for distributing the work associated with GDPs. This architecture uses a classic systems engineering approach for dealing with complexity, decomposing the overall plan for a GDP into a set of nearly independent subplans that can be developed by different individuals and that, when completed by each of these individuals, achieves the desired goals (assuming the plan is successfully implemented). The significance of the qualifier "nearly" should not be overlooked in terms of its importance, however. The reality is that there are cases where interactions among these different individuals are required, so the system design has to include mechanisms that support such interactions in order to ensure that the appropriate perspectives are considered in setting up a GDP, and that exceptions can be made for individual flights when that is required to deal with some overriding consideration.

Like the original GDP, this Enhanced GDP starts with the assumption that a "neutral resource broker" is needed because, in situations where a GDP is called for, the NAS Users are competing for a limited resource (arrival slots at the constrained airport). The critical difference, however, is the application of the following principle:

> The "referee" (the FAA) should only control the process at the level of detail necessary to achieve its goals concerned with safety and throughput, thus allowing NAS Users the

flexibility to try to achieve their own goals to the extent possible subject to this higher level constraint.

Thus, the critical change is the level of abstraction at which ATCSCC (the neutral referee) controls the process. Instead of determining which specific flights are allocated to specific arrival slots, ATCSCC determines the start and stop times for the GDP, the arrival rate for the constrained airport, and the departure airports to be included in the GDP, and then assigns arrival slots to specific NAS Users (such as a specific airline) rather than to specific flights (using a software tool implemented by Metron Aviation called the Flight Schedule Monitor [FSM], shown in Figure 26.1).

The NAS User can then decide for itself which of its flights to assign to one of its arrival slots. An airline might, for instance, have flights from Dallas, Chicago and Miami all scheduled to fly to LaGuardia in New York, all scheduled to arrive between 1800Z–1815Z, and all included in a GDP for LaGuardia. If that airline was given "ownership" of an arrival slot at 1855Z in a GDP for LaGuardia, it could assign that slot to any one of these three flights based on their relative importance to that airline's business concerns—considering factors such as passenger connections, aircraft requirements for later flights out of LaGuardia, crew time restrictions, and aircraft maintenance schedules.

26.4.1.3.2 Ration-by-Schedule

In order to accomplish this new process, there are several requirements. First, a traffic manager at ATCSCC has to set the start and end times and the AAR, and determine which departure airports to include. To do this, ATCSCC solicits input from the relevant FAA facilities and the NAS Users. This interaction takes the form of a teleconference that is held every 2 hours, during which ATCSCC can propose the use of a GDP and provide an opportunity for input from each of the participants. This decision-making process is supported by a simulation or "what-if" function in FSM that allows the user to input a set of parameters (proposed arrival rate, start and end times, and included departure airports) and view the predicted impact in terms of average and maximum delays, and the potential for a spike in demand at the airport after the end time for the GDP. Window 3 in Figure 26.1 shows such a demand pattern for San Francisco (SFO) in 1-hour time bins. The predicted peak demand, for instance, is 45 flights arriving during the 0200Z hour.

After considering these inputs, the ATCSCC traffic manager sets the parameters for the GDP, and lets FSM determine the arrival slot allocations for each NAS User. These allocations are based on "Ration-by-Schedule" (RBS) logic. The number of arrival slots each user gets is proportional to its share of the flights that are included in the GDP that were originally scheduled to arrive at the constrained airport. The slots "owned" by that NAS User are initially assigned to its aircraft based on the order of their originally scheduled arrival times (see Figure 26.2). Thus, if that NAS User originally has 20 flights out of a total of 80 flights that are included in the GDP and are scheduled to arrive at the constrained airport from 1300Z to 1400Z (for a GDP from 1200Z to 1900Z), and if the GDP requires this total of 80 to be reduced to 40, then that NAS User gets 10 slots from 1300Z–1400Z. As a default, the first 10 of its included flights scheduled to arrive after 1300Z are assigned these 10 slots. The arrival times for the remaining 10 flights are pushed back to slots after 1400Z.

Note that, to make this logic work, the GDP needs to cover a time period where, during the GDP or just after its end, there are valleys in the predicted demand that fall below the reduced AAR, so that the program does not create a huge peak in arrival demand at the end of the GDP. The parameters defining the GDP, along with the slot allocations, are then disseminated to the NAS Users.

26.4.1.3.3 Slot Swapping

Abstractly, the strategy of controlling the process at a more abstract level (by setting an AAR) and the strategy of using the RBS algorithm to ration slots to NAS Users are critical,

FSM live data monitor mode

The FSM display consists of four main windows. Clockwise, starting from the upper right, they are as follows:

1. The control window
2. The flight information window
3. The demand graph
4. The timeline

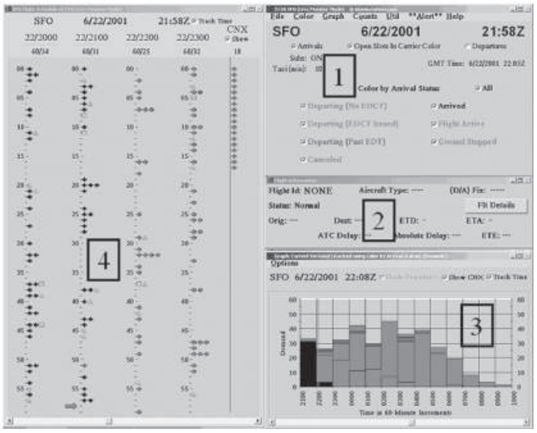

FIGURE 26.1 Screen display from FSM. Window 1 controls the display of information in FSM; Window 2 provides access to information about specific flights included in the GDP; Window 3 provides an indication of the predicted arrival rate, with the display changing based on the parameters set for the GDP, thus supporting "what-iffing"; Window 4 indicates the predicted arrival times for individual flights. (Data from Metron Aviation, Inc.)

as they make it possible to distribute the overall work as relatively independent subtasks. The task of the FAA (the neutral referee) is to set the high-level control parameters. The NAS Users can then work within the resultant constraints to implement plans for their own fleets that are most effective from a business perspective.

The NAS Users accomplish this by swapping flights among assigned arrival slots. Each NAS User can do this by swapping flights among its own slots (see Figure 26.3), or by making a swap with a slot "owned" by another NAS User if such a swap is available.

Traditionally, decisions about what to do with a particular flight were handled by the individual dispatcher responsible for that flight. However, this new process involves making global decisions that consider trade-offs among a number of flights. As a result, instead of requiring some type of potentially time consuming collaboration among the affected dispatchers in that NAS User's Flight Operations Center, the responsibility for managing participation in a GDP has been assigned to a single senior dispatcher (often a new position referred to as the Air Traffic Control [ATC] Coordinator).

Most ATC Coordinators manage the GDP for their fleets using another set of DSSs that allow the ATC Coordinator to

- Test alternative GDPs (GDPs with different parameters) to see which alternative is best from his fleet's perspective. (This information can be used for discussions during the planning teleconference in which the GDP is proposed, providing input to ATCSCC regarding the GDP parameters that should be used.)

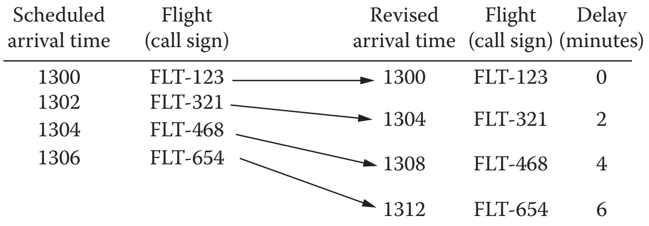

FIGURE 26.2 Arrival slot allocation using the Ration-By-Schedule algorithm. (Assume that the arrival airport can normally handle one arrival every two minutes. If the GDP reduces the arrival rate by 50% for all arrivals, then the flights are assigned revised arrival slots that keep the original ordering, but show increasing delay over time.)

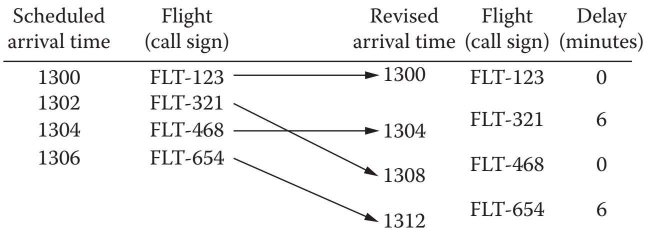

FIGURE 26.3 Arrival slot allocation after swapping FLT-321 and FLT-468. (Note that FLT-468 now has 0 minutes of delay instead of its original 4 minutes of delay.)

- Swap arrival slots among different flights in the fleet either manually or through an automated process. (It is not unusual to make swaps involving a hundred flights based on passenger connections. This requires a DSS that uses an algorithm to estimate the relative importance of the different flights. The ATC Coordinator can, however, constrain or override the solution recommended by the DSS.)
- Test for the impact of strategies for canceling flights or delaying their departure times.

Figure 26.3 illustrates swapping flights belonging to the same NAS User. One very important variation of this feature is canceling a flight and then using its slot to swap with another flight. This is important because this provides the incentive for the NAS User to provide the FAA with critical information:

> According to the "rules of the game" for GDPs (Smith et al. 2003), when the NAS User cancels a flight, that User gets to keep its arrival slot and can swap it just like any other slot under its control. In order to make swaps with canceled flights, however, the User must inform the FAA of the cancellation (accomplished through digital software communications).

This swapping process is further enhanced by a procedure that allows swapping among the different NAS Users. This procedure is referred to as Slot-Credit Substitution.

Slot-credit substitution is best understood in the context of making a decision to cancel a flight. Suppose Airline ABC has flights that arrive every hour on the hour from LGA (LaGuardia Airport) to ORD (Chicago O'Hare). As shown in Figure 26.4, these flights are scheduled to arrive at ORD at 1000Z, 1100Z, 1200Z, and 1300Z.

Suppose a GDP is issued for ORD that delays these flights, assigning revised arrival times (slots) of 1030Z, 1200Z, 1300Z, and 1400Z, respectively. In principle, each of these flights is still capable of departing on time and therefore arriving at its originally scheduled arrival time if a suitable swap could be found to eliminate its delay due to the GDP. Thus, the earliest runway time of arrival (ERTA) for each of these flights is the same as its originally scheduled arrival time. Each flight could, in principle, therefore be swapped to move its arrival to its ERTA. However, it could not be swapped earlier than its ERTA.

Given this situation, the ATC Coordinator for Airline ABC would be willing to cancel Flight 1 (and put the passengers on the next flight) if this would significantly reduce the delay on later flights. In the case shown in Figure 26.4,

Flight	Scheduled arrival time	ERTA(Z)	CTA(Z)	Delay (minutes)
1	1000	1000	1030	30
2	1100	1100	1200	60
3	1200	1200	1300	60
4	1300	1300	1400	60

FIGURE 26.4 Times associated with flights from LGA-ORD with departure delays assigned by a GDP.

however, even if he cancels Flight 1, the slot released is too early for Flight 2 (a flight with an 1100Z ERTA is too late to make use of a slot with a 1030Z CTA). However, there is another airline out there that wants a slot with a 1030Z CTA, and would gladly give up an 1100Z slot to get it. We know this because the ground delay program software detects that another airline has a flight with an 1100Z CTA and has set its ERTA to 1030Z or earlier.

In this case the steps in process work as follows: Airline ABC sends a message saying,

> I am willing to cancel Flight 1 and give up my 1030Z CTA *only if*
>
> a. I can get a slot at 1100Z and put Flight 2 into it
> b. Moving Flight 2 frees up a CTA at 1200Z into which I will put Flight 3
> c. Moving Flight 3 frees up a CTA at 1300Z into which I will put Flight 4.

The ground delay program software looks for a flight to form the necessary bridge and when it finds the one mentioned above, it approves the entire transaction. (If it could *not* find a suitable flight to form the bridge, it would have rejected the entire transaction and Airline ABC would not have been obligated to cancel Flight 1.)

Note that it is not the setting of the ERTA that kicks off the Slot-Credit Substitution process. (ERTAs are always set as a matter of course, by default set as the originally scheduled or filed arrival time for each flight.) Rather, it is the airline's request for a Slot-Credit Substitution transaction that causes the ground delay program software to search for a suitable bridge.

Overall, then, this process has truly distributed the work by changing the locus of control and the parameters of control for certain decisions. The ATCSCC traffic manager's task is to assign the parameters defining the GDP. The ATC Coordinators for each NAS User can then, subject to the constraints imposed by the established GDP, make decisions about which flights to assign to which slots and can even, by setting ERTAs, offer to swap arrival slots with other NAS Users.

26.4.1.3.4 Adapting to Deal with Uncertainty

The GDP process as described thus far basically assumes that the NAS is a deterministic process. If this assumption was true, and if the decision makers had perfect information, then the process would run in a flawless manner, with the right number of flights arriving at the constrained airport at the right time.

However, there are numerous sources of uncertainty in the NAS. The duration and extent of weather constraints are not totally predictable; the estimated time required to clear an aircraft with a blown tire off a runway may be wrong; a flight may miss its assigned departure slot (calculated by working backward from its assigned arrival time and its estimated air time); or a flight may take more or less time than predicted to arrive once airborne. To deal with these uncertainties, certain forms of adaptation have been built into the process.

First, ATCSCC can override the slot allocation for any individual flight, and assign it some other earlier time because of an extenuating circumstance. (In the parlance of the field, such a flight is referred to as a "white hat.") Second, if there are a number of slots before the end of the GDP that have not been filled with active flights, ATCSCC can run a "compression" algorithm that moves later flights up into those slots (subject to the constraints imposed by the ERTAs for those flights and the rule that a flight cannot be moved up to a slot that would require it to depart within the next 30 minutes). Third, ATCSCC can revise the GDP itself because the original predictions or resultant decisions have turned out to be too inaccurate, setting new parameters (such as a new AAR or a new end time) and causing a major shift in arrival slot assignments.

A fourth method for dealing with uncertainty is to pad the original estimate for the AAR. The major reason for doing this is to deal with potential "pop-up" flights. As described earlier, slots are allocated based on the available schedule for arrivals at an airport. However, many general aviation aircraft do not publish a schedule indicating where and when they plan to fly on a given day. They fly on an as-needed basis for their owners. Nevertheless, they still need to be accommodated by the system. To deal with such flights, when setting the AAR using FSM, the ATCSCC traffic manager can indicate the number of pop-ups to plan for, thus leaving some open slots for those flights. When such a flight files its flight plan, it is then assigned the average delay that was assigned to those flights that are now, under the GDP, expected to arrive in the same 15-minute period.

26.4.1.3.5 Administrative Controls

In addition to these real-time decisions, the overall process is monitored for problems. One such potential problem is the quality of the data submitted by a NAS User. To deal with this issue, three metrics are monitored:

- Time-out cancels. A time-out cancel is a flight that is expected to operate (one that was scheduled, but for which a cancellation message was never submitted), but either never operates, or operates well after its assigned departure slot.
- Cancelled-but-flew flights. A cancelled-but-flew flight is a flight that the participant cancels but that ends up operating.
- Undeclared flights. An undeclared flight is a flight belonging to a NAS User that normally submits a schedule of its expected flights for each day, and that operates without prior notice to the system.

NAS Users must demonstrate acceptable performance in terms of these metrics in order to continue to participate in using the slot-swapping functions provided by GDPs. This helps to ensure sufficient data integrity for the overall process to function as planned.

A second area requiring administrative oversight is a concern over gaming. Suppose, for example, that SFO has a GDP in effect because of reduced visibility at that airport. A flight that wants to fly to SFO should take a delay based on this GDP. However, if it files for OAK (Oakland, an airport very close to SFO) instead, and then requests an amendment to land instead at SFO once airborne, it has violated the spirit of the GDP program. ATCSCC monitors for such practices, and takes administrative actions to prevent them in the future.

26.4.1.4 Evaluation of the Implemented Solution

There are two components of the benefits from the Enhanced GDP which has been described above in terms of its major features. The first is the benefit to the NAS Users derived from swapping flights in order to reduce delays for their higher priority flights. These savings are clearly very substantial, but would be very difficult and time consuming to estimate. As a result, to date no study has been conducted to put a dollar figure on that class of benefits.

The second benefit arises from the use of the compression process to fill in unused arrival slots, therefore reducing overall delays. Figure 26.5 shows the frequency of use of the Enhanced GDP process since the introduction of the compression process in 1999. Note that, over the past 2 years, it has not been uncommon to run as many as 100 GDPs per month. Table 26.1 then provides an estimate of the minutes and dollars saved by the compression process alone, using a conservative average cost per minute of operation for a flight of $42/min. These estimates suggest that the use of the compression process alone reduced delay by 28,188,715 minutes from March 18, 1999 to June 30, 2005, thus saving over one billion dollars.

26.4.1.5 Conclusions

The Enhanced GDP illustrates a deliberate effort to design a distributed work system. The design strategy is to have one party (ATCSCC as a neutral referee) set a high-level constraint (the AAR), and to then let the other involved parties (the NAS Users) find solutions that meet their business needs as effectively as possible subject to that constraint (by swapping slots among flights to favor the highest priority flights). Taking this approach, knowledge and data remain distributed, matching the locus of control for the various decisions that need to be made.

TABLE 26.1
Time and Money Savings from the Use of the Compression Process in GDPs for 1999–2005

- Data Included in Analysis:
  - All compression from Mar. 18, 1999–June 30, 2005
  - 3,573,796 flights included
  - 28,188,715 total minutes reduced
  - $1,183,926,030 (@$42/min) dollars saved
- Departure Delay Performance
  - Average reduction: 7.7 minutes
- Percentiles:
  - Reductions greater than 15 minutes: 12.3% (440,889 flights)
  - Reductions greater than 30 minutes: 6.1% (218,886 flights)
  - Reductions greater than 45 minutes: 3.8% (137,424 flights)
  - Reductions greater than 60 minutes: 2.6% (93,558 flights)

Source: Metron Avitation, Inc.

This distribution also serves to reduce the cognitive complexity of the task confronting each individual. The ATCSCC traffic manager does not need to know anything about User priorities, and the ATC Coordinator for a NAS User does not need to become an expert at setting AARs. Finally, because exceptions are necessary to override poor decisions when they are proposed by someone due to a slip or due to insufficient access to the relevant knowledge or data, there must be a mechanism to support interactions among the different participants in order to exchange the necessary information and modify those decisions.

To make this process work, however, certain other requirements arose during its design:

- To make it politically acceptable, nonparticipants (NAS Users who do not choose to participate in slot swapping, etc.) must not be penalized. Such nonparticipants are initially assigned slots just like

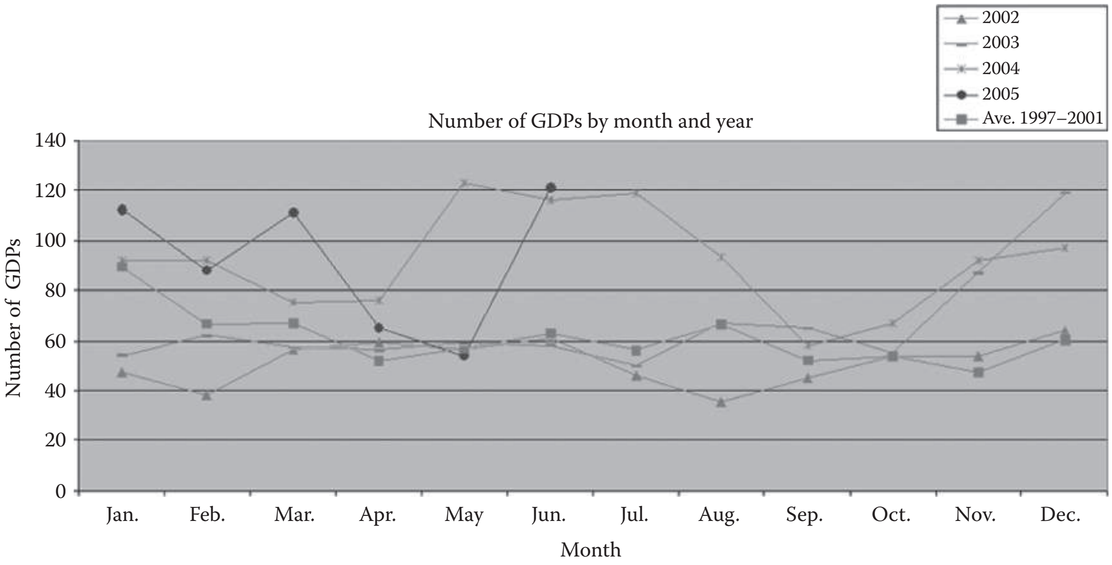

FIGURE 26.5 Frequency of use of the Enhanced GDP by year. (Data from Metron Aviation, Inc.)

everyone else, but their flights are never moved to a later slot as part of any swapping. (They may actually benefit from compression, however, if they are moved up to an earlier slot that is empty.)
- There must be an incentive for information sharing.
- DSSs must be available to provide:
  - Digital communication
  - Simulation of the predicted impact of alternative decisions (what-if capabilities)
  - Algorithmic support for identifying, evaluating and implementing complex decisions involving large numbers of flights (swapping)
  - Information displays that allow the user to understand the situation as relevant to that user's responsibilities, and to effectively evaluate the solution recommended by the technology
  - Control by the user to override the DSS's recommendations in cases where the technology exhibits brittleness
- Organizational changes in roles and responsibilities (new specialists at ATCSCC with the knowledge and skills to develop GDPs; ATC Coordinators for the NAS Users to look at trade-offs in delaying alternative flights).
- The overall procedures must support adaptation, so that decisions can be modified as the scenario evolves.

In summary, this case study serves to illustrate the importance of looking at design from a broad systems perspective when dealing with a distributed work environment, considering not just the detailed design issues necessary to implement a given DSS, but also considering the alternative strategies for distributing the work and the organizational changes required to match people with certain skills and knowledge with corresponding responsibilities, and to make the system resilient in the face of slips, mistakes, and unanticipated events.

26.4.2 Case Study B: Interactive Critiquing as a Form of Decision Support

This case study emphasizes the challenge for interaction designers in dealing with the use of decision-support tools that have the potential for brittle performance due to known or unknown limitations. While there are no perfect solutions to this problem, there are a number of approaches to help reduce its impact.

This case study looks at a tool that incorporates three complementary approaches to the design of an expert system in order to improve overall performance, while reducing the potential impact of brittle performance by the expert system. The first approach to deal with the impact of brittle performance by an expert system is to design a role that encourages the user to be fully engaged in the problem solving, and to apply his knowledge independently without being first influenced by the software. In this case study, the approach explored to achieve this is the use of the computer as a critic, rather than as the initial problem-solver (Fischer et al. 1991; Miller 1986; Silverman 1992; Tianfield and Wang 2004). Thus, instead of asking the person to critique the performance of the software, the computer is assigned the role of watching over the person's shoulder. Note that this is more accurately described as having the design team try to anticipate all of the scenarios that can arise, and then, for all of those scenarios, trying to incorporate the knowledge necessary to detect possible slips or mistakes on the part of the user and to provide alerts and assistance in recovering (Pritchett, Vandor, and Edwards 2002; Wogalter and Mayhorn 2005).

The second approach to reduce sensitivity to brittleness in the computer's performance is to incorporate metaknowledge into the expert system that can help it to recognize situations where it may not be fully competent. By doing so, the software may be able to alert the person to be especially careful because the computer recognizes that this is an unusual or difficult case.

The third approach to deal with brittleness is to develop problem-solving strategies that reduce susceptibility to the impact of slips or mistakes. In the software discussed in this case study, this is accomplished by incorporating a problem-solving strategy that includes the collection of converging evidence using multiple independent problem-solving strategies and sources of data to arrive at a final conclusion.

What follows, then, is a discussion of a specific expert system that incorporates these three strategies for dealing with brittleness. Empirical testing of the system suggests that this approach can significantly enhance performance, even on cases where the software is not fully competent (Smith and Rudmann 2005).

26.4.2.1 Application Area

The specific problem area considered in this case study is the design of a decision-support tool to assist blood bankers in the identification of compatible blood for a transfusion. One of the difficult tasks that blood bankers must complete as part of this process is the determination of whether the patient has any alloantibodies present in his blood serum, and if so, what particular antibodies are present.

26.4.2.1.1 Diagnosis as a Generic Task

Abstractly, this is a classic example of the generic task of abduction or diagnosis (Josephson and Josephson 1994; Psillos 2002). It involves deciding what tests to run (what data to collect), collecting and interpreting those data, and forming hypotheses, as well as deciding what overall combination of problem-solving strategies to employ. Characteristics of this generic task that make it difficult for people include the following:

- The occurrence of multiple solution problems, where more than one "primitive" problem is present at the same time
- The occurrence of cases where two or more "primitive" problems are present, and where one problem masks the data indicative of the presence of the other
- The existence of "noisy" data

- The existence of a large "data space" where data must be collected sequentially, so that the person must decide what data to collect next and when to stop
- The presence of time stress, where an answer must be determined quickly (Elstein, Shulman, and Sprafka 1978; Smith et al. 1998)

In this application, the "primitive" problems are the individual antibodies that may be present in the patient's blood serum. Time stress can arise when the patient is in an emergency situation and needs a transfusion quickly.

26.4.2.1.2 Sample Problem

To illustrate the nature of this diagnosis task, consider the following partial description of an interaction with the decision-support tool AIDA (the Antibody Identification Assistant) that is the focus of this case study (Guerlain et al. 1999). Initially, the medical technologist needs to determine whether the patient is type A, B, AB, or O, and whether the patient is Rh positive. Then the technologist determines whether the patient shows evidence of any autoantibodies or alloantibodies. As part of this determination, displays like the one shown in Figure 26.6 are provided by AIDA.

To make visual scanning easier on this data display, some of the rows have been highlighted by the technologist in yellow. In addition, to reduce memory load, the technologist has marked a number of intermediate conclusions, indicating that the f, V, Cw, Lua, Kpa, and Jsa antibodies are unlikely (marked in blue in the actual display and in light gray here), and that other antibodies indicated by the labels across the top row can be ruled out (marked in green in the actual display and in dark gray here). These color-coded intermediate answers are transferred to all other data displays to reduce the memory load for the technologist. Figure 26.6 also provides an example of a critique that AIDA has provided in response to an error made by the technologist in marking anti-E as ruled out. This critique was generated by the expert model (rule-based system) underlying AIDA, which monitors all of the test selections and markings made by the technologist as he solves the case using the interface provided by AIDA.

Thus, Figure 26.6 serves to illustrate the following:

- The technologist is responsible for completing the analysis, deciding what tests to run and what intermediate and final conclusions to reach, and is thus very engaged in the task.
- The computer provides an interface that makes it easy for the technologist to select the tests to run and to view the resultant data (using the highlighting to make visual scanning easier), as well as to remember intermediate conclusions (using color-coded markings to indicate these conclusions).
- Although the primary motivation for the technologist in marking the data forms is to make his task easier, when he does so the computer is provided with a great deal of data regarding what the user is thinking and can use those data to make inferences based on its expert model about when to provide a critique cautioning the user that he may have made a slip or mistake.

Cell #4 does not possess the E antigen. Therefore, even if anti-E was present, it could not possibly react with this cell. Consequently, this is not a good cell for ruling out anti-E.

FIGURE 26.6 **(See color insert.)** Full test panel with intermediate results marked using color coded markers provided by AIDA. In this case, AIDA has interrupted the user to suggest that an error may have been made in ruling out anti-E.

26.4.2.1.3 The Need for Decision Aiding

Initial laboratory and field studies indicated that the task of determining the alloantibodies present in a patient's blood is a difficult one for many technologists. A variety of causes of errors were observed, including slips, perceptual distortions, incorrect or incomplete knowledge (Guerlain et al. 1999), and cognitive biases (Brachman and Levesque 2004; Bradfield and Wells 2005; Fraser, Smith, and Smith 1992; Gilovich, Griffin, and Kahneman 2002; Haselton, Nettle, and Andrews 2005; Kahneman and Tversky 2000; Plous 1993; Poulton 1989).

26.4.2.2 Design Solution

It was the judgment of the design team that this task was sufficiently complex that, given the available development resources, it was unlikely that all of the possible scenarios could be anticipated and dealt with by the design team. It was also noted that, for this task, the cost of an erroneous diagnosis was potentially high. Thus it was decided that, instead of automating the task, a DSS should be developed that kept the person very much engaged in the task, and that provided other safety nets to reduce the chances of error for those cases where the computer's knowledge was incomplete. This conclusion was reinforced by a preliminary study regarding the impact of role on diagnostic accuracy in antibody identification. Guerlain et al. (1996) showed that, when the user was asked to critique the computer's performance instead of having the computer critique the user's performance, the final answer was wrong 31% more often on cases where the computer's knowledge was incomplete when, on that case, the person was assigned to the role of critic rather than having the computer critique the person.

26.4.2.2.1 Critiquing—Additional Design Considerations

The literature provided additional guidance in deciding whether and how to develop this software to play the role of a critic. For example, Miller (1986) developed a prototype system called ATTENDING that focused on anesthesiology. Based on studies of its use, Miller suggested that critiquing systems are most effective in applications where the user has a task that is frequently performed, but that requires the person to remember and apply a great deal of information in order to complete a case. Miller's conclusion was that, on such tasks, the person is more susceptible to slips and mistakes and would therefore benefit significantly from the DSS.

A second consideration was how intrusive the interactions with the knowledge-based system would be for the user. A number of researchers have suggested that an interface that requires that the user spend significant time entering data and informing the computer about what he has concluded is too cumbersome, and will therefore be unlikely to be adopted in actual practice (Berner et al. 1989; Harris and Owen 1986; Miller 1984; Shortliffe 1990; Tianfield and Wang 2004).

A third consideration was concern over the potential for complacency if the person played the role of critic, letting the computer complete an initial assessment and then having the person decide whether to accept this assessment. Parasuraman and Riley (1997) have shown that, in such a role, there is a risk that the person will become over reliant on the computer, and will not adequately apply his knowledge in completing the critique (Metzger and Parasuraman 2005). (Note, however, that a person could become over reliant even with the roles reversed, as the person might start to get careless and assume the computer will always catch his slips. Administrative controls, based on regular monitoring of the person's performance, might help reduce such complacency, but this is as yet an unexplored aspect regarding the use of critiquing systems.)

A final consideration was the timeliness of critiques. Waiting for the user to reach a final answer before providing a critique, as has been the case for many critiquing systems, is potentially inefficient and objectionable, as the user may have invested considerable time and effort in arriving at a mistaken answer that the computer could have headed off earlier in the person's problem-solving process. Furthermore, if the critique is given well after the user has made a slip or mistake, it may be difficult for him to remember exactly why he arrived at that intermediate conclusion (thus making it harder to decide whether to accept the computer's critique). This consideration therefore suggests the need for an interface that provides the computer with data about the user's intermediate conclusions rather than just the user's final answer, so that critiquing can be more interactive.

Based on these considerations, AIDA was developed as a critiquing system that supported the user as he completed the antibody identification task. In order to provide immediate, context-sensitive critiques, an interface was developed that encouraged the user to mark intermediate conclusions on the screen. As suggested earlier, these markings in fact reduced the perceptual and memory loads for the user, thus implicitly encouraging this form of communication and allowing the computer to detect and respond immediately with context sensitive critiques to potential slips and errors made by the person.

26.4.2.2.2 Complementary Strategies to Reduce Susceptibility to Brittleness

The considerations outlined above focused on how to keep the person engaged in the diagnosis task, and how to avoid triggering the cognitive biases that can arise if the computer suggests an answer before the person has explored the data himself (Larson and Hayes 2005; Smith, McCoy, and Layton 1997). AIDA also incorporated two additional design strategies to reduce the potential for error. One was the incorporation of metaknowledge into the knowledge-based system. The other was to include a problem-solving strategy that was robust even in the face of slips or mistakes by either the person or the computer (i.e., the design team).

Metaknowledge was included to help the computer identify cases where its knowledge might be incomplete. Such rules were developed by identifying the potential weak points in the computer's problem-solving process. An example was the use of thresholding by AIDA when applying rules such as the following:

If a test cell's reactions are 0 on a test panel for all three of the testing conditions (IS, LISS and IgG) as they are for the first test cell (Donor A478), shown in Figure 26.6, and if e is present (shown by a + in the column labeled e in the row corresponding to the first test cell) on that test cell but E is not (shown by a 0 in the column labeled E in the row corresponding to the first test cell), then mark e as ruled out.

This heuristic usually produces the correct inference. Since it does not directly reason with some form of probabilistic reasoning (Bochman 2004; Pearl 1988; Shafer and Pearl 1990; Shafer 1996), however, it can lead to ruling out an antibody that is actually present in the patient's serum with no consideration of the level of uncertainty. This is most likely to happen when the reaction strengths are weak. Thus, AIDA was provided with a rule that monitored for weak reactions on cells, and when this situation was detected and the user was observed trying to complete rule-outs without first enhancing the reactions with some alternative test phase, the system cautioned the user. In this way, AIDA put the user on alert to be especially careful in applying his normal strategies and rules.

A second strategy incorporated into AIDA as protection against brittleness was to monitor for the collection and consideration of converging evidence by the technologist. This problem-solving strategy was observed in use by one of the experts involved in the development of AIDA. She used this strategy to catch her own errors and those of the technologists working under her supervision. The strategy was based on the assumption that any one data source or line of reasoning could be susceptible to error, and that it is therefore wise to only accept a conclusion only if independent types of data (test results that are not based on the same underlying data or process) and independent sets of heuristics or problem-solving strategies have been used to test that conclusion. Based on this expert strategy, AIDA monitored the user's problem-solving process to see whether such converging evidence had been collected prior to reaching a final answer. If not, AIDA cautioned the user and suggested types of converging evidence that could be collected.

26.4.2.3 Evaluation of the Implemented Solution

From the standpoint of HCI, the key question is how effectively this human–machine system performs using this cooperative problem-solving paradigm (Erkens, Andriessen, and Peters 2003). To gain insights into this, an empirical study was conducted using AIDA.

This study of 37 practitioners at 7 different hospitals found that those blood bankers using AIDA with its critiquing functions turned on made significantly fewer errors ($p < .01$) than those that used AIDA as a passive interface. Errors in the final diagnoses (answers) were reduced by 31%–63%.

On those cases where AIDA was fully competent (posttest Cases 1, 2, and 4), errors (percentage of technologists getting the wrong final answer) were reduced to 0% when the critiquing functions were on (treatment group). On the case where AIDA was not fully competent (posttest Case 2), AIDA still helped reduce errors by 31% (Table 26.2).

These empirical results support the potential value of interactive critiquing, supplemented with the metaknowledge and problem-solving strategies that were embedded in the software, as a design strategy for applications where concerns regarding the potential brittleness of the technology are deemed significant.

TABLE 26.2
Percentage of Blood Bankers Arriving at the Wrong Final Answer on Four Test Cases

	Control Group (%)	Treatment Group (%)
Posttest case 1	33	0
Posttest case 2	50	19
Posttest case 3	38	0
Posttest case 4	63	0

26.4.3 Case Study C: Impact of a Decision-Support System on Individual versus Group Decision Making

This case study emphasizes how a DSS may have very different effects on an individual problem solver verses a group working jointly. System designers should not assume that groups will gain the same benefits from a DSS as individuals, or vice-versa.

The domain examined in this case study is military planning, specifically enemy course of action (ECOA) planning. In this task, small groups of planners (or intelligence analysts) examine intelligence information gathered from scouts in the field, radio traffic, sensors, satellite data and other sources and try to form hypotheses about what possible and likely plans of action the enemy forces may take. Each of these plans is called an ECOA. Friendly forces then use the ECOAs, which are their best guesses as to what the enemy may do, to develop a set of friendly courses of action (FCOA) that will allow them to respond to all the likely and dangerous actions which the enemy may pursue.

26.4.3.1 Decision-Support System to Assist Military Planners

This case study examines Weasel, a DSS designed to assist military planners in systematically identifying all ECOAs based on the most likely positions of resources and activities identified by intelligence (Ravinder 2003; Hayes and Ravinder 2003). Note, that Weasel does not find all possible ECOAs, just the most likely based on intelligence.

Weasel interacts with the user in the role of an intelligent planning assistant. Users do their own planning and make their own judgments, but they can ask Weasel to suggest ECOAs. Users can then decide which ECOAs to include in their own solution sets. They can also modify Weasel's ECOAs.

Figure 26.7 shows an example of an ECOA. Each rectangle represents a military unit. The large arrows represent the direction of movement of the attacking forces, and roughly

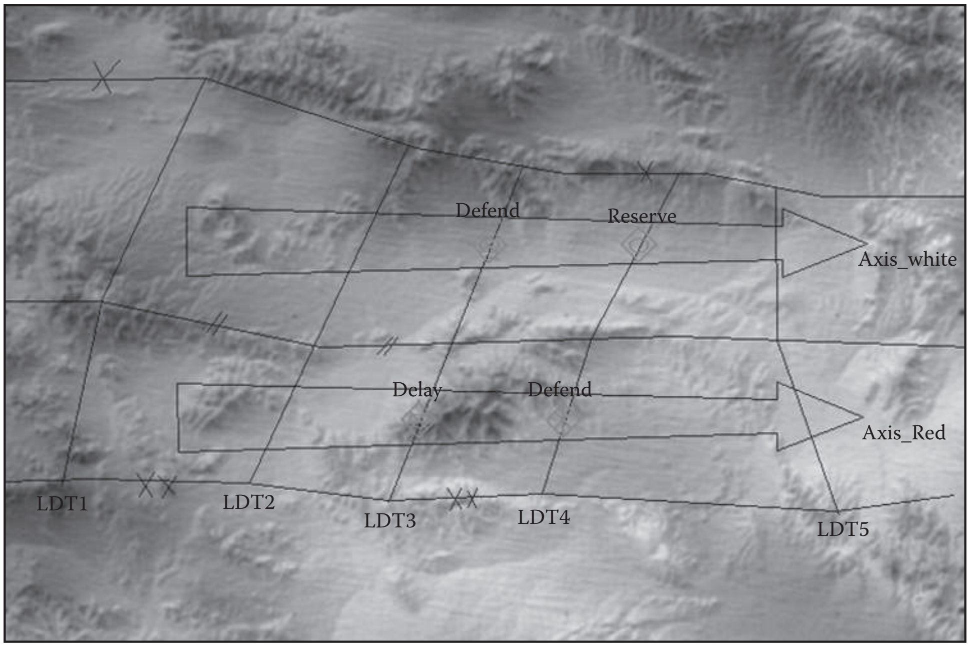

FIGURE 26.7 (See color insert.) An example of an enemy course of action (ECOA). The diamond-shaped figures represent the enemy units. Each unit is further labeled by role played by the unit in this scenario: Defend, Reserve, or Delay. The enemy units move along two corridors in the terrain indicated by large arrows and labeled Axis White and Axis Red. Friendly units move in the direction of the arrows, enemy units move in the reverse direction. LDT means Line of Defensible Terrain. LDT 1 through 5 are used as reference lines to mark how far the units have advanced. In this snapshot, all enemy units are currently positioned on LDT 3 and LDT 4.

mark out the area in which units will move. The ECOAs generated by Weasel are at a very high level of abstraction, specifying primarily the current positions of each enemy unit or resource, but not all the steps in the plan. This is a standard abstraction used by the military to represent ECOAs before much of the detail is known; each ECOA is essentially a "shorthand" for a whole family of more detailed ECOAs that might arise from that plan.

While ECOA planning is couched as a planning task, it is in many ways very similar to a diagnostic task (Simmons 1988). The intelligence information gathered is analogous to the observations made by medical personnel and the result of diagnostic tests ordered. And, as in diagnosis:

- The data may be noisy.
- The data space is very large.
- There is time pressure to develop a set of ECOAs quickly, and dangerous consequences for bad decisions. In military situations, lives may be lost if decisions are not timely and on target.
- There may be many possible explanations for the observed data. In diagnosis one problem may mask another. In ECOA planning, the enemy may take one set of actions to trick the opposition into believing their plan is different than it really is.

As it is impossible to know for certain what the enemy is really planning, the job of an ECOA planner is to identify several ECOAs that he or she deems as likely, or especially dangerous even if unlikely.

By planning for multiple possibilities, the friendly forces can prepare in advance for whatever the enemy may do, and avoid being taken by surprise. However, in practice, it is often difficult for people to systematically think of all the possibilities, of all the many ways in which the enemy may distribute its forces and allocate its resources. By offering a DSS to perform a systematic and thorough search of the solution space, the goal is to combine computers' thoroughness, with human judgment and flexibility to produce a system that produces better results than either alone.

26.4.3.2 As an Assistant for Individuals

Larson and Hayes (2005) conducted a study in which they assessed whether using Weasel had an impact on the quality of ECOAs produced by individual military planners working alone. Quality was judged independently by two expert military planners. Eighteen subjects participated in the experiment (9 Air Force and 9 Army subjects). The average length of experience across all 18 subjects was 5.03 years. Five subjects were categorized as domain experts, and 13 as intermediates. Experts were those having 6 or more years of military experience on active duty, in the National Guard or Reserves.

Each subject was individually asked to generate a set of ECOAs which they would pass on to their commander, for various scenarios. They did these tasks without Weasel's assistance and with Weasel's assistance. Scenario, method, and order were systematically varied. The two expert judges each independently assigned quality scores to the final set of ECOAs produced by each individual. The results demonstrated that Weasel significantly improved performance for individuals ($p = .018$).

26.4.3.3 As an Assistant for Groups

Larson repeated this experiment five years later, but this time he additionally examined the impact of Weasel on *groups* of planners working together to generate ECOAs, which is more representative of how ECOA planning is done in practice (Larson 2010). Larson studied 12 groups, each of which had 3 members, one of whom played the role of group leader. The group leader was assigned randomly. As in the experiment above, the groups were asked to create sets of ECOAs which they would pass on to their commander without the aid of Weasel, and with the aid of Weasel. Their ECOA sets were independently given quality scores by two different expert evaluators, who were different individuals than those that participated in the previous experiment. The evaluators also independently assigned quality scores to ECOA sets produced by 18 individuals. Again, Weasel significantly improved the quality of the ECOA sets produced by individuals, but not by groups. The best predictors of solution quality for groups were not whether or not they used Weasel, but the total number of ECOAs produced in order to develop the solution set (even though most of those ECOAs did not end up in the final solution set), and the amount of interaction between the group members.

A closer look at the data provides insights into these results. First of all, teams and individuals earned almost the same average solution quality scores when they used Weasel. However, without Weasel, teams typically performed better than did individuals. Thus, Weasel brought the performance of individuals up further than the performance of teams.

An examination of the interactions between group members provides additional insights into why the teams performed better than individuals without Weasel; group mates provided error checking on others' solutions, and produced alternative ECOAs which others did not think of. High-performing groups produced more ECOAs overall en route to a solution because multiple "heads" were able to think up a larger numbers of distinctly different ECOAs than could any one individual, and more ECOAs were associated with higher quality solutions. Furthermore, the high performing groups often worked together to make notations on the same sheet of paper, or looked over the shoulder of another teammate while commenting on the solutions. In addition, the "technical lead" of the group was not always the assigned group leader.

In contrast, groups that performed poorly communicated less frequently with each other. In the videotapes of the groups, one can see the lack of connection in the body language of the poorly performing groups. Each sat side by side working on his or her own sheet, or doing nothing. Occasionally someone would speak but the others might not answer or even move in response.

These insights may jointly provide an explanation as to why Weasel provided more benefit to individuals than groups. It appeared that for individuals, the Weasel DSS played the role of an additional group member by providing an alternative perspective and additional ECOAs that the individual would not have thought of on his or her own. However, the groups already had two other group mates to perform the role which the DSS played for the individuals. Thus, it did not provide as much of a performance "boost" to the teams; they already got that boost from their team mates.

26.4.3.4 Lessons Learned

The main take away point of these studies for the DSS designer is that groups may not derive the same benefits that individuals derive from a DSS, particularly if the DSS is designed to play the role of an intelligent assistant or additional team mate. This is particularly important in work that is typically carried out by groups. If one designs a DSS and demonstrates that it improves performance for individuals, one cannot assume that it will provide the same benefits (or any benefits) when used in practical situations by groups.

26.4.4 Case Study D: Rules of Social Interaction—Interruptions and Their Uses

This case study provides some insights into how designing DSSs to follow culturally expected norms for interaction can improve performance benefits of DSSs. This case study examines rules for when to interrupt. This is important because it is usually inappropriate to interrupt someone in the middle of an important task and it can be dangerous to interrupt a life-critical task (Dorneich et al. 2010). People are likely to become irritated with "rude" DSSs that interrupt at inappropriate and inconvenient times, and turn them off. However, it can be equally inappropriate and dangerous to fail to interrupt in a timely manner with critical information.

Dorneich et al. (2010) performed two studies of DSSs to assist dismounted soldiers in life-critical tasks. The first system, the Communications Scheduler, reduced soldiers' cognitive workload during high workload periods by converting low priority radio messages into text which was displayed on a handheld display carried by the soldier. Examples of high workload periods included times when the soldier was executing a complex maneuver in an urban battle environment, or when the soldier was avoiding gunfire. Essentially, the Communications Scheduler reduced interruptions during high workload times so that the soldier could concentrate on the task.

The second system, the Tactile Navigation Cueing System, delivered navigation directions to the dismounted soldiers by "prodding" them with vibrating pads attached to a belt (called a tactor belt) worn around the waist. The direction of the vibration on the belt indicated the direction in which the soldier needed to travel in order to avoid (simulated) landmines in a field. Thus, the Tactile Navigation Cueing System did the opposite of the Communications Scheduler; it added interruptions, rather than reducing them, but its interruptions provided safety-critical information intended to keep the soldier from stepping on a mine.

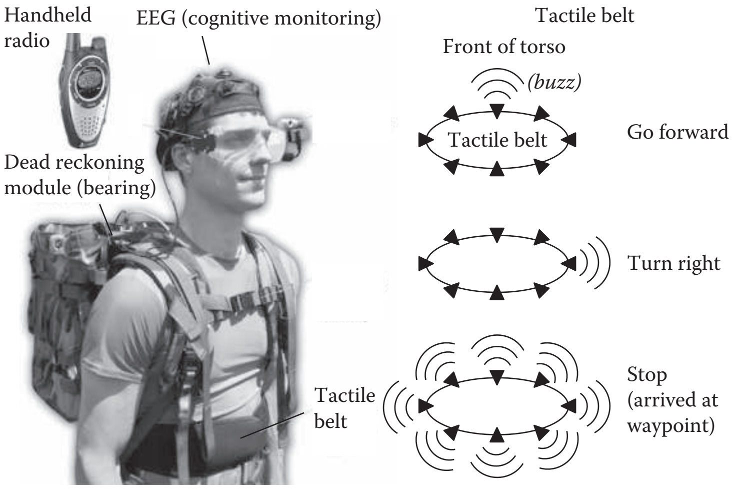

FIGURE 26.8 Equipment for the communications scheduler and tactile navigation cueing systems.

26.4.4.1 Experimental Setup

The setup for both experiments was very similar, and is shown in Figure 26.8, the difference being that the Communications Scheduler did not use a tactor belt. Both systems are portable and mounted on the body so that dismounted soldiers can carry the system along with them in the field. The computer was carried in a backpack, and sensors and other equipment were mounted on the head and body. Both systems monitor the soldier's cognitive state using EEG (brain activity) and ECG (heart) sensors. The EEG sensors are incorporated into a special cap that participants wore. The ECG sensors were glued to the torso with a medical adhesive patch. All sensors were connected wirelessly to the computer in the backpack. These sensors are used to assess the soldier's cognitive workload (high or low). Soldiers also carried a radio clipped to their shoulders, and a handheld display.

26.4.4.2 Reducing Low-Priority Interruptions

Eight subjects tested the Communication scheduler. Each was asked to perform multiple tasks while navigating outdoors in a partially wooded field used as a mock battle environment, including monitoring radio traffic, keeping a count of the number of civilians and soldiers sighted.

The complexity of the navigation route and the frequency of radio messages were varied to produce high workload and low workload situations. When the Communications Scheduler detected that the soldier was experiencing a high workload (through the EEG and ECG sensors), it converted radio messages pertaining to low-priority tasks into text messages, allowing only the high-priority radio messages through, thus reducing the total number of interruptions.

Subjects were each tested in scenarios in a 2 × 2 within subjects design in which they performed multiple simultaneous tasks without the Communications Scheduler being available to them, and with the Communications Scheduler, under both high and low workload conditions.

The results showed that use of the Communications Scheduler significantly improved soldiers' accuracy during high workload periods for the high-priority tasks, for example, maintaining counts of civilians and soldiers sighted ($p < .05$) and monitoring the maneuvers of their own unit ($p < .05$). There was no significant impact of the Communications Scheduler during low workload periods.

However there was also a cost associated with using the Communications Scheduler. While it reduced interruptions, therefore allowing soldiers to concentrate on the high-priority tasks, they rarely went back to read all the lower priority (but still important) text messages that had been taken out of the radio traffic stream and sent to their handheld displays. This resulted in reduced situation awareness as they did not absorb that information.

26.4.4.3 Increasing Safety-Critical Interruptions

Six subjects tested the Tactile Navigation Cueing System. Subjects used the same equipment as the experiment above, plus a tactor belt to navigate the same outdoor environment (a partially wooded field). In this study, subjects were also asked to perform multiple tasks simultaneously: maintain counts of civilians and soldiers sighted, monitor the maneuvers of their own unit, and perform math tasks. However, their primary task was to navigate a complex path through the field, while avoiding sites representing landmines and surveillance cameras.

Subjects were asked to perform these simultaneous tasks in a 2 × 2 within subjects design, without and with the availability of the Tactile Navigation Cueing System, under high and low workload conditions. High workload conditions were created by making the path through the mine field more complex, and the radio messages more frequent.

The results revealed that subjects were able to complete the navigation task more quickly, running into fewer (pretend) mines and surveillance cameras, when using the Tactile Navigation Cueing System. Despite the additional interruptions from the tactor belt, they also increased their accuracy in the math task, while accuracy in other tasks remained unchanged.

This may show that, by allowing the DSS to take over the navigation task so they did not have to think about which way to go anymore, it freed up cognitive resources for other tasks. However, as in the previous experiment, the increased performance came at the cost of situation awareness. One soldier's attention was so focused on the vibrating tactor belt and its directions that he forgot to attend to what was around him and he ran into a low hanging tree branch.

26.4.4.4 Lessons Learned

DSSs that do not follow appropriate rules for interaction, for example by interrupting at inappropriate times, often irritate users and may result in disuse of that system. This case study demonstrates that designing a DSS to follow appropriate social rules for interruption can improve performance. Reduced interruptions during high workload periods can improve performance, as can appropriate interruptions to deliver critical information.

However, even when interruptions are appropriately filtered or delivered, they come at a cost of which DSS designer should be aware. Use of such strategies may reduce situation awareness, a cost which must be carefully balanced with the DSS's benefits.

26.5 CONCLUSION

One goal of this chapter has been to outline different conceptual approaches to support the design of DSSs, including the use of CTAs and work domain analyses. A second goal has been to review relevant knowledge about the psychologies of both the designers and users of DSSs, identifying important design questions that need to be considered in the development of such software systems. Finally, the chapter emphasizes the need to take a broader systems perspective when deciding how to integrate DSSs into a work environment, as there are a number of other high-level design parameters (such as deciding how to distribute the work among a team of people and machines) that may offer alternative opportunities for effectively incorporating DSSs into the overall system.

27 Online Communities

Panayiotis Zaphiris, Chee Siang Ang, and Andrew Laghos

CONTENTS

27.1 INTRODUCTION

It is estimated that there were over 1.70 billion Internet users globally in 2009 (Pingdom 2010). The expansion of the Internet has resulted in an increase in the usefulness of computer-mediated communication (CMC) and the popularity of online communities. One in four Internet users has participated in chat rooms or online discussions (Madden and Rainie 2003). Just on the social network site Facebook, there are around 350 million users, and 50% of these users log in everyday (Pingdom 2010).

This chapter begins by defining online communities and CMC and by discussing their main pros and cons. This is followed by a review of the different types of CMC, while the evolution of game-based and wiki communities are described in more depth. These two relatively new areas of online sociability create new opportunities and challenges in the way people work, learn, and play online.

Massively multiplayer online role-playing games (MMORPGs) have taken the social aspects of computer game playing to a new dimension, where players interact, socialize, and form networks of communities by having fun online. Wiki-based communities facilitate new models of social collaboration, where the creation of online content is no longer an individual action but rather it is transformed into a social, collaborative activity.

The analysis and evaluation of online communities require a good understanding of all the available evaluation frameworks and methodologies that exist. Online communities are a source of valuable data that, when properly analyzed, can provide us with insights about the social experience people who are part of them have. For this reason, we provide a description of the key methods in Section 27.3. We then demonstrate the application of some of these methods to characteristic case studies. Our first case study looks at how learning communities can be analyzed and how results from this analysis can be used for improving the pedagogical value of e-learning. The second case study investigates the use of activity theoretical frameworks in the analysis of computer game-based communities.

The chapter concludes with a brief summary and suggestions for new directions in the area of online communities.

27.2 COMPUTER-MEDIATED COMMUNICATION AND ONLINE COMMUNITIES

27.2.1 Computer-Mediated Communication

One of the most important characteristics of this medium is the opportunities it offers for human–human communication through computer networks. As Metcalfe (1992) points out, communication is the Internet's most important asset. E-mail is just one of the many modes of communication that can occur through the use of computers. Jones (1995) points out that through communication services, such as the Internet, Usenet, and bulletin boards, online communication has for many people supplanted the postal service, telephone, and even the fax machine. All these applications where the computer is used to mediate communication are called CMC.

December (1997) defines CMC as "the process by which people create, exchange, and perceive information using networked telecommunication systems (or nonnetworked computers) that facilitate encoding, transmitting, and decoding messages." He emphasizes that studies of CMC view this process from different interdisciplinary theoretical perspectives (social, cognitive/psychological, linguistic, cultural, technical, and political) and often draw from fields such diverse as human communication, rhetoric and composition, media studies, human–computer interaction (HCI), journalism, telecommunications, computer science, technical communication, and information studies.

27.2.2 Online Communities

Online communities emerge through the use of CMC applications. The term online community is multidisciplinary in nature, meaning different things to different people, and is slippery to define (Preece 2000). For purposes of a general understanding of what online communities are, Rheingold's definition of online communities is presented:

> [online] communities are social aggregations that emerge from the Net when enough people carry on those public discussions long enough, with sufficient human feeling, to form webs of personal relationships in cyberspace. (Rheingold 1993, p. 5)

Online communities are also often referred to as cyber societies, cyber communities, web groups, virtual communities, web communities, virtual social networks, and e-communities among several others.

The cyberspace is the new frontier in social relationships, and people are using the Internet to make friends, colleagues, lovers, and enemies (Suler 2004). As Korzenny (1978) pointed out, even as early as 1978, online communities are formed around interests and not physical proximity. In general, what brings people together in an online community is common interests such as hobbies, ethnicity, education, and beliefs. As Wallace (1999) points out, meeting in online communities eliminates prejudging based on someone's appearance, and thus people with similar attitudes and ideas are attracted to each other.

The emergence of the so called "global village" was predicted years ago (McLuhan 1964) as a result of television and satellite technologies. However, it is argued by Fortner (1993) that "global metropolis" is a more representative term (Choi and Danowski 2002). If one takes into account that the estimated world population of 2002 was 6.2 billion (U.S. Census Bureau 2004), then the online population is nearly 10% of the world population—a significant percentage that must be taken into account when analyzing online communities. In most online communities, time, distance, and availability are no longer disseminating factors. Given that the same individual may be part of several different and numerous online communities, it is obvious why online communities keep increasing in numbers, size, and popularity.

CMC has its benefits and limitations. For instance, CMC discussions are often potentially richer than face-to-face discussions. However, users with poor writing skills may be at a disadvantage when using text-based CMC (SCOTCIT 2003).

27.2.3 Examples of Computer-Mediated Communication and Online Communities

Examples of CMC include asynchronous communication like e-mail and bulletin boards; synchronous communication like chatting; and information manipulation, retrieval, and storage through computers and electronic databases (Ferris 1997).

Audio conferencing is a real-time communication mechanism, because the communication happens synchronously. Depending on the application, text chat and graphics may also be supported. Videoconferencing, like audio conferencing, offers a useful mode of communication, but has the added benefit of also being able to see the participants, instead of just hearing them.

Internet relay chats (IRCs) and chats also support synchronous communication, since they enable the users to carry out conversations through the use of text messaging. Multi-user domains (MUDs) build on chats by providing avatars and graphical environments where the users can engage in interactive fantasy games (Preece 2000).

www websites are usually asynchronous, providing community information and links to other sites, but sometimes also have synchronous software, like chats, embedded in them (Preece 2000).

E-mail is an asynchronous mode of communication usually in the form of text. However, the ability to add attachments to e-mail messages makes it possible for audio, video, and graphics to be used also. Voice mail is an expansion of e-mail whereby users may record themselves speaking out a message and then send that voice file to their contact, instead of typing it. Newsgroups, like e-mail, provide an asynchronous mode of communication, but unlike e-mail where the messages come to the users, it is a "pull" technology, meaning the users must go to the UseNet groups themselves (Preece 2000). Finally, discussion boards, also referred to as forums or bulletin boards, provide an asynchronous mode of communication where the users post messages for others to see and respond at their own time.

In Section 27.2.3.1, we describe a special type of online communities, that of online virtual game communities.

27.2.3.1 Online Virtual Game Communities

With the advent of ubiquitous broadband Internet connection and the increasing graphical processing power of personal computers, a new paradigm of gaming has emerged. MMORPGs have changed the game industry dramatically. MMORPGs provide a fictional setting where a large group of users voluntarily immerse themselves in a graphical virtual environment and interact with each other by forming a community of users.

Although the concept of multiplayer gaming is not new, the game world of most local network multiplayer games, as opposed to MMORPG, are simplistic and can accommodate only around 16 concurrent players in a limited space.

A MMORPG enables thousands of players to play in an evolving virtual world simultaneously over the Internet. The game world is usually modeled with highly detailed three-dimensional (3D) graphics, allowing individuals to interact not only with the gaming environment but also with other players. Usually, this involves the players representing themselves through the use of avatars—the visual representation of the player's identity in the virtual world.

The MMORPG environment is a new paradigm in computer gaming in which players are part of a persistent world, a world that exists independent of the users (Yee 2005). Unlike other games where the virtual world cease to exist when players switch off the game, in an MMORPG, the world exists before the user logs on and continues to exist when the user logs off. More importantly, events and interactions occur in the world even when the user is not logged on, as there are many other players who are constantly interacting, thus transforming the world. To accommodate the large number of users, the worlds in MMORPGs are vast and varied in terms of "geographical locations," characters, monsters, items, and so on. More often than not, new "locations" or items are added by the game developers from time to time according to the demand of the players.

On the one hand, an MMORPG, like a role-playing game (RPG), involves killing monsters, collecting items, developing characters, and so on. However, it contains an extra aspect, which is the internal sociability within the game. Unlike single player games, which rely on other external modes of communication (such as mailing lists, discussion forums outside the game) to form the gaming culture, the culture is formed within the MMORPG environment itself.

In such a way, these MMORPG virtual worlds represent the persistent social and material world, which is structured around narrative themes (usually fantasy), where players are engaged in various activities: they slay monsters, attack castles, scavenge goods, trade merchandise, and so on. On the one hand, the game's virtual world represent the escapist fantasy; on the other hand, it supports social realism (Kolbert 2001).

That means games are no longer meant to be a solitary activity played by a single individual. Instead, the player is expected to join a virtual community that is parallel with the physical world, in which societal, cultural, and economical systems arise. It has been gradually becoming a world that allows players to immerse into experiences that closely match those of the real world: virtual relationship is sought, virtual marriage is held, virtual shops are set up, and so on.

The MMORPG genre now boasts hundreds of thousands of users and accounts for millions of dollars in revenue each year. The number of people who play the games (and the time they invest in terms of activities within and around the game) is astounding. The MMORPG, Lineage (NCsoft 2005), for example, had more than 2.5 million current subscribers in 2002 (Vaknin 2002) and, within a year, Ultima Online (Electronic Art 2005) attracted more than 160 million person-hours (Kolbert 2001).

Such games are ripe for cultural analysis of the social practices around them. Although fundamentally, MMORPGs are video games with virtual spaces with which the players interact, they should be regarded not just as a piece of game software; they are a community, a society, and if you wish, a culture. These games are becoming the most interesting interactive CMC and networked activity environment (Taylor 2002). Thus, understanding the pattern of participation in these game communities is crucial, as such virtual communities function as a major mechanism of socialization of the players to the norms of the game culture that emerges, as Squire and Steinkeuhler (in press) has noted:

> Playing one's character(s) and living in [these virtual worlds] becomes an important part of daily life. Since much of the excitement of the game depends on having personal relationships and being part of [the] community's developing politics and projects, it is hard to participate just a little (Squire and Steinkeuhler in press).

Recently, game designers have tried to stretch the boundaries further by structuring in-game activities to maximize interaction. One of the examples of sociability by design in MMORPG is Star Wars Galaxies (Sony 2005), which is organized so that players are steered toward certain locations in the game world where social playing is expected to take place (Ducheneaut, Moore, and Nickell 2004).

Such communities formed around the game can be broadly divided into two categories: in-game and out-of-game communities. Most MMORPGs are created to encourage long-term relationships among the players through the features that support the formation of in-game communities. One of the most evident examples is the concept of guilds. Guilds are a fundamental component of MMORPG culture for people who are natural organizers to run a virtual association that has formalized membership and rank assignments to encourage participation. Sometimes, a player might join a guild and get involved in a guild war to fight for the castle. Each guild usually has a leader and several guilds could team up in a war. This involves a complicated leader–subordinate and leader–leader relationship.

In addition, to encourage social interaction, MMORPGs are specially designed in such a way that some game goals are almost impossible to be achieved without forming communities. For example, one player alone could spend a long period of time collecting all the items needed to assemble a device. But a guild could ask its members to fan out in small groups and collect all the necessary components in one day. Complex devices beyond the reach of any individual player could be quickly constructed by the guild. The guild could also accept donations from members and then distribute those contributions to others according to their needs, benefiting everyone as a result of this collaboration (Kelly 2004).

Apart from relatively long-term relationships such as guild communities, MMORPGs also provide many opportunities for short-term relationship experiences. For example, a player could team-up with another player to kill monsters to develop the abilities of their avatars (level up) or some more expert players could help newer players to get through the game.

When trying to win the game, players often need to get information from other resources: guidebooks, discussion forums, other players, and so on. Therefore, game playing is generally more concerned with player–player interaction than with player–game interaction. What is at first confined to the game alone soon spills over into the virtual world beyond it (e.g., websites, chat rooms, and e-mail) and even life off-screen (e.g., telephone calls, face-to-face meetings).

Apart from these external communities around the game that are mediated through e-mails or online forums (which also exist in many other games), there is an interesting phenomenon that fuses the internal and external game communities. The participation in an external community starts to break the magic circle of the game—that game space is no longer separate from real life—as the out-of-game community trades in-game items for real money.

For example, Norrath, the world of EverQuest, was estimated to have the seventy-seventh largest economy in the real world based on buying and selling in online auction houses.

> About 12,000 people call it their permanent home, although some 60,000 are present there at any given time. The nominal hourly wage is about USD3.42 per hour, and the labors of the people produce a GNP per capita somewhere between that of Russia and Bulgaria. A unit of Norrath's currency is traded on exchange markets at USD0.0107, higher than the Yen and the Lira. (Castronova 2001, p. 1)

Having illustrated the social phenomenon around such playful virtual community, it is believed that it is fruitful to research such communities as we might be able to derive some useful implications on how successful computer-supported collaborative work and computer-supported collaborative learning environments can be designed. For this reason, in Section 27.3, we will describe some of the methodologies that can be used in such studies, and in Section 27.4, we will present the application of some of these methods to two case studies.

27.3 ANALYZING ONLINE COMMUNITIES: FRAMEWORKS AND METHODOLOGIES

There are various aspects and attributes of CMC that can be studied to help us better understand online communities: for instance, the analysis of the frequency of exchanged messages and the formation of social networks or the analysis of the content of the exchanged messages and the formation of virtual communities. To achieve such an analysis, a number of theoretical frameworks have been developed and proposed. For example, Henri (1992) provides an analytical model for cognitive skills that can be used to analyze the process of learning within messages exchanged between students of various online e-learning communities. Mason's work (1991) provides descriptive methodologies using both quantitative and qualitative analysis. Furthermore, five phases of interaction analysis are identified in Gunawardena, Lowe, and Anderson model (1997):

1. Sharing/comparing of information
2. The discovery and exploration of dissonance or inconsistency among ideas, concepts, or statements
3. Negotiation of meaning/co-construction of knowledge
4. Testing and modification of proposed synthesis or co-construction
5. Agreement statement(s)/applications of newly constructed meaning

In this section, we provide a description of some of the most commonly used online community evaluation techniques and their weaknesses and strengths.

27.3.1 Query-Based Techniques and User Profiles: Interviews, Questionnaires, and Personas

27.3.1.1 Interviews

An interview can be defined as a type of conversation that is initiated by the interviewer to obtain research relevant information. The interview reports have to be carefully targeted and analyzed to make an impact (Usability Net 2003). Interviews are usually carried out on a one-to-one basis, where the interviewer collects information from the interviewee. Interviews can take place by telephone and face-to-face (Burge and Roberts 1993). They can also take place via nonreal-time methods like fax and e-mail, although in these cases, they function like questionnaires. Interviews are useful for obtaining information that are difficult to elicit through approaches such as background knowledge and general principles. There are three types of interviews: (1) structured interviews: consist of predetermined questions asked in fixed order, like a questionnaire; (2) semistructured interviews: questions are determined in advance but may be reordered, reworded, omitted, and elaborated; (3) unstructured interviews: it is not based on predetermined questions but instead the interview has a general area of interest and the conversation may develop freely.

Interviews can be used to gain insights about general characteristics of the participants of an online community and their motivation for participating in the community under investigation. The data collected comes straight from the participants of the online communities, whereby they are able to provide feedback based on their own personal experiences, activities, thoughts, and suggestions.

Advantages of interviews (Usability Net 2003) include the following: what is talked about can address directly the informant's individual concerns; mistakes and misunderstandings can be quickly identified and cleared up; more flexible than a questionnaire; can cover low-probability events.

Disadvantages of interviews include the following: danger of analyst bias toward own knowledge and beliefs; accuracy and honesty of responses; often must be used with other data collection techniques to improve quality of data collected.

27.3.1.2 Questionnaires

A questionnaire is a self-reporting query-based technique. Questionnaires are typically produced on printed paper, but due to recent technologies and in particular the Internet, many researchers engage in the use of online questionnaires, thus saving time, money, and eliminating the problem of a participant's geographical distance. There are three types of questions that can be used with questionnaires: (1) open questions, where the participants are free to respond however they like; (2) closed questions, which provide the participants with several choices for the answer; and (3) scales where the respondents must answer on a predetermined scale.

For online communities, questionnaire can be used to elicit facts about the participants, their behavior, and their beliefs/attitudes. Like interviews, questionnaires are an important technique for collecting user opinions and experiences they have had through the use of CMC and their overall existence in online communities.

The main advantages of questionnaires are as follows: they are faster to carry out than observational techniques; can cover low-probability events. Their disadvantages include the following: information is idealized version of what should rather than what does happen; responses may lack accuracy or honesty; danger of researcher bias toward subset of knowledge he/she possesses; must be used in conjunction with other techniques for validity.

27.3.1.3 Personas

Findings from interviews and questionnaires can be further used as a basis for developing user profiles using personas. A persona is a precise description of the user of a system and what he/she wishes to accomplish. (Cooper 1999). The specific purpose of a persona is to serve as a tool for software and product design. Although personas are not real people, they represent them throughout the design stage (Blomkvist 2002) and are best based on real data collected through query-based techniques.

Personas are rich in details, include name, social history, and goals, and are synthesized from findings through the use of query-based techniques with real people (Cooper 1999). The technique takes user characteristics into account and creates a concrete profile of the typical user (Cooper 1999).

For online communities, personas can be used to better understand the participants of the community and their background. Personas can also be used as a supplement to social network analysis (SNA; described in Section 27.3.4 in this chapter) to get a greater overview of the characteristics of key participants of a community. Using personas, web developers gain a more complete picture of their prospective and/or current users and are able to design the interfaces and functionality of their systems, to be more personalized and suited for the communication of the members of their online communities.

Advantages of personas include the following: can be used to create user scenarios; can be anonymous protecting use privacy; represent the user stereotypes and characteristics.

Disadvantages of personas include the following: if not enough personas are used, users are forced to fall into a certain persona type that might now accurately represent them; time-consuming.

27.3.2 Log Analysis

A log, also referred to as web-log, server log, or log-file, is in the form of a text file and is used to track the users' interactions with the computer system they are using. The types of interaction recorded include key presses, device movements, and other information about the user activities. The data are collected and analyzed using specialized software tools, and the range of data collected depends on the log settings. Logs are also time-stamped and can be used to calculate how long a user spends on a particular task or how long a user is lingering in a certain part of the website (Preece, Rogers, and Sharp 2002). In addition, an analysis of the server logs can help us find out when people visited the site, the areas they navigated, the length of their visit, the frequency of their visits, their navigation patterns, from where they are connected, and details about the computer they are using.

Log analysis is a useful and easy to use tool when analyzing online communities. For example, someone can use log analysis to answer more accurately questions such as student attendance of an online learning community. Furthermore, logs can identify the web pages users spend more time viewing and also the paths that they used. This helps identify the navigation problems of the website, but also gives a visualization of the users' activities in the virtual communities. For instance, in the case of e-learning communities, the log files will show which students are active in the CMC postings even if they are not active participants (few postings themselves), but just observing the conversations. Preece and Maloney-Krichmar (2003) notes that data logging does not interrupt the community, while at the same time can be used to examine mass interaction.

Advantages of logs (Preece, Rogers, and Sharp 2002) are as follows: helps evaluators analyze users' behavior; helps evaluators understand how users worked on specific tasks; it is unobtrusive; and large volumes of data can be logged automatically.

Disadvantages of logs (Preece, Rogers, and Sharp 2002) are as follows: powerful tools are needed to explore and analyze the data quantitatively and qualitatively; user privacy issues.

27.3.3 Content and Textual Analysis

Content analysis is an approach for understanding the processes that participants engage in as they exchange messages (McLoughlin 1996). There have been several frameworks created for studying the content of messages exchanged in online communities. Examples include work from Archer et al. (2001), Gunawardena, Lowe, and Anderson's (1997) model for examining the social construction of knowledge in computer conferencing, Henri's (1992) content analysis model, and Fahy, Crawford, and Ally's (2001) transcript analysis tool (TAT), which is described in more detail below.

The TAT focuses on the content and interaction patterns at the component level of the transcript (Fahy, Crawford, and Ally 2001). After a lengthy experience with other transcript tools and reviews of previous studies, Fahy, Crawford, and Ally (2001) chose to adapt Zhu's (1996) analytical model for the TAT. Zhu's (1996) model examines the forms of electronic interaction and discourse, the forms of participation, and the direction of participant interaction in computer conferences. The TAT also contains echoes of Vygotskian theory, primarily those dealing with collaborative sense-making, social negotiation, and proximal development (Cook and Ralston 2003). The TAT developers have come up with the following strategic decisions (Fahy 2003): the sentence is the unit of analysis; the TAT is the method of analysis; interaction is the criterion for judging conference success and topical progression (types and patterns).

The TAT was designed to permit transcript content to be coded reliably and efficiently (Fahy, Crawford, and Ally 2001). The advantages of TAT are (Fahy 2003; Cook and Ralston 2003; Fahy, Crawford, and Ally 2001) the following: it reveals interaction patterns that are useful in assessing different communication styles and online behavioral preferences among participants; it recognizes the complexity of e-conferences and measures the intensity of interaction; it enables the processes occurring within the conferences to be noted and recorded; it probes beyond superficial systems data, which mask the actual patterns of discussion; it relates usefully to other work in the area; it discriminates among the types of sentences within the transcript; it reflects the importance of both social- and task-related content and outcomes in transcript analysis research.

The unit of analysis of the TAT is the sentence. In the case of highly elaborated sentences, the units of analysis can be independent clauses, which, punctuated differently, could be sentences (Fahy 2003). Fahy, Crawford, and Ally (2001) have concluded that the selection of message-level units of analysis might partially explain problematic results that numerous researchers have had with previous transcript analysis work. They also believe that the finer granularity of sentence-level analysis results in several advantages (Fahy 2003): reliability; ability to detect and describe the nature of the widely varying social interaction, and differences in networking pattern, in the interactive behavior of an online community, including measures of social network density and intensity; confirmation of gender associations in epistolary/expository interaction patterns and in the use of linguistic qualifiers and intensifiers. Table 27.1 shows the TAT categories (Fahy, Crawford, and Ally 2001; Fahy 2003).

27.3.4 Social Network Analysis

"Social Network Analysis (SNA) is the mapping and measuring of relationships and flows between people, groups, organizations, computers or other information/knowledge processing entities. The nodes in the network are the people and groups while the links show relationships or flows between the nodes. SNA provides both a visual and a mathematical analysis of human relationships" (Krebs 2004, p. 1). Preece (2000) adds that it provides a philosophy and a set of techniques for understanding how people and groups relate to each other and has been used extensively by sociologists (Wellman 1982, 1992), communication researchers (Rice 1994; Rice et al. 1990), and others. Analysts use SNA to determine if a network is tightly bounded, diversified, or constricted; to find its density and clustering; and to study how the behavior of network members is affected by their positions and connections (Gartom, Haythornhwaite, and Wellman 1997; Scott 2000). Network researchers have developed a set of theoretical perspectives of network analysis. Some of these are (Bargotti 2000) as follows:

- Focus on relationships between actors than the attributes of actors
- Sense of interdependence: a molecular rather atomistic view
- Structure affects substantive outcomes
- Emergent effects

"The aim of social network analysis is to describe why people communicate individually or in groups" (Preece 2000, p. 183). The goals of SNA are (Dekker 2002) as follows:

- To visualize relationships/communication between people and/or groups using diagrams
- To study the factors that influence relationships and the correlations between them
- To draw out implications of the relational data, including bottlenecks
- To make recommendations to improve communication and workflow in an organization

Beidernikl and Paier (2003) list the following as the limitations of SNA:

- More theory that speaks directly to developers of online communities is needed.

TABLE 27.1
Transcript Analysis Tool Categories

Category

1: Questioning

The questioning category is further broken down into two types of questions:

1A: Vertical questions

These are questions that assume a "correct" answer exists and that they can be answered if the right authority to supply it can be found. Example: "Does anybody know what time the library opens on Saturdays?"

1B: Horizontal questions

For these questions, there may not be only one right answer. These questions invite negotiation. Example: "Do you really think mp3 files should become illegal or do you not see any harm by them?"

2: Statements

This category consists of two subcategories:

2A: Nonreferential statements

These statements contain little self-revelation and usually do not invite response or dialogue and their main intent is to impart facts or information. Example: "We found that keeping content up-to-date, distribution and PC compatibility issues were causing a huge draw on Ed. Centre time."

2B: Referential statements

Referential statements are direct answers to questions. They can include comments referring to specific preceding statements. Example: "That's right, it is the 1997 issue that you want."

3: Reflections

Reflections are significant personal revelations, where the speaker expresses personal or private thoughts, judgments, opinions, or information. Example: "My personal opinion is that it should not have been a penalty kick."

4: Scaffolding and engaging

Scaffolding and engaging initiate, continue, or acknowledge interpersonal interaction. They personalize the discussion and can agree with, thank, or otherwise recognize someone for their helpfulness and comments. Example, "Thanks Dave, I've been trying to figure that out for ages ☺."

5: References/authorities

Category 5 is compromised of two types:

5A: Quotations, references to, paraphrases of other sources.

Example, "You said, 'I'll be out of the city that day'."

5B: Citations, attributions of quotations, and paraphrases

Example: "Mathew, P. (2001). A beginner's guide to mountain climbing."

- The data collected may be personal or private.
- The analysis of the data is quantitative and specific to the particular network, whereas common survey data are qualitative and generalize answers on the parent population.

It is also worth pointing out that network analysis is concerned about dyadic attributes between pairs of actors (such as kinship, roles, and actions), whereas social science is concerned with monadic attributes of the actor (such as age, sex, and income).

There are two approaches to SNA as follows:

1. Ego-centered analysis: Focuses on the individual as opposed to the whole network, and only a random sample of network population is normally involved (Zaphiris, Zacharia, and Rajasekaran 2003). The data collected can be analyzed using standard computer packages for statistical analysis such as SAS and SPSS (Garton, Haythornthwaite, and Wellman 1997).
2. Whole network analysis: The whole population of the network is surveyed and this facilitates conceptualization of the complete network (Zaphiris, Zacharia, and Rajasekaran 2003). The data collected can be analyzed using microcomputer programs such as UCINET and Krackplot (Garton, Haythornthwaite, and Wellman 1997).

The following are important units of analysis and concepts of SNA (Garton, Haythornthwaite, and Wellman 1997; Wellman 1982; Hanneman 2001; Zaphiris, Zacharia, and Rajasekaran 2003; Wellman 1992):

- Nodes: The actors or subjects of study.
- Relations: The strands between actors. They are characterized by content, direction, and strength.
- Ties: Connect a pair of actors by one or more relations.
- Multiplexity: The more relations in a tie, the more multiplex the tie is.

- Composition: This is derived from the social attributes of both participants.
- Range: The size and heterogeneity of the social networks.
- Centrality: Measures who is central (powerful) or isolated in networks.
- Roles: Network roles are suggested by similarities in network members' behavior.
- Density: The number of actual ties in a network compared with the total amount of ties that the network can theoretically support.
- Reachability: To be reachable, connections that can be traced from the source to the required actor must exit.
- Distance: The number of actors that information has to pass through to connect one actor with another in the network.
- Cliques: Subsets of actors in a network, who are more closely tied to each other than to the other actor who is not part of the subset.

SNA is a very valuable technique when it comes to analyzing online communities, as it can provide a visual presentation of the community and, more importantly, it can provide us with qualitative and quantitative measures of the dynamics of the community. The application of SNA to the analysis of online communities is further demonstrated with a case study in Section 27.4 of this chapter.

27.4 CASE STUDIES

In this section, we present two case studies that demonstrate the use of theoretical and analytical techniques for studying online communities. In the first case study, we demonstrate how the results from an attitude toward thinking and learning questionnaire can be combined with SNA to describe the dynamics of a computer-aided language learning (CALL) online community. In the second case study, we present a theoretical activity theory model that can be used for describing interactions in online game communities.

27.4.1 Computer-Aided Language Learning Communities

In the first case study, we demonstrate a synthetic use of quantitative (SNA) and qualitative (questionnaires) methods for analyzing the interactions that take place in a CALL course. Data were collected directly from the discussion board of the "Learn Greek Online" (LGO) course (Kypros-Net Inc 2005).

LGO is a student-centered e-Learning course for learning Modern Greek and was built through the use of a participatory design and distributed constructionism methodology (Zaphiris and Zacharia 2001). In an ego-centered SNA approach, we have carried out an analysis of the discussion postings of the first 50 actors (in this case, the students of the course) of LGO.

To carry out the SNA, we used an SNA tool called "NetMiner" (Cyram 2004), which enabled us to obtain centrality measures for our actors. The "in and out degree centrality" was measured by counting the number of interaction partners per each individual in the form of discussion threads (e.g., if an individual posts a message to three other actors, then his/her out-degree centrality is 3, whereas if an individual receives posts from five other actors, then his/her in-degree is 5).

Because of the complexity of the interactions in the LGO discussion, we had to make several assumptions in our analysis as follows:

- Posts that received zero replies were excluded from the analysis. This was necessary to obtain meaningful visualizations of interaction.
- Open posts were assumed to be directed to everyone who replied.
- Replies were directed to all the existing actors of the specific discussion thread unless the reply or post was specifically directed to a particular actor.

In addition to the analysis of the discussion board interactions, we also collected subjective data through the form of a survey. More specifically, the students were asked to complete an Attitudes Towards Thinking and Learning Survey (ATTLS). The ATTLS measures, through the use of 20-Likert scale questions, the extent to which a person is a "connected knower" (CK) or a "separate knower" (SK). People with higher CK scores tend to find learning more enjoyable and are often more cooperative, congenial, and more willing to build on the ideas of others, whereas those with higher SK scores tend to take a more critical and argumentative stance to learning (Galotti et al. 1999).

The out-degree results of the SNA are depicted in Figure 27.1 in the form of a sociogram, and the in-degree results are depicted in Figure 27.2. Each node represents one student (to protect the privacy and anonymity of our students, their names have been replaced by a student number). The position of a node in the sociogram is representative of the centrality of that actor (the more central the actor the more active). As can be seen from Figure 27.1, students S12, S7, S4, S30 (with out-degree scores ranging from 0.571 to 0.265) are at the centre of the sociogram and possess the highest out-degree. The same students also posses the highest in-degree scores (Figure 27.2). This is an indication that these students are the most active members of this online learning community, posting and receiving the largest number of postings. In contrast, participants in the outer circle (e.g., S8, S9, S14, etc.) are the least active with the smallest out-degree and in-degree scores (all with 0.02 out-degree scores).

In addition, a clique analysis was carried out (Figure 27.3), and it showed that 15 different cliques (the majority of which are overlapping) of at least three actors each have been formed in this community.

As part of the ego-centered analysis for this case study, we look in more detail at the results for two of our actors: S12, who is the most central actor in our SNA analysis, that is, with the highest out-degree score, and S9, an actor with the smallest out-degree score. It is worth noting that both members joined the discussion board at around the same time.

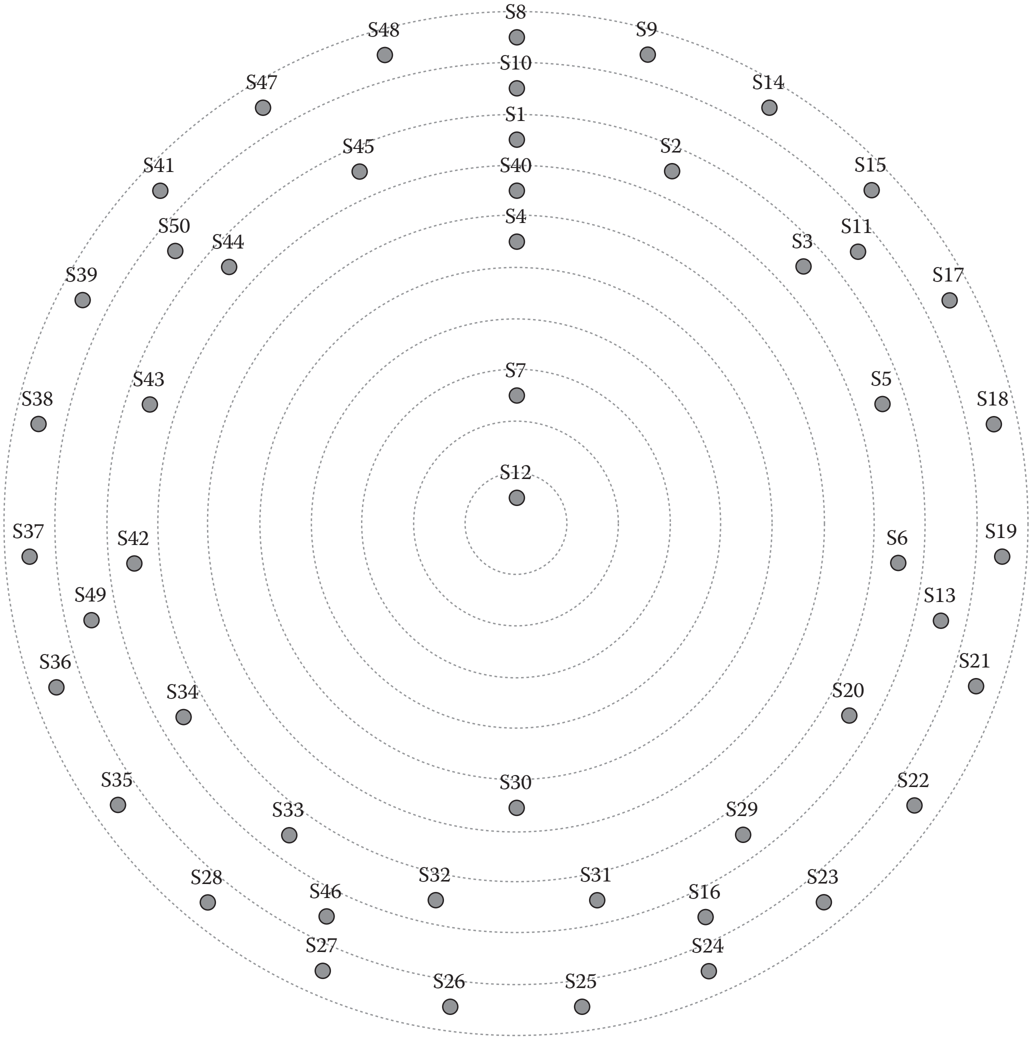

FIGURE 27.1 Out-degree analysis sociogram.

First, through a close look at the clique data (Table 27.2), we can see that S12 is a member of 10 out of the 15 cliques, whereas S9 is not a member of any, an indication of the high interactivity of S12 versus the low interactivity of S9. In an attempt to correlate the actors' position in the SNA sociogram with their self-reported attitudes toward teaching and learning, we looked more closely at the answers these two actors (S12 and S9) provided to the ATTLS. Actor S12 answered all 20 questions of the ATTLS with a score of at least 3 (on a 1–5-Likert scale), whereas S9 had answers ranging from 1 to 5. The overall ATTLS score of S12 is 86, whereas that of S9 is 60. A clear dichotomy of opinions occurred on 5 of the 20 questions of the ATTLS. S12 answered all 5 of those questions with a score of 5 (strongly agree), whereas S9 answered them with a score of 1 (strongly disagree). More specifically, S12 strongly agreed on the following:

1. She or he is more likely to try to understand someone else's opinion than to try to evaluate it.
2. She or he often finds herself or himself arguing with the authors of books read, trying to logically figure out why they're wrong.
3. She or he finds that he or she can strengthen his or her own position through arguing with someone who disagrees with them.
4. She or he feels that the best way to achieve his or her own identity is to interact with various other people.
5. She or he likes playing devil's advocate—arguing the opposite of what someone is saying.

S9 strongly disagreed with all the above statements. These are all indications that S12 is a CK, whereas S9 is a SK.

This case study showed that the combination of quantitative and qualitative techniques can facilitate a better and deeper understanding of online communities. SNA was found to be a very useful technique for visualizing interactions and quantifying strengths and dynamics in online communities. In combination with the ATTLS, it was possible to

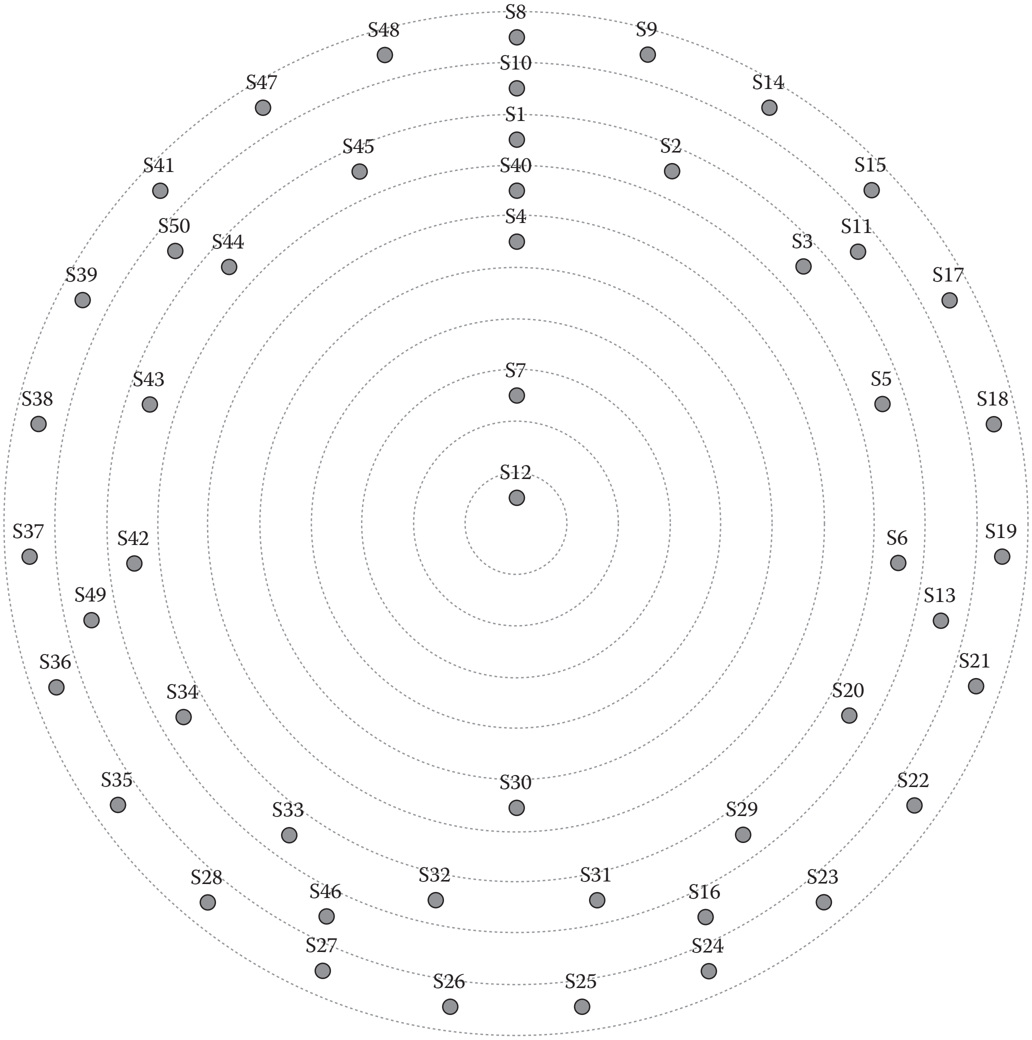

FIGURE 27.2 In-degree analysis sociogram.

identify the key players of the e-learning community. These members' roles show them to be more powerful and central in the discussions. Identifying their characteristics enables us to make re-enforcements to the community by making other participants more active in the discussion board communication. This active learning approach could in-turn improve the pedagogical value of e-learning within these communities.

27.4.2 Game Communities and Activity Theoretical Analysis

The main motivation of the second case study arises from the more general area of computer game-based learning. Game-based learning has focused mainly on how the game itself can be used to facilitate learning activities, but we claim that the educational opportunity in computer games stretches beyond the learning activities in the game per se. Indeed, if you observe most people playing games, you will likely see them download guidelines from the Internet and participating in online forums to talk about the game and share strategies. In actuality, almost all game playing could be described as a social experience, and it is rare for a player to play a game alone in any meaningful sense (Kuo 2004). This observation is even more evident in MMORPGs, which has been discussed in Section 27.2.3.1. For example, the participation in a MMORPG is constituted through language practice within the in-game community (e.g., in-game chatting and joint task) and out-of-game community (e.g., the creation of written game-related narratives and fan-sites). The learning is thus not embedded in the game, but it is in the community practice of those who inhabit it.

27.4.2.1 Types of Game Communities

Therefore, we believe that the study on computer games should be expanded to include the entire game community. Computer game communities can be categorized into three classes, which we have identified (Figure 27.4; Ang, Zaphiris, and Wilson 2005) as follows:

Single Game–play Community: this refers to a game community formed around a single player game. Although players of a single player game such as The Sims 2 and Final Fantasy VII play the game individually, they are associated with an out-of-game community, which discusses the game either virtually or physically.

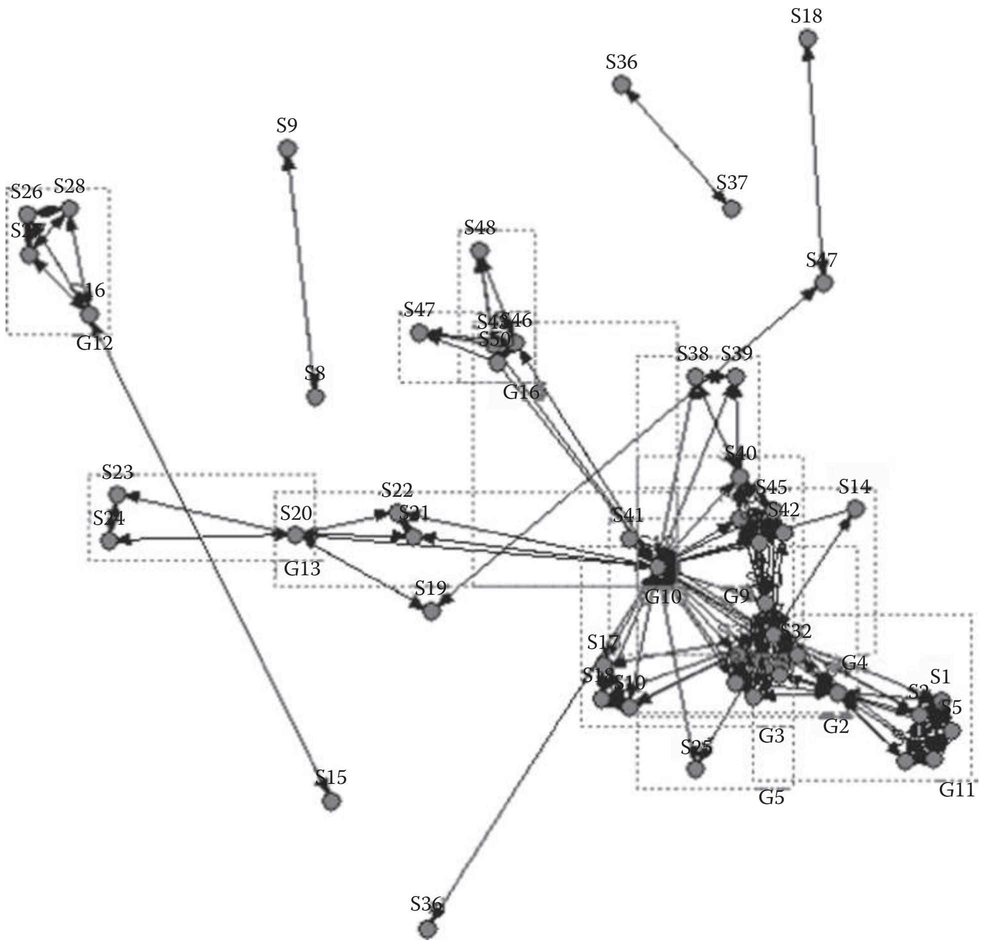

FIGURE 27.3 Clique analysis sociogram.

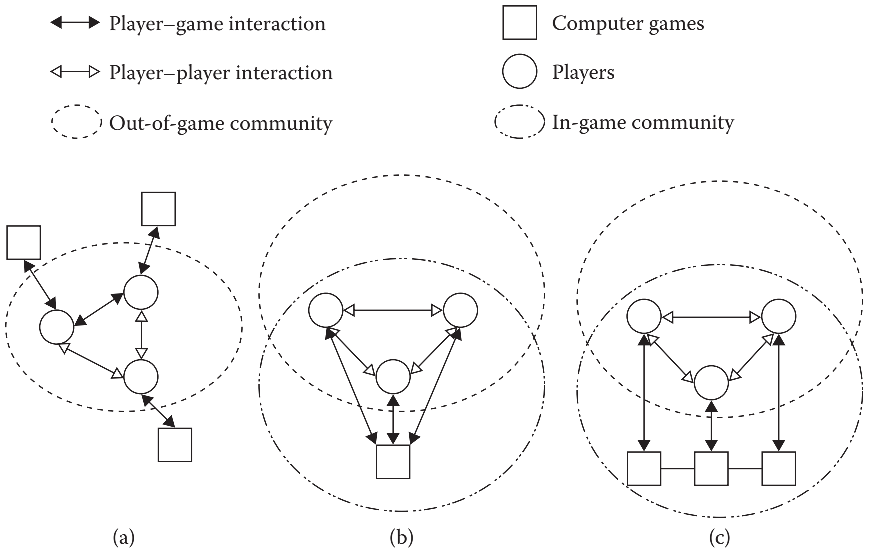
TABLE 27.2
Clique Analysis of the Learn Greek Online Discussions

Cliques	Actors
K1	S12, S7, S30, S40, S43, S44, S45
K2	S12, S7, S30, S4
K3	S12, S7, S10, S11, S13
K4	S12, S7, S14
K5	S12, S7, S25
K6	S12, S7, S41
K7	S12, S20, wS21, S22
K8	S12, S29, S4, S30, S31, S32, S33, S34
K9	S12, S38, S39, S40
K10	S12, S46, S49, S50
K11	S1, S2, S3, S4, S5, S6, S7
K12	S16, S26, S27, S28
K13	S23, S20, S24
K14	S47, S46, S49, S50
K15	S48, S46, S49, S50

Social Game–play Community: this refers to multiplayer games, which are played together in the same physical location. It creates game communities at two levels: in-game and out-of-game. Occasionally, these two levels might overlap. The out-of-game interaction might be affected by issues beyond the specific game system; for example, the community starts exchanging information about another game.



(a) Single game–play community (b) Social game–play community (c) Distributed game–play community

FIGURE 27.4 Types of game communities.

Distributed Game–play Community: this is an extension of social game–play community, but it emphasizes the online multiplayer game in which multiple sessions of game are established in different geographical locations.

The study of game communities, especially out-of-game communities, from the perspective of education is still very much unexplored. We believe the potential of games in education is not limited to what is going on in the game. Educators could benefit by studying games as a social community because games are now becoming a culture that permeates the life of everyone, especially the younger generation. Black (2004) has investigated the interactions among participants in a virtual community of Japanese comic fans, which involve a lot of reading and writing throughout the site. She examines how the community of fans helps each other with English language writing skills and with cross-cultural understanding. In this section, we have pointed out that game communities can emerge from both single-player and multiplayer games. We believe that by further studying the social interaction in the game community, we will be able to utilize games in learning in a more fruitful way. In Section 27.4.2.2, we apply and evaluate one of these models of game communities to a specific scenario in knowledge building using activity theory.

27.4.2.2 Activity Theory

In this case study, we demonstrate how activity theory can be used to analyze an out-of-game community around a single-player game, which is based on constructionist activities as proposed by Papert (1980). Papert claims that even for adults, learning remains essentially bound to context, in which knowledge is shaped by the use of external supports. His approach helps us understand how learning is actualized when individual learners construct their own favorite artifacts or object-to-think-with (Papert 1980).

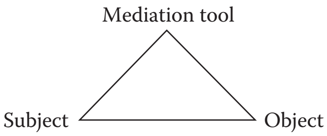


FIGURE 27.5 Vygotsky's mediation.

Although Papert's theory provides a solid framework for understanding children's and even adults' ways of learning by designing, it does not offer a systematic framework for analyzing the construction activities within a learning community. Analyzing constructionist activities can be useful as it could help inform constructional design for educational purposes. The most significant analysis includes the learning within a community and the development of an individual. We are also interested in finding out how tools such as computers help learners construct artifacts and knowledge. Hence, we would like to draw from the Vygotskian naturalist approach, which emphasizes human activity systems. Vygotsky (1930) formulated a theoretical concept that is very different from the prevailing understanding of psychology, which was dominated by behaviorism at that time. This new orientation was a model of tool-mediation and object-orientedness. He proposes the classic triangle model to demonstrate the idea of mediation:

In Figure 27.5, the subject is the individual engaged in the mediated action, the mediating artifact or tool could include physical artifacts and/or prior knowledge of the subject. The object is the goal/objective of the activity. Although constructionist learning relies very much on computational tools, the concept of mediation is not explicated. Figure 27.5 shows explicitly that the relationship between the subject and the object is no longer straightforward; instead, it is mediated by the tool. For example, when building a website, the subject is working toward an objective (e.g., to add a table in the webpage) using not only the computer (external tools) but also her internal understanding of how websites and computers work (internal tools).

TABLE 27.3
Hierarchy of Activity

Unit of Analysis	Stimulus	Subject	Language Learning Example
Activity	Object	Community	Engage in a meaningful conversation
Action	Goal	Individual	Sentence construction
Operation	Conditions	Unconscious	Word selections, grammar rules

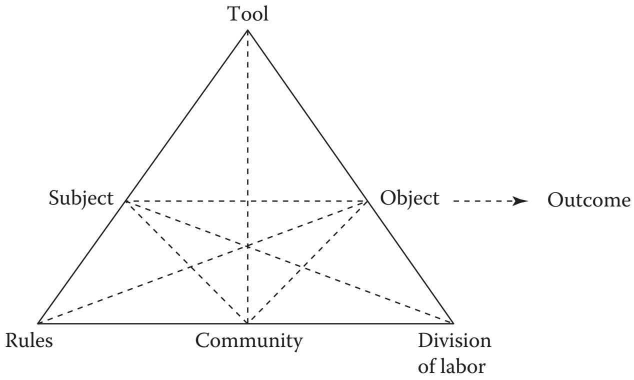

FIGURE 27.6 The triangle activity system diagram.

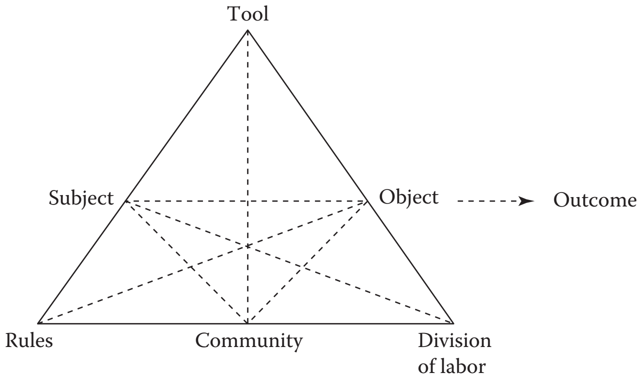

FIGURE 27.7 The transformation of individual action-operation.

Leont'ev (1978) extends this notion of activity to differentiate between an individual action and a collective activity by proposing a hierarchy of activity (Table 27.3). Collective activity is connected to the object of the whole community, of which each individual subject is often not consciously aware. An individual action is connected to a conscious goal. Below the collective activity and individual action, there is a level of operations dependent on the conditions in which the action is performed. Thus, an activity system can be analyzed at three levels: (1) the activity level, which is oriented toward the object/objective and carried out by the whole community; (2) the action level, which is directed at the individual goal; and (3) the operation level, which is elicited by conditions and is performed unconsciously.

This hierarchy is crucial in explaining the learning process in an activity system. We would like to illustrate an example of this hierarchy in learning a foreign language (Table 27.3). The overall objective is to be able to engage in a meaningful conversation. In the beginning, the learner has to work on the grammar and the choice of words at a conscious level. When the learner has reached a higher proficiency level, these actions are transformed into operations. The learner no longer needs to select appropriate words and check grammar rules deliberately as these have been learned thoroughly and are now operating unconsciously. The consciousness of the learner is now focused on expressing himself properly depending on the objective of the conversation. Grammatical rules become invisible to the learner, and he is only selecting appropriate goals to be achieved. Therefore, it can be inferred that activity theory treats learning as the shift from the higher level (action) to the lower level (operation) in the hierarchy.

Drawing on work by Vygotsky and Leont'ev, Engeström (Engestrom 2001) views all human activities as contextualized within an interdependent activity system. Engeström adds collective mediation to Vygotsky's tool mediation and presents the triangle model of activity system (Figure 27.6).

In the diagram, the subject is the individual or a group who are selected as the point of view of the analysis. The object refers to the raw material or the problem space at which the activity is directed and which is transformed into outcomes with the help of external and internal tools. Tools are the concepts, physical tools, artifacts, or resources that mediate a subject's interactions with an object. The community refers to those with whom the subject shares the same general object. The division of labor (DOL) is the classification of tasks among the members on the community, whereas the rules are the regulations, norms, and conventions within the activity system.

Constructionist learning can be described and visualized through this activity triangle. Mediated by the tool and the community, the learner externalizes her initial stage of knowledge through object construction. The individual externalization (mediated by the tool) can be broken down into actions and operations. Actions are directed toward a personal goal and are carried out with careful deliberation. For example (Figure 27.7), in a book-writing activity, the author (an expert word processor user) will operate (e.g., typing) the word processor at the unconscious level and consciously acts on the book (to select appropriate words, construct meaningful sentences, and paragraphs) she is writing. At a certain point, the author encounters a new condition with the word processor, which she is not familiar with: say to insert a table into the book. Under this new condition, a breakdown is said to have happened. The conscious effort of the author is not placed anymore on the book itself but instead is now placed on the word processor (e.g., to achieve the action [insert tables], the author performs the operation [read help files]). Once the author has thoroughly learned about the table insert, she can again act on the book consciously and development is said to have happened.

27.4.2.3 Activity Theoretical Analysis for Constructionist Learning

We have conducted a study to analyze a wiki-based game community using activity theory. The goal of this study was to demonstrate the usefulness of activity theory in researching online communities. The collaborative construction activity in a wiki-supported community devoted to writing a game guidebook is examined. Activity theory is used as an analytical tool to investigate this community. In this section, experiences and challenges from the analysis are reported to give some insights into how activity theory can be helpful for online community research.

The analysis on online communities can be done through the lens of various concepts associated with activity theory such as the levels of activity hierarchy and different perspectives of the triangle model as explained in Section 27.4.2.2.

For instance, we can start our analysis with the most basic aspect of the constructionism by simply examining the relationship between subjects and the object. Then, we can analyze Vygotsky's mediation model of activity system consisting of individual actions and tools. The analysis is also possible to be extended to the whole community of this system to include emerging rules and DOL that mediate the community. The focus can also be placed mainly on the constructionist concept of externalizing the internal meanings onto a sharable artifact through mediation. More specifically, we can look into (but are not limited to) these aspects:

- Subject–object: What are the constructionist actions that act on the object and transform the object into outcome?
- Subject–tool–object: How do actions shift to operations and vice versa? How do tools mediate individual actions and operations? What is the nature of the mediating tools? How do they support knowledge building?
- Subject–rules–object and subject–DOL–object: What is the nature of implicit and explicit rules? How is DOL manifest in the community? How do rules and DOL support knowledge building?

Apart from its focus on both individual and collective development through action–operation transformation, activity theory also helps analyze the tools, capture the rules and the DOL, which mediates these actions. These must be further explained to differentiate individual mediation and collective mediation. Taking the example of our study on game community, individual mediation places its emphasis on "how a user uses the tool to write the game guide, without taking into account how other users act in the community." In other words, it is about the affordance of the tool to support what an individual can do.

Collective mediation is about the community, which consists of two major components: rules and DOL. Rules define what can be done and cannot be done in a community. This should not be confused with the affordance of the tool. The tool might afford certain actions such as writing in abusive language, but the rules might want to ban this action. DOL is self-explained: how the work load is divided among many users in a community.

Activity theory appears to be a promising framework as it gives an analytical lens on analyzing and interpreting the data. Activity theory provides different perspectives of analysis, as it casts different light on the collected data as researchers can examine it from many perspectives by focusing on different subtriangles of the activity system diagram. It also helps us examine learning process: how learning occurs individually and collectively through the transformation of hierarchy of activity from action to operation. Furthermore, both individual and collective aspects are given equal importance. Activity theory informs the development of the whole community and the individual development. It explains how individual development contributes to the community growth and vice versa.

On the basis of our study, individual actions help sharpen the mediation tool, whereas collective actions bring about new rules or refine existing rules that mediate the collective action. In short, activity theory is useful to analyze the community in the following ways:

- It helps understand the individual mediation process: subject–tool–object
- It clearly presents the collective mediation process: subject–community–object
- It reveals the emerging rules and DOL in the community

In a wiki space, knowledge is socially constructed; it is created individually with tools, negotiated, and agreed within a community based on emerging rules and DOL. It starts as a single unit of information (a page in this context) and grows organically and evolves into a complex and well-structured set of knowledge. From our findings, we induce what contributes to the development of the community:

- Users share some historical backgrounds: they already share some of the tools/rules before joining the community, and they also share the interest on the same game.
- Users share the same object (goal), which is to build a game guide book.
- A user's individual action: this goal-oriented individual action triggers negotiations that lead to the growth of the space.
- The community's agreement on the object: not only share the same object, the community must be able to negotiate and agree on the object.
- Tools that support these actions and negotiations.
- Emerging rules that coordinate the activity.
- DOL that divide the responsibilities.

The evolution of a knowledge-building community needs more than a group of devoted users who share the same object. It involves negotiation and agreement among the users on the object. Although every user tends to act toward their own goal, it takes the compromise of the entire community to agree on the object.

Activity theory helps online community researchers identify design issues at two aspects: the software application as tools and the social interaction within the community around the tool. It also reveals the development of the community-building process from the individual and collective level through the shift of activity hierarchy. We thus believe that analyzing online communities with activity theory will yield fruitful results and give insights on online community design.

Finally, we must reiterate the fact that activity theory itself is not limited to what is presented in the triangle diagram as proposed by Engeström. Although his model is tremendously useful, it overlooks several significant concepts of activity theory. One major limitation is the static representation of activity theory. The triangle diagram represents only a snapshot of a particular time, thus making it hard to analyze the activity across time. It is understood that Engeström's model is intended to be open so that it can be used in various domains, but this has proven to pose a serious difficulty among the practitioners as some researchers have started to operationalize it so that it is more practical in day-to-day methodology (Korpela, Soriyan, and Olufokunbi 2000; Barab, Hay, and Yamagata-Lynch 2001; Mwanza 2002). Hopefully, with the increasing attention drawn by activity theory, the theory will be expanded and operationalized to fit the purpose of HCI research in general and online community in particular.

27.5 ANALYZING AND DESIGNING ONLINE COMMUNITIES WITH SOCIAL SIMULATION

Developing online communities involves usability design, which supports consistent, controllable, and predictable human–computer interaction, and sociability design, which focuses on human–human interaction (i.e., social interaction) and social policies (Preece 2000).

The majority of research on sociability design has so far been revolved around conventional HCI methods such as query-based techniques (e.g., questionnaires, interviews), observation, and content analysis to identify the sociability requirements of the online community through various aspects: purpose, people, and policies (Preece 2000).

For instance, several studies have already analyzed the content of messages that people post in online communities (Savicki, Lingenfelter, and Kelley 1996; Klemm et al. 1999; Golder and Donath 2004) and constructed typology of information exchange that described people's online behavior (Burnett 2000). Others investigated and contrasted the interaction patterns in different types of communities (Turner et al. 2005). Using query-based techniques, some have examined people's motivation of certain online behavior such as altruistic helping behavior in an open-source software development community. (Raymond 1999; Kollock 1999; Niedner, Hertel, and Hermann 2000).

These methods often aim to generate a rich description of the current state of the community, which can then be transformed into needs and requirements so that a social software system can be developed to facilitate users' needs and activities.

When developing online communities, we believe that it is useful to be able to compare design alternatives. For instance, how different social policies will lead to the growth of the community. In addition, we would also like to find out how changes in an existing community will affect its future trend.

However, online communities are complex phenomena as they encompass humans interacting with each other, exchanging and diffusing information. Such a system is dynamic and complex, continually changing and evolving.

Current research practice on (online) community offers little opportunity for causal analysis (Jager, Popping, and Sande 2001). Interaction patterns leading to the emergence of different types of social networks are difficult to study experimentally.

One possible way of making comparisons is through simulation. Suppose we have an online community of elderly people on the topic of depression and we notice that there are too many off-topic discussions. We want to introduce a new policy/new design that would reduce off-topic discussion, but we are not sure whether doing so will be beneficial or detrimental to the future growth of the community. Often it is impractical to run a large-scale social experiment on such a massive online community. Furthermore, it could involve complicated ethics issues when conducting experiments that deal with this sensitive population. In this case, we could develop a social simulation that mimics the interaction behavior of the existing community and conduct "virtual" experiment with the simulation.

In other words, simulations can provide a test-bed for what-if situations, which cannot be studied otherwise through other methods.

27.5.1 Agent-Based Model

In terms of social simulation (Gilbert and Troitzsch 2005), an agent-based model (ABM) is a computational model for studying the process of the social system as a whole through simulating the actions and interactions of autonomous individuals, known as agents. Agents can include a whole range of social actors with data-gathering and decision-making ability, sometimes equipped with sophisticated learning capabilities and are adaptive to the environment.

The ABM described in this chapter simulates the interaction behaviors of individual members of an online community to understand the dynamics of the social network in the online community and to understand how various interventions affect community performance.

ABMs are models between natural language and mathematical symbols. They model reality with formal language (i.e., programming language), which is understood by the computer.

Agents impose four key assumptions (Wooldridge and Jennings 1995).

- They are autonomous: the system is not modeled as a globally integrated entity. The global patterns emerge from local interaction among autonomous decision-making agents.
- They are interdependent: agents are influencing each other's behavior directly or indirectly.
- They follow simple rules: each individual is modeled with simple behavior, which could produce complex global patterns.
- They are adaptive: agents could learn from their past experience, thus alter their behavior.

The global process of online communities is distributed since there is limited/no central control and the result depends largely on the interactions between agents. Hence, agent-based modeling approach is bottom-up: it is a nonlinear system, which is more than the sum of their parts (Waldrop 1992). The macro-behavior can be different from the underlying micro-motives.

The goal of such modeling is often to reproduce macro-events from the bottom-up and to obtain emergent regularities.

We maintain that ABM can benefit sociability design of online communities. Most importantly, the models can help define good design, that is, how a given design decision is positive for the community. By generating many runs with different conditions, large data sets of online communities can be accumulated.

Traditionally, sociologists have understood social life as a system of institutions and norms that shape individual behavior from top-down. From the view point of SNA, Haythornthwaite and Wellman (1998) argued that individuals' behavior is affected by the kind of ties and the network in which they are involved than by attributes they possess. We believe that the reverse is also true, in which the ties and the network are affected by the individuals' behavior. In this study, we developed an ABM to study the effect of player interaction on the formation of social networks of the guild community from bottom-up.

Dealing with linear systems, the behavior of the whole system corresponds exactly with the sum of its constituting parts (such as multiple regression models). In nonlinear systems, even if the observer has a good understanding of how each part works, it will not be possible to understand the system as a whole. Instead of starting from the system as a whole and decompose it (top-down), it will be more fruitful to start from its constitutive parts (bottom-up). In such systems, coherent behaviors not defined a priori may spontaneously emerge from the aggregate dynamics. Even a simple ABM can exhibit complex behavior patterns and provide valuable information about the dynamics of the real-world system that it emulates.

ABM simulation can work like a virtual laboratory through which the researcher can test hypotheses, manipulating variables and constraints of the model and observe the outcome. Therefore, ABMs are a powerful tool in theoretical development and explanation. We can use ABMs to explore plausible mechanisms underlying the observed patterns.

Research using ABM has demonstrated the ability to grow societies (Epstein and Axtell 1997). Various social phenomena have been studied using ABM, including the simulation of digital markets (López-Sánchez et al. 2004), violence and conflict modeling (Epstein 2002; Jager, Popping, and Sande 2001), trust and cooperation (Macy and Sato 2002), archaeological simulation (Doran et al. 1994), ecosystem management (Antona et al. 2002), and so on. Clearly, not all social phenomena can be meaningfully modeled through the bottom-up approach. Therefore, ABMs are most appropriate for examining processes that lack central coordination.

27.5.2 Simulating Social Networks

The main strength of ABM lays in its focus on relational simulation for theoretical research that bridge between micro and macro levels of analysis. Therefore, not surprisingly, ABM has been applied to simulate interaction of agents in social networks. In most cases, AMB is applied to study two situations in social networks. First, simulations are developed to examine agents' interaction and the aggregate interaction dynamics within specific topology of social networks. Wilhite (2001), for instance, examined trading interaction, that is, search, negotiation, and exchange within four types of social network topology: global network, local disconnected network, local connected network, and small-world network. Instead of exploring the process of network formation, he was interested in understanding how different types of social network configurations affect trading behaviors.

More common in the research of social network simulation is the generation of social network based on agents' interactions. For example, some work has been carried out by Ahrweiler, Pyka, and Gilbert (in press), Lamieri and Ietri (2004), and Özman (2007) to explore the network formation based on the simulation of innovation creation and knowledge diffusion in the industry. In another study, Zhang, Ackerman, and Adamic (2007a,b) used simulations to replicate the structural characteristics of an online Java discussion forum and to evaluate how different types of expert ranking algorithm may perform in communities with different characteristics. Apart from these, ABM has also been used in studying network evolution over time (Carley, Ju-Sung, and Krackhardt 2001; MaxTsvetovat and Carley 2002).

27.5.3 Application to Online Community Design

One obvious question is of course "how do we practically relate design/policy decisions to the simulation parameters." We believe this is where conventional HCI methods meet social simulations.

Existing HCI methods that focus on empirical study can be easily integrated into simulation study. Experimental studies can be carried out to examine the effect of a policy change/graphical user interface element on interaction behavior at individual/micro level. For instance, we could conduct a small-scale experiment with 30 people and estimate how much a particular "reward system" (a design decision) increase/decrease their initiation of acting (a simulation parameter). Then, we can plug in this empirical result into the simulation to predict the social network that might arise through the introduction of this reward system.

27.5.4 Simulations Are a Powerful Technique for Understanding Sociability in Online Communities

Since we are unable to directly modify the community, we need an alternative way to study how the underlying characteristic of the community influences the social network that arises. We believe that simulations allow us to understand this causal relationship by generating data that may not be obtainable empirically.

This understanding can also enable us to design better ways to transform and expand these communities with minimal risks.

27.6 DISCUSSION AND CONCLUSIONS

This chapter looked at the definitions of CMC and online communities and pointed out the multidisciplinary nature of the definitions and the way online communities are being analyzed and studied. In Section 27.2, we introduced the different types of CMC and online communities. In Section 27.3, we provided an overview of some of the most commonly used techniques and theoretical frameworks for analyzing online communities. Then in Section 27.4, we used two case studies to demonstrate the use of those techniques. Online communities are widely used for general entertainment and current affairs discussions as well. Professional communities (e.g., business, art, and industry specific) are also being formed within the online environment.

The study of online communities is flourishing, primarily due to the increasing popularity of online services and tools that provide the construction of such networks of users. The study of such complex communities requires the use of a synthesis of methodologies and theoretical foundations. In our first case study, we demonstrated how SNA can be used to model and visualize online community interactions; in the second one, the theoretical foundations based on activity theory were applied to the domain of game-based communities.

At the beginning of the Internet technology, online communities were solely used for synchronous (often just chat) or asynchronous (most commonly discussion board) textual interaction. This is no longer the case as people are interacting in online communities using new and more innovative interaction paradigms. Game-based communities, for instance, allow users to represent themselves (through the use of 3D avatars) visually in virtual environments, which are often depicted as a fantasy and unrealistic world. They can navigate, change, or even create the virtual world (and thus the context of the community) they interact with. As such, the traditional boundary between author and reader is distorted as the designer (authors) is not the only one who determines what the system is like. Rather, the participants (readers) are co-constructing the virtual world as they are not anymore using the tool to communicate; they are creating and interacting with a virtual environment through which they can meet, socialize, and work with others. Preece (2000) was the first to identify and stress this important social dimension of online communities. Now, this online sociability is becoming more mature and more central to the online communities with which we interact.

This new paradigm of interaction poses new challenges for researchers and practitioners. The importance of appropriate representation of emotions and other social cultural cues in online communities is now becoming even more important. With textual interfaces, there was an attempt to represent these social cues through the use of emoticons. How can this, for example, be transferred to the domain of virtual game communities? Do we want our avatars to behave like us or do we want them to have some alternate and illusionary identities with extraordinary abilities or unusual behaviors? How can we come up with new interfaces and new interaction paradigms that can facilitate this better, in order to cope with the new demands from the users in such online communities?

A second area that is gaining popularity is the research of online communities, or Internet research. Content analysis and query-based techniques were sufficient if what we wanted was a first good impression of the interactions taking place in an online textual community. This is not anymore the case. Studying the sociability of a game-based community, for example, requires the synthesis of more techniques. We might want to immerse ourselves in that community, engage in long-term ethnographic studies of its environment, and get the first-hand experiences of what happens in it. We might have to use a social cultural theoretical framework (e.g., activity theory) to get a better understanding of the way people behave, differently from the real world, in these inherently social environments. We might have to quantify, through the use of SNA for example, the dynamics of the networks and subgroups that evolve around these communities.

The possibility of online communities is unlimited with the emergence of more mature and imaginative virtual worlds. Only by treating them in equality with their physical counterparts, which encapsulate the practices of economy, politics, ideology, and everyday life, can we research and study them intellectually.

28 Virtual Environments

Kay M. Stanney and Joseph V. Cohn

CONTENTS

28.1 INTRODUCTION

Interactive computing has evolved through the years from cryptic command-based interfaces to a collection of task-based applications to ecologically valid immersive environments, each advance dissolving more of the barrier between users and their desired actions. To many, with virtual environments (VEs), we have reached the panacea in interactive computing. Such environments immerse users in realistic settings, allowing them to engage in an intuitive and intimate manner with their digital universe. Such capability affords the opportunity to "learn by doing," "train like we fight," and "involve me and I understand." Although early VEs were low in resolution and sluggish in responsiveness, advances in display and tracking technology have largely resolved these issues such that today VE applications abound. However, considerable human–computer interaction (HCI) research and development are required to resolve lingering issues, such as cybersickness and usability, if VE technology is to be openly embraced by users. This chapter reviews the current state of the art in VE technology, provides design and implementation strategies, discusses health and safety concerns and potential countermeasures, and presents the latest in VE usability engineering approaches. Current efforts in a number of application domains are reviewed. This chapter should enable readers to better specify design and implementation requirements for VE applications and prepare them to use this advancing technology in a manner that minimizes health and safety concerns.

28.2 SYSTEM REQUIREMENTS

A VE is a computer-generated immersive environment that can simulate both real and imaginary worlds, often times in three dimensions (3D). Current VE applications are primarily intriguing visual and auditory experiences, with a smaller number incorporating additional sensory modalities, such as haptics and smell. These worlds are driven by hardware, which provides the hosting platform and multimodal presentation, allows for physical interaction, and tracks the whereabouts of users as they traverse the virtual world and software to model and generate the virtual world and their autonomous agents and support communication networks that link multiple users (see Figure 28.1).

More specifically, hardware interfaces consist primarily of the following:

- Interface devices used to present multimodal information and sense the VE
- Tracking devices used to identify head and limb position and orientation
- Interaction techniques that allow users to navigate through and interact with the virtual world

Software interfaces include the following:

- Modeling software used to generate VEs
- Autonomous agents that inhabit VEs
- Communication networks used to support multiuser VEs

28.2.1 Hardware Requirements

VEs require very large physical memories, high-speed processors, high-bandwidth mass-storage capacity, and high-speed interface ports for interaction devices (Durlach and Mavor 1995). These requirements are easily met by today’s high-speed, high-bandwidth computing systems, many of which have surpassed the Gigahertz barrier. The future looks even brighter with promises of massive parallelism in multicore and many-core processor architectures (Holmes, Williams, and Tilke 2010), which will allow tomorrow’s computing systems to be exponentially faster than their ancestors. With the rapidly advancing ability to generate complex and large-scale virtual worlds, hardware advances in multimodal input/output (I/O) devices, tracking systems, and interaction techniques are needed to support generation of increasingly engaging virtual worlds. In addition, the coupling of augmented cognition and VE technologies can lead to substantial gains in the ability to evaluate their effectiveness.

28.2.1.1 Multimodal Inputs/Outputs

To present a multimodal VE (see Chapter 18), multiple devices are used to present information to VE users. In terms of VE projection systems, the one that has received the greatest attention, both in hype and disdain, is almost certainly the head-mounted display (HMD). One benefit of HMDs is their compact size, as an HMD when coupled with a head tracker can be used to provide a similar visual experience as a multitude of bulky displays such as those associated with spatially immersive displays (SIDs) and desktop solutions. In addition, HMDs are suggested to enhance situation awareness (SA), enable correct decision making, and reduce workload by allowing users to turn their heads and eyes to fully perceive the environment, decreasing multimodal clutter, providing an intuitive means of presenting spatialized multimodal warnings and alerts, and redundantly coding critical cues (e.g., external threats, navigational waypoints),

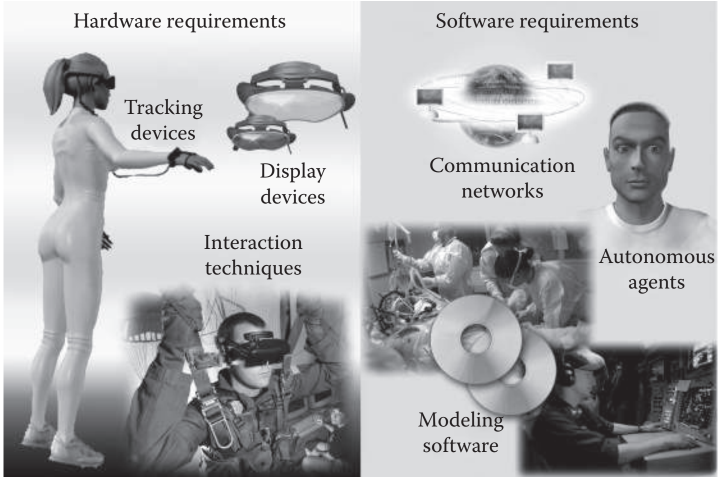

FIGURE 28.1 Hardware and software requirements for virtual environment generation.

for example, by using audio cues to direct visual attention (Melzer and Rash 2009).

There are three main types of HMDs: (1) monocular (e.g., one image source is viewed by a single eye), (2) biocular (e.g., one image source viewed by both eyes), and (3) binocular (e.g., stereoscopic viewing via two image generators, with each eye viewing an independent image source) (Melzer et al. [2009]). A monocular HMD design is best when projecting moving maps or text information that must be read on the move (e.g., dismounted Warfighter) or to allow viewing of imagery with the simplest, lightest (in terms of head-supported weight/mass), and least costly (both monetarily and in terms of power consumption) solution. The downside of monocular displays is that they have a small field-of-view (FOV), convey no stereoscopic depth information, have the potential for a laterally asymmetric center-of-mass (CM), and may have issues associated with focus, eye dominance, binocular rivalry, and ocular-motor instability. For a wide FOV, more effective target recognition, and a more comfortable viewing experience, a biocular or binocular solution is needed. Biocular solutions present no interocular rivalry and are lighter, easier to adjust, and less expensive than binocular solutions. The disadvantages of biocular displays are that they are heavier, more complex to align, focus, and adjust, and have reduced luminance when compared with monocular displays. Binocular displays can present stereo viewing (via field-sequential single-screen displays with shutter glasses, single-screen polarized displays, or dual-screen HMDs), which provides for better depth information than monocular and biocular solutions and have a symmetrical CM. On the downside, binocular solutions are heavy, require more complex alignment, focus, and adjustments than monocular, and are expensive. Biocular and binocular solutions are particularly well suited when creating fully immersive VEs for gaming or training systems, as their large FOV provides a more compelling sense of immersion.

When coupled with tracking devices, HMDs can be used to present 3D visual scenes that are updated as a user moves his or her head about a virtual world. Although this often provides an engaging experience, due to poor optics, sensorial mismatches, and slow update rates, these devices are also often associated with adverse effects such as eyestrain and nausea (Stanney and Kennedy 2008). In addition, although HMDs have come down substantially in weight, rendering them more suitable for extended wear, they are still hindered by cumbersome designs, obstructive tethers, suboptimal resolution, and insufficient fields of view. These shortcomings may be the reason behind why, in a review of HMD devices, approximately a third had been discontinued by their manufacturers (Bungert 2007). Nevertheless, of the HMDs available, there are several low- to mid-cost models, which are relatively lightweight and provide a horizontal FOV and resolution far exceeding predecessor systems.

Low-technology stereo viewing VE display options include anaglyph methods, where a viewer wears glasses with distinct color polarized filters, usually with the left-image data placed in the red channel of an electronic display and the right-image data in the blue channel; parallel or cross-eyed methods, in which right and left images are displayed adjacently (parallel or crossed), requiring the viewer to actively fuse the separate images into one stereo image; parallax barrier displays, in which an image is made by interleaving columns of two images from a left- and right-eye perspective image of a 3D scene; polarization methods, in which the images for the left and right eyes are projected on a plane through two orthogonal linearly polarizing filters (e.g., the right image is polarized horizontally; the left is polarized vertically) and glasses with polarization filters are donned to see the 3D effect; Pulfrich methods, in which an image of a scene moves sideways across the viewer's FOV and one eye is covered by a dark filter so that the darkened image reaches the brain later causing stereo disparity; and shutter glass methods in which images for the right and left eyes are displayed in quick alternating sequence and special shutter glasses are worn that "close" the right or left eye at the correct time (Konrad and Halle 2007; Vince 2004). All these low-technology solutions are limited in terms of their resolution, the maximum number of views that they can display, and clunky implementation; they can also be associated with pseudoscopic images (e.g., the depth of an object can appear to flip inside out).

Other options in visual displays include SIDs (e.g., displays that surround viewers physically with panoramic large FOV imagery generally projected via fixed front or rear projection display units; Konrad and Halle [2007]; Majumder [2003]), desktop stereo displays, and volumetric displays that fill a volume of space with a "floating" image (Konrad and Halle 2007). Examples of SIDs include the Cave Automated VE (CAVE) (Cruz-Neira, Sandin, and DeFanti 1993), PowerWall and Infinity Wall (Majumder, He, Towles, and Welch, 2000). Issues with SIDs include a stereo view that is correct for only one or a few viewers, noticeable overlaps between adjacent projections, and image warp on curved screens. Blue-c addresses some of these concerns by combining simultaneous acquisition of multiple 3D video streams with advanced 3D projection technology (Gross et al. 2003).

Desktop display systems have advantages over SIDs because they are smaller, easier to configure in terms of mounting cameras and microphones, easier to integrate with gesture and haptic devices, and more readily provide access to conventional interaction devices, such as mice, joysticks, and keyboards. Issues with such displays include stereo that is only accurate for one viewer and a limited display volume.

Volumetric displays provide visual accommodation depth cues and vertical parallax, which are particularly useful for scenes that require viewing from a multitude of viewing angles, generally without the need for goggles; however, they do not maintain accurate occlusion cues (often considered the strongest depth cues) for all viewers (Konrad and Halle 2007). Perspecta is an example of a swept-volume display that uses a flat, double-sided screen with a rotating projected image to sweep out a hemispherical image volume (Favalora 2005). DepthCube is an example of a static-volume display that uses electronically addressable elements (i.e., a digital micromirror device imaging system) to scan out the image volume (Sullivan 2004). Issues with volumetric displays include low resolution and the tendency for transparent images to lose interposition cues. Also, view-independent shading of objects is not possible with volumetric displays, and current solutions do not exhibit arbitrary occlusion by interposition of objects (Konrad and Halle 2007).

The way of the future seems to be direct virtual retinal displays, where images are projected directly onto the human retina with a low-energy laser or LCDs (McQuaide et al. 2003), as well as displays that represent the physical world around us, such as autostereoscopic omni-directional light-field displays, which present interactive 3D graphics to multiple simultaneous viewers 360° around the display (Jones et al. 2007). If designed effectively, these next-generation devices should eliminate the tethers and awkwardness of current designs while enlarging the FOV and enhancing resolution.

When VEs provide audio (see Chapter 10), the interactive experience is generally greatly enhanced (Shilling and Shinn-Cunningham 2002). Audio can be presented via spatialized or nonspatialized displays. Just as stereo visual displays are a defining factor for VE systems, so are "interactive" spatialized audio displays (e.g., those with "on-the-fly" positioning of sounds). VRSonic's SoundScape3D (http://www.vrsonic.com/), Firelight's FMod (http://www.fmod.org/), and AuSIM3D (http://ausim3d.com/) are examples of positional 3D audio technology. There have been promising developments in new sound modeling paradigms (e.g., VRSonic's ViBe technology) and sound design principles that will hopefully lead to a new generation of tools for designing effective spatial audio environments (Fouad 2004; Fouad and Ballas 2000; Jones, Stanney, and Fouad 2005).

Developers must decide if sounds should be presented via headphones or speakers. For nonspatialized audio, most audio characteristics (e.g., timbre, relative volume) are generally considered to be equivalent, whether projected via headphones or speakers. This is not so for spatialized audio, in which the presentation technique impacts how audio is rendered for the display and presents the developer with important design choices.

While in the past, headphone spatialization required expensive, specialized hardware to achieve real-time rates, modern multicore processors and the availability of powerful graphics processing units (GPU) have made it possible to render complex audio environments over headphones using general-purpose computers. With binaural rendering, a sound can be placed in any location, right or left, up or down, near or far, via the use of a head-related transfer function (HRTF) to represent the manner in which sound sources change as a listener moves his or her head (Begault 1994; Butler 1987; Cohen 1992). However, for optimal results, the HRTFs used for rendering must be personalized for each individual user. One method of doing this is to actually measure each user's HRTF for use in rendering. This approach generally involves a fairly lengthy measurement procedure using specialized hardware. Recently, there have been efforts to develop fast and low-cost approaches to HRTF measurements (Zotkin et al. 2006), which may, in the future, make personalized HRTF rendering practical for general use. An alternative approach to measure HRTFs is to use a best-fit HRTF selection process in which one finds the nearest matching HRTF in a database of candidate HRTFs by either comparing the physiological characteristics of stored HRTFs with those of a target user (Algazi et al. 2001) or by using a subjective selection process to find the best-fit HRTF (Seeber and Fastl 2003). Another consideration that should be taken into account when choosing headphone rendering is that, for immersive displays, head trackers must be used to achieve proper relative positioning of sound sources. Also, rendering spatial audio for groups of users over headphones may not be practical for more than a few users.

An alternative approach to headphone spatialization is the use of loudspeaker arrays (Ballas et al. 2001). Loudspeaker arrays can range in size from relatively small surround sound configurations with 2, 4, 5, 7, or 10 loudspeakers up to hundreds of loudspeakers. The differentiating factors among loudspeaker arrays are the speaker layout, number of loudspeakers comprising the array, and algorithms used to render spatial audio. Generally speaking, increasing the number of loudspeakers in the array results in more accurate spatialization. The manner in which loudspeakers are laid out in a listening area is closely related to the size of the array. Planar loudspeaker configurations require a smaller number of loudspeakers, but are only capable of creating a 2D sound field. Volumetric configurations, on the other hand, can create a 3D sound field, but require a larger number of loudspeakers and a more elaborate setup. Recently, VRSonic introduced a spherical loudspeaker array system called the AcoustiCurve. It provides a volumetric array in a spherical configuration around the listening space (see Figure 28.2).

The rendering algorithm used for spatialization is also closely tied to the loudspeaker array size and configuration. Pair-wise panning algorithms are the simplest form of spatialization and create a positional sound source by manipulating the amplitude of the signal arriving at two adjacent loudspeakers in the array (Mouba 2009). An extension to this idea is vector based amplitude panning, where the source is panned among three loudspeakers forming a triangle in a volumetric array (Pulkki 1997). Another spatialization algorithm that is gaining popularity is wave field synthesis (WFS); a technique based on Huygens' Principle (Spors and Ahrens 2010). The WFS technique creates a positional source within the listening space by recreating the incident wavefront of a virtual source using a loudspeaker array. The advantage of WFS is that it does not suffer from the "sweet spot" problem, and so listeners can get an accurate impression of the synthesized sound field at any location within the listening space; this is not the case with pair-wise panning (Shilling and Shinn-Cunningham 2002). The primary drawback of WFS is that it requires a large number of loudspeakers and considerable processing power to recreate the incident wavefront.

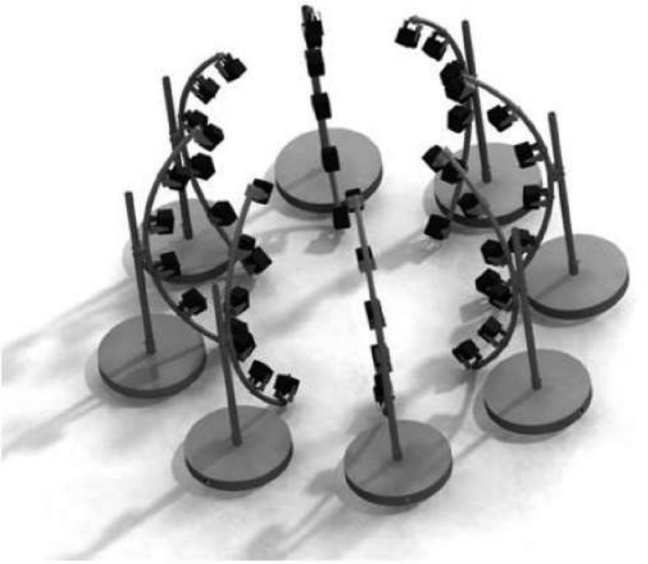

FIGURE 28.2 Volumetric speaker array

Whether using headphones or loudspeaker arrays, spatialization is only one component of simulating a sound field, and developers should carefully consider the level of fidelity required by the application when choosing an audio rendering system. Properly synthesizing a virtual soundscape requires modeling the full propagation path of sound, including source model, spreading loss, air absorption, material absorption, and material reflection. Accurately modeling the full propagation path in real time is beyond the capabilities of current computers. However, there is promising research in the use of GPU processors to achieve real-time rates using ray casting methods (Jedrzejewski 2004).

Although not as commonly incorporated into VEs as visual and auditory interfaces, haptic devices (see Chapter 9) can be used to enhance aspects of touch and movement of the hand or body segments while interacting with a VE. Haptic devices have been classified as passive (unidirectional; e.g., keyboard, mouse, trackball) versus active (bidirectional, thereby supporting two-way communications between human and interactive system; Hale and Stanney [2004]; e.g., force-reflecting robotic arm), grounded (e.g., joystick) versus ungrounded (e.g., exoskeleton-type haptic devices), net-force (e.g., PHANTOM device or textured surfaces) versus tactile devices (e.g., tactile pin arrays), and impedance control (i.e., user's input motion is measured and an output force is returned) versus admittance control (e.g., user's input forces are measured and motion is fed back to the user) (Basdogan and Loftin 2008). In general, haptic displays are effective at alerting people to critical tasks (e.g., warning), providing a spatial frame of reference within one's personal space, and supporting hand–eye coordination tasks. Texture cues, such as those conveyed via vibrations or varying pressures, are effective as simple alerts and may speed reaction time and aid performance in degraded visual conditions (Akamatsu 1994; Biggs and Srinivasan 2002; Massimino and Sheridan 1993; Mulgund et al. 2002). Kinesthetic devices are advantageous when tasks involve hand–eye coordination (e.g., object manipulation), where haptic sensing and feedback are key to performance. Currently available haptic-interaction devices include static displays (e.g., convey deformability or Braille); vibrotactile, electrotactile, and pneumatic displays (e.g., convey tactile sensations such as surface texture and geometry, surface slip, surface temperature); force feedback systems (e.g., convey object position and movement distances); and exoskeleton systems (e.g., enhance object interaction and weight discrimination) (Hale and Stanney 2004). Minamizawa et al. (2008) suggest that to provide natural haptic feedback, such interfaces should be bimanual and wearable and aim to enhance the existence and operability of virtual objects while not disturbing the motion and behavior of users. Currently, there are several wearable haptic displays that can be used in VEs, such as CyberGlove Systems' CyberGlove, CyberTouch, CyberGrasp, and CyberForce (http://www.cyberglovesystems.com/) and Immerz's KOR-fx (Kinetic Omni-directional Resonance effect) acousto-haptic technology, the latter of which translates the audio signals from an interactive environment into vibrations that can be felt throughout the body and experienced as the sensation of rain, wind, weight shift, and G-forces (www.Immerz.com). Beyond supporting hand–eye coordination tasks and conveying simple alerts, haptic can be used to communicate a grammar through structured strings of tactile symbols (Fuchs et al. 2008). Such a tactile language has been used at a concept level to support urban military operations, specifically in support of unit coordination and room clearing tasks (Johnston, Hale and Axelsson 2010). Beyond communicating a command-based vocabulary, haptics can also be used to provide exteroceptive feedback, for example, by presenting tactile cues to enhance SA or optimize human performance. It has been suggested that such a solution could more closely couple operators with unmanned aerial systems (Johnston et al. 2010). The future may bring volumetric haptic displays, which project a touch-based representation of a surface onto a 3D volumetric space and allow users to feel the projected surface with their hands (Acosta and Liu 2007) through haptic-rendering techniques (Basdogan et al. 2008), tearables that allow users to experience the real sense of tearing paper (Maekawa et al. 2009), and other such interactive tactile solutions.

The "vestibular system can be exploited to create, prevent, or modify acceleration perceptions" in VEs (Lawson, Sides, and Hickinbotham 2002, p. 137). For example, by simulating acceleration cues, a person can be psychologically transported from his or her veridical location, such as sitting in a chair in front of a computer, to a simulated location, such as the cockpit of a moving airplane. Although vestibular cues can be stimulated via many different techniques in VEs, three of the most promising methods are physical motion of the user (e.g., motion platforms), wide FOV visual displays that induce vection (e.g., an illusion of self-motion), and locomotion devices that induce illusions of self-motion without physical displacement of the user through space (e.g., walking in place, treadmills, pedaling, foot platforms) (Hettinger 2002; Hollerbach 2002; Lawson, Sides, and Hickinbotham 2002). Of these options, motion platforms are probably the most advanced. For example, Sterling, Magee, and Wallace (2000) integrated a small motion-based platform with a VE designed for helicopter landing training and found it to be comparable with a high-cost, large-scale helicopter simulator in terms of training effectiveness. Motion platforms are generally characterized via their range of motion/degrees of freedom (DOF) and actuator type (Isdale 2000). In terms of range of motion, motion platforms can move a person in many combinations of translational (e.g., surge-longitudinal motion, sway-lateral motion, heave-vertical motion) and rotational (e.g., roll, pitch, yaw) DOF. A single-DOF translational motion system might provide a vibration sensation via a "seat shaker." A common 6 DOF configuration is a hexapod, which consists of a frame with six or more extendable struts (actuators) connecting a fixed base to a movable platform. In terms of actuators, electrical actuators are quiet and relatively maintenance free; however, they are not very responsive and they cannot hold the same load as can hydraulic or pneumatic systems. Hydraulic and pneumatic systems are smoother, stronger, and more accurate; however, they require compressors, which may be noisy. Servos are expensive and difficult to program.

Olfaction could be added to VE systems to stimulate emotion or enhance recall (Basdogan and Loftin 2008). There have been several efforts made to support advances in olfactory interaction (Gutierrez-Osuna 2004; Jones et al. 2004; Washburn and Jones 2004; Washburn et al. 2003). One example of an olfactory system is the Scent Pallet (http://www.enviroscent.com/), which is a computer peripheral, USB device that uses up to 8 scent cartridges, fans, and an air compressor to deliver different types of scents. This system has been incorporated into the Full Spectrum Virtual Iraq/Afghanistan PTSD Therapy Application to provide the smell of rubber, cordite, garbage, body odor, smoke, diesel fuel, gunpowder, and other scents of the battlefield (Rizzo, Rothbaum, and Graap 2006). These scents can be used as direct stimuli (e.g., scent of burning rubber) or as general cues to increase immersion (e.g., ethnic food cooking). The Scent Pallet was used to present vanilla, pizza, coffee, whiskey, beer, brandy, tequila, gin, scotch, red wine, white wine, cigarette smoke, and pine tree scents in an alcohol cue reactivity assessment system, which was found to be highly effective in stimulating subjective alcohol cravings (Bordnick et al. 2008). Although several have mentioned the incorporation of gustatory stimulation, there are currently no functioning systems (Basdogan and Loftin 2008).

28.2.1.2 Tracking Systems

Tracking systems allow determination of users' head or limb position and orientation or the location of hand-held devices to allow interaction with virtual objects and traversal through 3D computer-generated worlds (Foxlin 2002). Tracking is what allows the visual scene in a VE to coincide with a user's point of view, thereby providing an egocentric real-time perspective. Tracking systems must be carefully coupled with the visual scene, however, to avoid unacceptable lags (Kalawsky 1993). Advances in tracking technology have been realized in terms of drift-corrected gyroscopic orientation trackers, outside-in optical tracking for motion capture, and laser scanners (Foxlin 2002). The future of tracking technology is likely hybrid tracking systems (http://www.intersense.com/hybrid_technology.aspx), such as optical-inertial, GPS-inertial, magnetic-inertial, digital acoustic-inertial, and optical-magnetic hybrid solutions.

Tracking technology also allows for gesture recognition, in which human position and movement are tracked and interpreted to recognize semantically meaningful gestures (Turk 2002). Gestures can be used to specify and control objects of interest, direct navigation, manipulate the environment, and issue meaningful commands. Gesture tracking devices that are worn (e.g., gloves, bodysuits) are currently more advanced than passive techniques (e.g., computer vision), yet the latter hold much promise for the future, as they can provide more natural, noncontact, and less obtrusive solutions than those that must be worn; yet limitations need to be overcome in terms of accuracy, processing speed, and generality (Erol et al. 2007).

28.2.1.3 Interaction Techniques

Although one may think of joysticks and gloves when considering VE interaction devices, there are many techniques that can be used to support interaction with and traversal through a VE. Interaction devices support traversal, pointing, and selection of virtual objects, tool usage (e.g., through force and torque feedback), tactile interaction (e.g., through haptic devices), and environmental stimuli (e.g., temperature, humidity) (Bullinger, Breining, and Braun 2001).

Supporting traversal throughout a VE, via motion interfaces, is of primary importance (Hollerbach 2002). Motion interfaces are categorized as either active (e.g., locomotion) or passive (e.g., transportation). Active motion interfaces require self-propulsion to move about a VE (e.g., treadmill, pedaling device, foot platforms). Passive motion interfaces transport users within a VE without significant user exertion (e.g., inertial motion, as in a flight simulator, or noninertial motion, such as in the use of a joystick or gloves). The utility, functionality, cost, and safety of locomotion interfaces beyond traditional options (e.g., joysticks) have yet to be proven. In addition, beyond physical training, concrete applications for active motion interfaces have yet to be clearly delineated. There are, however, some example applications, such as Arch-explore, which is a real walking user interface that adapts redirected walking to allow exploration of large-scale virtual models of architectural scenes in a room-sized VE (Bruder, Steinicke, and Hinrichs 2009).

Another interaction option is speech control (see Chapter 16). Continuous speech recognition systems are currently under development, such as Parakeet (Vertanen and Kristensson 2009), PocketSphinx (Huggins-Daines et al. 2006), and PocketSUMMIT (Hetherington 2007). For these systems to provide effective interaction, however, additional advances are needed in acoustic and language-modeling algorithms to improve the accuracy, usability, and efficiency of spoken language understanding; such systems are still a ways away from offering conversational speech.

To support natural and intuitive interaction, a variety of interaction techniques can be coupled. For example, combining speech interaction with nonverbal gestures and motion interfaces can provide a means of interaction that closely captures real-world communications.

28.2.1.4 Augmented Cognition Techniques

Augmented cognition is an emerging computing paradigm in which users and computers are tightly coupled via physiological gauges that measure the cognitive state of users and adapt interaction to optimize human performance (Stanney et al. 2009). If incorporated into VE applications, augmented cognition could provide a means of evaluating their engaging and compelling nature. For example, neuroscience studies have established that differential aspects of the brain are engaged when learning different types of materials, and the areas in the brain that are activated change with increasing competence (Carroll et al. 2010; Kennedy et al. 2005). Thus, if VE users were immersed in an educational experience, augmented cognition technology could be used to gauge if targeted areas of the brain were being activated and dynamically modify the content of a VE learning curriculum if desired activation patterns were not being generated. Physiological measures could also be used to detect the onset of cybersickness (see Section 28.4.1) and to assess the engagement, awareness, and anxiety of VE users, thereby potentially providing much more robust measures of immersion and presence (see Section 28.5.2). Such techniques could prove invaluable to entertainment VE applications (cf., Badiqué et al. [2002]) that seek to provide the ultimate experience, military training VE applications (cf., Knerr et al. [2002]) that seek to emulate the "violence of action" found during combat, medical training applications (Wiecha et al. 2010) that seek to enhance traditional laboratory-based and classroom training practices, and therapeutic VE applications (cf., North, North, and Coble 2002; Strickland et al. [1997]) that seek to overcome disorders such as fear of heights or flying.

28.2.2 Software Requirements

Software development of VE systems has progressed tremendously, from proprietary and arcane systems to development kits that run on multiple platforms (e.g., general-purpose operating systems to workstations). VE system components have become modular and distributed, thereby allowing VE databases (e.g., editors used to design, build, and maintain virtual worlds) to run independently of visualizers and other multimodal interfaces via network links. Standard application program interfaces (APIs; e.g., OpenGL, Open Inventor, Direct3D, Mesa3D) allow multimodal components to be hardware-independent. VE programming languages are maturing, with APIs, libraries (OpenGL Performer), and scripting languages (e.g., JavaScript, Lua, Linden, Mono, Perl, Python, Ruby) allowing nonprogrammers to develop virtual worlds (Stanney and Zyda 2002). Advances are also being made in modeling of autonomous agents and communication networks used to support multiuser VEs.

28.2.2.1 Modeling

A VE consists of a set of geometry, the spatial relationships between the geometry and the user, and the change in geometry invoked by user actions or the passage of time (Kessler 2002). Generally, modeling starts with building the geometry components (e.g., graphical objects, sensors, viewpoints, and animation sequences) (Kalawsky 1993). These are often converted from CAD data. These components then get imported into the VE modeling environment and rendered when appropriate sensors are triggered. Color, surface textures, and behaviors are applied during rendering. Programmers control the events in a VE by writing task functions, which become associated with the imported components.

A number of 3D modeling languages and toolkits are available that provide intuitive interfaces and run on multiple platforms and renderers (e.g., 3D Studio Max, AC3D, ZBrush, modo 401, Nexus, AccuRender, 3d ACIS Modeler, Ashlar-Vellum's Argon/Xenon/Cobalt, Carrara, CINEMA 4D, DX Studio, EON Studio, solidThinking) (Ultimate 3D Links 2010). In addition, there are scene management engines (e.g., OpenSceneGraph, NVIDIA's SceniX) and game engines (e.g., Real Virtuality) that allow programmers to work at a higher level, defining characteristics and behaviors for more holistic concepts (Karim et al. 2003; Menzies 2002). There have also been advances in photorealistic rendering tools (e.g., EI Technology's Amorphium), which are evolving toward full-featured, physics-based global illumination rendering systems (e.g., RenderPark). Taken together, these advances in software modeling allow for the generation of complex and realistic VEs that can run on a variety of platforms, permitting access to VE applications by both small- and large-scale application-development budgets.

28.2.2.2 Autonomous Agents

Autonomous agents are synthetic or virtual human entities that possess some degree of autonomy, social ability, reactivity, and proactiveness (Allbeck and Badler 2002). There are several types of agents (Serenko and Detlor 2004), including user agents (i.e., assist users by interacting with them, knowing their preferences and interests, and acting on their behalf), service agents (i.e., seamlessly collaborate with different parts of a system and perform more general tasks in the background, unbeknownst to users), embedded agents (i.e., interact with user and system to hide task complexity and make the overall user experience more exciting and enjoyable), and stand-alone agents (i.e., employ leading-edge technologies and lay down the foundation for new architectures, standards, and innovative formats of agent-based computing). Autonomous agents can have many forms (e.g., human, animal), which are rendered at various levels of detail and style, from cartoonish to physiologically accurate models; the form of the agent has been found to influence behavior both during and post VE exposure (i.e., the Proteus Effect, where people infer their expected behaviors and attitudes from observing the appearance of their avatar; Yee, Bailenson, and Ducheneaut [2009]). Such agents are a key component of many VE applications involving interaction with other entities, such as adversaries, instructors, or partners (Stanney and Zyda 2002). Considerable work is being done to enhance the believability of such agents. For example, Heylen et al. (2008) found that when human-like eye gaze behavior was incorporated into agents, users communicated with such agents more effectively, and of utmost importance, human performance was also found to be enhanced with the more life-like agents. As our understanding of how best to design autonomous agents evolves, such principles will be important to incorporate into their design to enhance the overall engagement and effectiveness of virtual worlds.

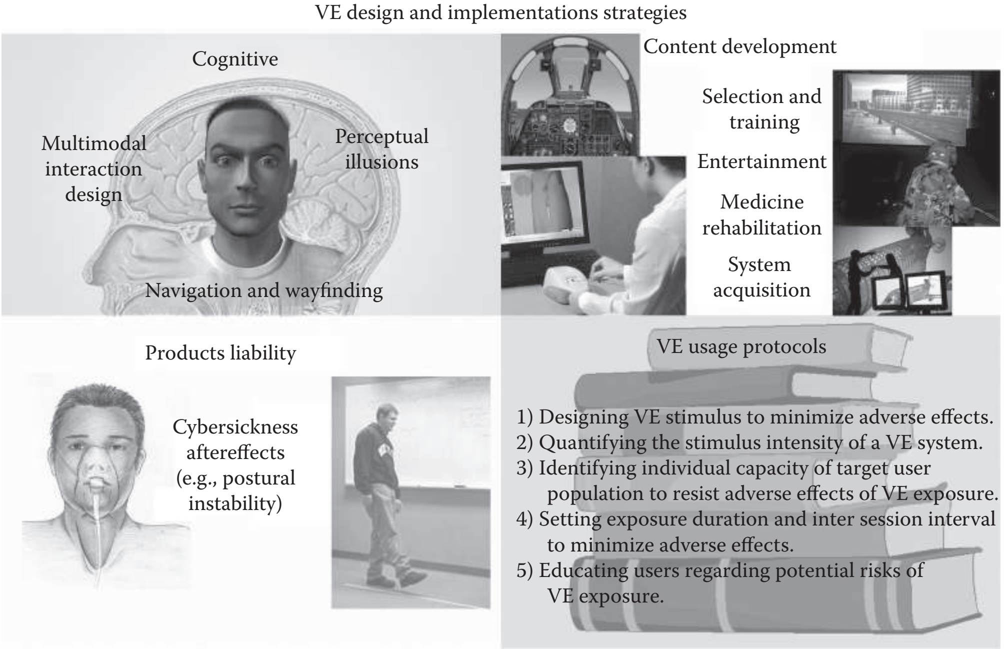
There has been significant research and development in modeling embodied autonomous agents. As with object geometry, agents are generally modeled off-line and then rendered during real-time interaction. Although the required level of detail varies, modeling of hair and skin adds realism to an agent's appearance (Allbeck and Badler 2002). There are a few toolkits available to support agent development, with one of the most notable offered by Boston Dynamics, Inc. (BDI) (http://www.bostondynamics.com/bd_diguy.html/), a spin-off from the MIT Artificial Intelligence Laboratory. BDI's DI-Guy allows VE developers to quickly integrate humans into their VEs, providing artificial intelligence to the characters, thereby enabling agents to autonomously navigate and react to their changing environment. Another option is ArchVision's 3D Rich Photorealistic Content (RPC) People (http://www.archvision.com/RPCPeople.cfm).

28.2.2.3 Networks

Distributed networks allow multiple users at diverse locations to interact within the same VE. Improvements in communication networks are required to allow realization of such shared experiences in which users, objects, processes, and autonomous agents from diverse locations interactively collaborate (Durlach and Mavor 1995). Yet, the foundation for such collaboration has been built within Internet2 (http://www.internet2.edu/), a next-generation Internet Protocol (IP) that delivers production network services for research and education institutions. This optical network could meet the high-performance demands of VEs, as it allows user-based allocation of high-capacity data circuits over a fiber-optic network. In addition, the Large Scale Networking (LSN) Coordinating Group (http://www.nitrd.gov/subcommittee/lsn.aspx) aims to develop leading-edge networking technologies and services, including programs in network security, new network architectures, heterogeneous networking (optical, mobile wireless, sensornet, etc.), federation across networking domains, grid and collaboration networking tools and services, with a goal of assuring that the next generation of the Internet will be scalable, trustworthy, and flexible. There are additional novel network technologies including IP multicasting (i.e., a routing technique to prioritize one-to-many communication over an IP infrastructure in a network), quality of service (i.e., resource reservation control mechanisms), and IPv6 (i.e., also called IPng [or IP Next Generation], a next-generation IP addressing system) that could support distributed VE applications, which can leverage the special capabilities (e.g., high-bandwidth, low-latency, and low-jitter) of these advancing network technologies to provide shared virtual worlds.

28.3 DESIGN AND IMPLEMENTATION STRATEGIES

Although many conventional HCI techniques can be used to design and implement VE systems, there are unique cognitive, content, product liability, and usage protocol considerations that must be addressed (see Figure 28.3).



VE design and implementations strategies
Cognitive
Multimodal interaction design
Perceptual illusions
Navigation and wayfinding
Content development
Selection and training
Entertainment
Medicine rehabilitation
System acquisition
Products liability
Cybersickness aftereffects (e.g., postural instability)
VE usage protocols
1) Designing VE stimulus to minimize adverse effects.
2) Quantifying the stimulus intensity of a VE system.
3) Identifying individual capacity of target user population to resist adverse effects of VE exposure.
4) Setting exposure duration and inter session interval to minimize adverse effects.
5) Educating users regarding potential risks of VE exposure.

FIGURE 28.3 Design and implementation considerations for virtual environments.

28.3.1 Cognitive Aspects

The fundamental objective of VE systems is to provide multimodal interaction or, when sensory modalities are missing, perceptual illusions that support human information processing in pursuit of a VE application's goals, which could range from training to entertainment. Ancillary yet fundamental to this goal is to minimize cognitive obstacles, such as navigational difficulties, that could render a VE application's goals inaccessible.

28.3.1.1 Multimodal Interaction Design

VEs are designed to provide users with immersive experiences that allow for direct manipulative and intuitive interaction with multisensory stimulation (Bullinger et al. 2001). The goals of providing this multimodal interaction within a VE are to achieve human–system interaction that is as natural as possible and to increase the robustness of this interaction by using redundant or complementary cues (Reeves et al. 2004). If designed effectively, engagement in such immersive multimodal VE experiences can lead to high levels of SA and, in turn, high levels of human performance; however, multimodal interaction within the VE must be appropriately designed to lead to this enhanced awareness. Specifically, the number of sensory modalities stimulated and the quality of this multisensory interaction are critical to the immersiveness and potential effectiveness of VE systems (Popescu, Burdea, and Trefftz 2002). There are some emerging guidelines that can guide the design of such multimodal interaction. For example, Stanney et al. (2004) provided a set of preliminary crossmodal integration rules. These rules consider aspects of multimodal interaction, including (1) temporal and spatial coincidence, (2) working memory capacity, (3) intersensory facilitation effects, (4) congruency, and (5) inverse effectiveness. When multimodal sensory information is provided to users, it is essential to consider such rules governing the integration of multiple sources of sensory feedback. VE users have adapted their perception–action systems to "expect" a particular type of information flow in the real world; VEs run the risk of breaking these perception–action couplings if the full range of sensory is not supported or if it is supported in a manner that is not contiguous with real-world expectations. Such pitfalls can be avoided through consideration of the coordination between sensing and user command and the transposition of senses in the feedback loop. Specifically, command coordination considers user input as primarily monomodal and feedback to the user as multimodal. Designers need to consider which input modalities are most appropriate to support execution of a given task within the VE, if there is any need for redundant user input, and whether or not users can effectively handle such parallel input (Stanney, Mourant, and Kennedy 1998; Stanney et al. 2004). Additional multimodal design guidelines have been provided by Hale et al. (2009), who have outlined how a number of sensory cues may effectively be used to enhance specific SA components (i.e., object recognition, spatial, temporal) within a VE, with the goal of optimizing SA development.

A limiting factor in supporting multimodal sensory stimulation in VEs is the current state of interface technologies. With the exception of the visual modality, current levels of technology simply cannot even begin to reproduce virtually those sensations, such as haptic and audition, that users expect in the real world. One solution to current technological shortcomings, sensorial transposition, occurs when a user receives feedback through senses other than those expected, which may occur because a command coordination scheme has substituted available sensory feedback for those that cannot be generated within a VE. Sensorial substitution schemes may be one for one (e.g., visual for force) or more complex (e.g., visual for force and auditory; visual and auditory for force). If designed effectively, command coordination and sensory substitution schemes should provide multimodal interaction that allows for better user control of the VE. However, if designed poorly, these solutions may in fact exacerbate interaction problems.

28.3.1.2 Perceptual Illusions

When sensorial transpositions are used, there is an opportunity for perceptual illusions to occur. With perceptual illusions, certain perceptual qualities perceived by one sensory system are influenced by another sensory system (e.g., "feel" a squeeze when you see your hand "grabbing" a virtual object). Such illusions could simplify and reduce the cost of VE development efforts (Storms 2002). For example, when attending to a visual image coupled with a low-quality auditory display, auditory–visual crossmodal perception allows for an increase in the perceived quality of the visual image. Thus, in this case if the visual image is the focus of the task, there may be no need to use a high-quality auditory display.

There are several types of perceptual illusions that can be used in the design of VEs (Steinicke and Willemsen 2010). Visual illusions can be used to substitute for missing proprioceptive and vestibular senses, as vision usually dominates these senses. For example, vection (i.e., a compelling illusion of self-motion throughout a virtual world) is known to be enhanced via a number of visual display factors, including a wide FOV and high spatial frequency content (Hettinger 2002), as well as visual jitter (Kitazaki, Onimaru, and Sato 2010). In addition, change blindness (i.e., failing to notice alterations in a visual scene) can be used to apply subtle manipulations to the geometry of a VE and direct movement behavior, such as redirecting a user's walking path throughout a VE (Suma et al. 2010). Other such illusions exist and could likewise be leveraged if perceptual and cognitive design principles are identified that can be used to trigger and capitalize on these illusory phenomena. For example, acoustic illusions (e.g., a fountain sound; Riecke, Väljamäe, and Schulte-Pelkum 2009) could also be used to create a sense of vection in a VE, even when no such visual motion is provided. In addition, haptic illusions (Hayward 2008) could be used to provide users with the impression of actually feeling virtual objects when they are in fact touching real-world props or traveling along a trajectory path that may even vary in size, shape, weight, or surface from their virtual counterparts without users perceiving these discrepancies (e.g., feel an illusory bump when actually touching a flat surface [Robles-De-La-Torre and Hayward 2001]; feel an illusory sharp edge when hand actually travels along a smooth trajectory [Portillo-Rodríguez et al. 2006]).

28.3.1.3 Navigation and Wayfinding

Effective multimodal interaction design and use of perceptual illusions can be impeded if navigational complexities arise. Navigation is the aggregate of wayfinding (e.g., cognitive planning of one's route) and the physical movement that allows travel throughout a VE (Darken and Peterson 2002). A number of tools and techniques have been developed to aid wayfinding in virtual worlds, including maps, landmarks, trails, and direction finding. These tools can be used to display current position, current orientation (e.g., compass), log movements (e.g., "breadcrumb" trails), demonstrate or access the surround (e.g., maps, binoculars), or provide guided movement (e.g., signs, landmarks) (Chen and Stanney 1999). For example, Burigat and Chittaro (2007) found 3D arrows to be particularly effective in guiding navigation throughout an abstract VE. Darken and Peterson (2002) provided a number of principles concerning how best to use these tools. If effectively applied to VEs, these principles should lead to reduced disorientation and enhanced wayfinding in large-scale VEs.

28.3.2 Content Development

Content development is concerned with the design and construction of the virtual objects and synthetic environment that support a VE experience (Isdale et al. 2002). Although this medium can leverage existing HCI design principles, it has unique design challenges that arise due to the demands of real-time, multimodal, collaborative interaction. In fact, content designers are just starting to appreciate and determine what it means to create a full-sensory experience with user control of both point of view and narrative development. Aesthetics is thought to be a product of agency (e.g., pleasure of being), narrative potential, presence and co-presence (e.g., existing in and sharing the virtual experience), and transformation (e.g., assuming another persona) (Murray [1997]). Content development should be about stimulating perceptions (e.g., sureties, surprises), and contemplation over the nature of being (Isdale et al. 2002).

Existing design techniques, for example, from entertainment, video games, and theme parks, can be used to support VE content development (see Chapters 31 and 34). Game development techniques that can be leveraged in VE content development include but are not limited to providing a clear sense of purpose, emotional objectives, perceptual realism, intuitive interfaces, multiple solution paths, challenges, a balance of anxiety and reward, and an almost unconscious flow of interaction (Isdale et al. 2002). From theme park design, content development suggestions include (1) having a story that provides the all-encompassing theme of the VE and thus the "rules" that guide the design, (2) providing location and purpose, (3) using cause-and-effect to lead users to their own conclusions, and (4) anchoring users in the familiar (Carson 2000a,b). Although these suggestions provide guidelines for VE content development, considerable creativity is still an essential component of the process. Isdale et al. (2002) suggested that the challenges of VE content development highlight the need for art to compliment technology.

> I expect that the user experience of VR in 2025 will be something close to seamless; that is, the person will experience little if anything that intrusively indicates that 'this experience is a simulation and not reality' (Koltko-Rivera 2005).

Although the content incorporated into the virtual worlds of today is mostly quite separate from the real world, in recent years, life and technology have been more tightly coupled, the result being that computers are starting to have an awareness of themselves and the people who interact with them in 3D virtual spaces are evolving into a "second life." Virtual worlds are in fact penetrating our native space, and content development for future generations will likely aim to allow us to seamlessly use our own native language, with its wide range of verbal and physical gestures and emotions, thereby more fully entwining our first and second (virtual) lives (Rolston 2010).

28.3.3 Products Liability

Those who implement VE systems must be cognizant of potential product liability concerns. Exposure to a VE system often produces unwanted side effects that could render users incapable of functioning effectively upon return to the real world. These adverse effects may include nausea and vomiting, postural instability, visual disturbances, and profound drowsiness (Stanney et al. 1998). As users subsequently take on their normal routines, unaware of these lingering effects, their safety and well being may be compromised. If a VE product occasions such problems, liability of VE developers or system administrators could range from simple accountability (e.g., reporting what happened) to full legal liability (e.g., paying compensation for damages) (Kennedy and Stanney 1996; Kennedy, Kennedy, and Bartlett 2002). To minimize their liability, manufacturers and corporate users should design systems and provide usage protocols to minimize risks, warn users about potential aftereffects, monitor users during exposure, assess users' risk, and debrief users after exposure.

28.3.4 Usage Protocols

To minimize product liability concerns, VE usage protocols should be carefully designed. A comprehensive VE usage protocol will involve the following activities (see Stanney, Graeber, and Kennedy [2005]):

1. Designing VE stimulus to minimize adverse effects:
   a. Ensure system lags/latencies are minimized and stable

   b. Ensure frame rates are optimized
   c. Ensure interpupilary distance (IPD) of visual display is adjustable and set appropriately
   d. Determine if size of FOV is causing excessive vection, such that the spatial frequency content of the visual scene should be reduced
   e. Determine if multimodal feedback is integrated into the VE such that sensory conflicts are minimized
2. Quantifying stimulus intensity of a VE system using the Simulator Sickness Questionnaire (Kennedy et al. 1993) or other means and comparing the outcome with other systems (see Stanney et al. [2005]). If a given VE system is of high intensity (say the fiftieth or higher percentile) and is not redesigned to lessen its impact, significant dropouts can be expected.
3. Identifying individual capacity of target user population to resist adverse effects of VE exposure via the Motion History Questionnaire (Kennedy and Graybiel 1965) or other means.
   a. For highly susceptible populations, redesigning the VE to reduce stimulus intensity or expect high dropout rates
   b. Providing warnings for those with severe susceptibility to motion sickness, seizures, migraines, cold, flu, or other ailments
4. Setting exposure duration and intersession interval to minimize adverse effects by (see Stanney et al. [2005]) the following:
   a. Limiting initial exposures (e.g., 10 minutes or less)
   b. Setting intersession exposure intervals 2–5 days apart to enhance individual adaptability
   c. Incrementally increasing VE stimulus intensity within one exposure (incremental adaptation) or across multiple exposures (incremental habituation)
   d. Determining if users are able to complete an adaptive process at each increment of stimulus intensity (e.g., depressing sensitization to pre-exposure levels or below); if not, lowering stimulus intensity
   e. Avoiding repeated exposure intervals occurring less than 2 hours apart if adverse effects are experienced in an exposure
5. Educating users regarding potential risks of VE exposure (e.g., inform users they may experience nausea, malaise, disorientation, headache, dizziness, vertigo, eyestrain, drowsiness, fatigue, pallor, sweating, increased salivation, and vomiting).
6. Educating users regarding potential adverse aftereffects of VE exposure (e.g., inform users they may experience disturbed visual functioning, visual flashbacks, and unstable-locomotor and postural control for prolonged periods post exposure).
7. Instructing users to terminate VE interaction if they start to feel ill.
8. Providing adequate air flow and comfortable thermal conditions.
9. Adjusting equipment to minimize fatigue.
10. For strong VE stimuli, warning users to avoid extraordinary maneuvers (e.g., flying backward or experiencing high rates of linear or rotational acceleration) during initial interaction.
11. Providing an attendant to monitor users' behavior and ensure their well being:
    a. Attendant should terminate exposure if they see red flags (e.g., excessive sweating, verbal frustration, prolonged lack of movement in VE, and less overall movement [e.g., restricting head movement] or if users verbally request termination or complain of excessive symptoms).
    b. Attendant should assess well being of users' postexposure (e.g., can use battery similar to field sobriety tests; Tharp, Burns, and Moskowitz [1981]).
12. Specifying amount of time postexposure that users must remain on premises before driving or participating in other such high-risk activities. Do not allow individuals who fail postexposure tests or experience adverse aftereffects to conduct high-risk activities until they have recovered (e.g., have someone else drive them home).
13. Calling users the next day or having them call to report any prolonged adverse effects.

Regardless of the strength of the stimulus or the susceptibility of the user, following a systematic usage protocol can minimize the adverse effects associated with VE exposure.

28.4 HEALTH AND SAFETY ISSUES

The health and safety risks associated with VE exposure complicate usage protocols and lead to product liability concerns. It is thus essential to understand these issues when utilizing VE technology. There are both physiological and psychological risks associated with VE exposure, the former being related primarily to sickness and aftereffects and the latter primarily being concerned with the social impact.

28.4.1 Cybersickness, Adaptation, and Aftereffects

Motion-sickness-like symptoms and other aftereffects (e.g., balance disturbances, visual stress, altered hand–eye coordination) are unwanted byproducts of VE exposure (Stanney and Kennedy 2008). The sickness related to VE systems is commonly referred to as "cybersickness" (McCauley and Sharkey 1992). Some of the most common symptoms exhibited include dizziness, drowsiness, headache, nausea, fatigue, and general malaise (Kennedy et al. 1993). More than 80% of users will experience some level of disturbance, with approximately 12% ceasing exposure prematurely due to this adversity (Stanney et al. 2003). Of those who drop out, approximately 10% can be expected to have an emetic response (e.g., vomit); however, only 1–2% of all users will have such a response. These adverse effects are known to increase in incidence and intensity with prolonged exposure duration (Kennedy, Stanney, and Dunlap 2000). Although most users will experience some level of adverse effects, symptoms vary substantially from one individual to another and from one system to another (Kennedy and Fowlkes 1992). These effects can be assessed via the Simulator Sickness Questionnaire (Kennedy et al. 1993), with values above 20 requiring due caution (e.g., warn and observe users) (Stanney et al. [2005]).

To overcome such adverse effects, individuals generally undergo physiological adaptation during VE exposure. This adaptation is the natural and automatic response to an intersensorily imperfect VE and is elicited due to the plasticity of the human nervous system (Welch 1978). Because of technological flaws (e.g., slow update rate, sluggish trackers), users of VE systems may be confronted with one or more intersensory discordances (e.g., visual lag, a disparity between seen and felt limb position). To perform effectively in the VE, they must compensate for these discordances by adapting their psychomotor behavior or visual functioning. Once interaction with a VE is discontinued, these compensations persist for some time after exposure, leading to aftereffects.

Once VE exposure ceases and users return to their natural environment, they are likely unaware that interaction with the VE has potentially changed their ability to effectively interact with their normal physical environment (Stanney and Kennedy 1998). Several different kinds of aftereffects may persist for prolonged periods following VE exposure (Welch 1997). For example, hand–eye coordination can be degraded via perceptual-motor disturbances (Kennedy et al. 1997; Rolland et al. 1995), postural sway can arise (Kennedy and Stanney 1996), as can changes in the vestibulo-ocular reflex, or one's ability to stabilize an image on the retina (Draper, Prothero, and Viirre 1997). The implications of these aftereffects are the following:

1. VE exposure duration may need to be minimized.
2. Highly susceptible individuals or those from clinical populations (e.g., those prone to seizures) may need to avoid or be banned from exposure.
3. Users should be closely monitored during VE exposure.
4. Users' activities should be closely monitored for a considerable period of time postexposure to avoid personal injury or harm.

28.4.2 Social Impact

VE technology, like its ancestors (e.g., television, computers), has the potential for negative social implications through misuse and abuse Kallman [1993]. Yet violence in VE is nearly inevitable, as evidenced by the violent content of popular video games. Such animated violence is a known favorite over the portrayal of more benign emotions such as cooperation, friendship, or love (Sheridan [1993]; also see Chapter 5. The concern is that users who engage in what seems like harmless violence in the virtual world may become desensitized to violence and mimic this behavior in the look-alike real world.

Currently, it is not clear whether or not such violent behavior will result from VE exposure; early research, however, is not reassuring. Calvert and Tan (1994) found VE exposure to significantly increase the physiological arousal and aggressive thoughts of young adults (Calvert and Tan 1994). Perhaps, more disconcerting was that neither aggressive thoughts nor hostile feelings were found to decrease due to VE exposure, thus providing no support for catharsis. Such increased negative stimulation may then subsequently be channeled into real-world activities. The ultimate concern is that VE immersion may potentially be a more powerful perceptual experience than past, less interactive technologies, thereby increasing the negative social impact of this technology (Calvert 2002). A proactive approach is needed, which weighs the risks and potential consequences associated with VE exposure against the benefits. Waiting for the onset of harmful social consequences should not be tolerated. Koltko-Rivera (2005) suggests that a proactive approach would involve determining the (1) types and degree of VE content (e.g., aggressive, sexual, etc.), (2) types of individuals or groups exposed to this content (e.g., their mental aptitude, mental conditioning, personality, world-view, etc.), (3) circumstances of exposure (e.g., private experience, family, religion, spiritual, etc.), and (4) effects of exposure on psychological, interpersonal, or social function.

28.5 VIRTUAL ENVIRONMENT USABILITY ENGINEERING

Most VE user interfaces are fundamentally different from traditional graphical user interfaces, with unique I/O devices, perspectives, and physiological interactions. Thus, when developers and usability practitioners attempt to apply traditional usability engineering methods to the evaluation of VE systems, they find few if any that are particularly well suited to these environments (for notable exceptions, see Gabbard, Hix, and Swan [1999]; Hix and Gabbard [2002]; Stanney, Mollaghasemi, and Reeves [2000]). There is a need to modify and optimize available techniques to meet the needs of VE usability engineering and to better characterize factors unique to VE usability, including sense of presence and VE ergonomics.

28.5.1 Usability Techniques

Assessment of usability for VE systems must go beyond traditional approaches, which are concerned with the determination of effectiveness, efficiency, and user satisfaction (Bowman, Gabbard, and Hix [2002]; see Chapter 53). Evaluators must consider whether multimodal input and output is optimally presented and integrated, navigation is supported to allow the VE to be readily traversed, object manipulation is intuitive and simple, content is immersive and engaging, and the system design optimizes comfort while minimizing sickness and aftereffects. The affective elements of interaction become important when evaluating VE systems (see Chapter 31). It is an impressive task to ensure that all these criteria are met.

Gabbard, Hix, and Swan (1999) have developed a taxonomy of VE usability characteristics that can serve as a foundation for identifying and evaluating usability criteria particularly relevant to VE systems. Stanney, Mollaghasemi, and Reeves (2000) used this taxonomy as the foundation on which to develop an automated system, Multicriteria Assessment of Usability for VE (MAUVE), which assesses VE usability in terms of how effectively each of the following are designed: (1) navigation, (2) user movement, (3) object selection and manipulation, (4) visual output, (5) auditory output, (6) haptic output, (7) presence, (8) immersion, (9) comfort, (10) sickness, and (11) aftereffects. MAUVE can be used to support expert evaluations of VE systems, similar to the manner in which traditional heuristic evaluations are conducted. Because of such issues as cybersickness and aftereffects, it is essential to use these or other techniques (cf., Modified Concept Book Usability Evaluation Methodology; Swartz [2003]) to ensure the usability of VE systems, not only to avoid rendering them ineffective but also to ensure that they are not hazardous to users. Recently, guidelines have been evolving for enhancing the design of social VEs (e.g., Second Life by Linden Labs, Whyville by Numedeon, Inc.), such as those promoted by the Center for Disease Control and Prevention for reaching individuals with timely health information that may relate to campaigns and upcoming events (CDC 2010).

28.5.2 Sense of Presence

One of the usability criteria unique to VE systems is sense of presence. VEs have the unique advantage of leveraging the imaginative ability of individuals to psychologically “transport” themselves to another place, one that may not exist in reality (Sadowski and Stanney 2002). To support such transportation, VEs provide physical separation from the real world by immersing users in the virtual world via an HMD, then imparting sensorial sensations via multimodal feedback that would naturally be present in the alternate environment. Focus on generating such presence is one of the primary characteristics distinguishing VEs from other means of displaying information.

Presence has been defined as the subjective perception of being immersed in and surrounded by a virtual world rather than the physical world one is currently situated in (Stanney et al. 1998). VEs that engender a high degree of presence are thought to be more enjoyable, effective, and well received by users (Sadowski and Stanney 2002). High presence VEs are also suggested to be effective learning environments (Mantovani and Castelnuovo 2003), as well as to enhance behavioral modeling outcomes and lead to greater imitation in the physical world (Fox, Bailenson, and Binney 2009). To enhance presence, designers of VE systems should spread detail around a scene, let user interaction determine when to reveal important aspects, maintain a natural and realistic, yet simple appearance, and utilize textures, colors, shapes, sounds, and other features to enhance realism (Kaur 1999). To generate the feeling of immersion within the environment, designers should isolate users from the physical environment (use of an HMD may be sufficient), provide content that involves users in an enticing situation supported by an encompassing stimulus stream, provide natural modes of interaction and movement control, and utilize design features that enhance vection (Stanney, Mollaghasemi, and Reeves 2000). To enhance presence in learning environments, the design of perceptual features (i.e., perceptual realism, interactivity, and control), individual factors (i.e., imagination and suspension of disbelief, identification, motivation and goals, and emotional state), content characteristics (i.e., plot, story, narration, and dramaturgy), and interpersonal, social, and cultural context should be carefully considered (Mantovani and Castelnuovo 2003). Presence can be assessed via Witmer and Singer’s (1998) Presence Questionnaire or techniques used by Slater and Steed (2000), as well as by a number of other means (Sadowski and Stanney 2002).

28.5.3 Virtual Environment Ergonomics

Ergonomics, which focuses on fitting a product or system to the anthropometric, musculoskeletal, cardiovascular, and psychomotor properties of users, is an essential element of VE system design (McCauley-Bell 2002). Supporting user comfort while donning cumbersome HMDs or unwieldy peripheral devices is an ergonomics challenge of paramount importance; discomfort could supersede any other sensations (e.g., presence, immersion). If a VE produces discomfort, participants may limit their exposure time or possibly avoid repeat exposure. Overall, physical discomfort should thus be minimized, while user safety is maximized.

Ergonomic concerns affecting comfort include visual discomfort resulting from visual displays with improper depth cues, poor contrast and illumination, or improperly set Ensure interpupilary distance IPDs (Stanney et al. 2000). Physical discomfort can be driven by restrictive tethers; awkward interaction devices; or heavy, awkward, and constraining visual displays. To enhance the ergonomics of VE systems, several factors should be considered, including (McCauley-Bell 2002) the following:

- Is operator movement inhibited by the location, weight, or window of reach of interaction devices or HMDs?
- Does layout and arrangement of interaction devices and HMDs support efficient and comfortable movement?
- Is any limb overburdened by heavy interaction devices or HMDs?

- Do interaction devices require awkward and prolonged postures?
- If a seat is provided, does it support user movement and is it of the right height with adequate back support?
- If active motion interfaces are provided (e.g., treadmills), are they adjustable to ensure fit to the anthropometrics of users?
- Are the noise and sound levels within ergonomic guidelines and do they support user immersion?

28.6 APPLICATION DOMAINS

The wide range of VE types and designs makes them ideal tools for supporting a range of performance-enhancing tasks. Most commonly, VEs are used as training aids; a less common but increasingly well-supported use is as a selection tool, the flip side to the training application. Other applications for VE include their growing potential for providing entertainment, their use as medical rehabilitative tools, and even their implementation within the training system acquisition cycle of the U.S. government.

28.6.1 Virtual Environment as a Selection and Training Tool

Perhaps the most common application for VEs is as training tools. The U.S. military has focused considerable resources on VE as a means to resolve many of the training deficits that result from the rigors of military life (e.g., sustaining schoolhouse-gleaned skills and knowledge sets during prolonged deployment periods, acquiring new skills and knowledge while away from the schoolhouse, providing large-scale environments for multitrainee distributed training exercises. Military VE training applications have been developed in a wide variety of areas, such as perceptual and cognitive performance (Carroll et al. 2010), decision making under stress (Carroll et al. 2010; Hill et al. 2003), operational readiness (Barba et al. 2006), and cross-cultural communication (Deaton et al. 2005; Stanney et al. 2010). Similarly, VE applications are being used as interactive tools for teaching medical students, nurses, and doctors such knowledge and skills as varied as the basics of human anatomy, complicated surgical procedures, communication skills, and decision-making skills (Grantcharov et al. 2004; Johnsen et al. 2005; Segal and Fernandez 2009; Fried et al. 2010; Hassinger et al. 2010).

As VE training exercises become more closely aligned to real-world conditions, a series of factors, including training transfer effectiveness, cost, logistics, and safety, move to the forefront. Further, in terms of applying VE to enhance human performance, training is actually the second stage of a two-stage process. Ideally, one would like to ensure that those individuals for whom training is being provided have a certain degree of "performance capability." In this approach, VE systems can be used as part of a comprehensive performance-enhancement program that focuses on selecting those users with the correct set of knowledge, skills, and abilities (KSAs) and then providing, when needed, training to fine-tune those KSAs.

Given the potentially high cost of developing VEs, this makes sense. Given the broader, yet equally high costs of bringing individuals into an organization and training them to some level of proficiency, it becomes glaringly obvious that having an ability to select individuals who are most likely to benefit from VE training is critical. For example, in the U.S. Air Force, the cost of a single individual student pilot failing to complete basic flight school can run to $100,000 (Siem, Carretta, and Mercatante 1988). Student failure can be attributed to both inadequate selection techniques and deficient training techniques. Clearly, both selection and training play critical roles in producing effective users. The challenge is to develop a program that ensures a smooth union between the two, which identifies the best candidates and then provides the optimum training.

Traditional approaches to selection focus on social and psychophysical assessments. For example, aptitude tests ranging from traditional pen-and-paper-type efforts (Carretta and Ree 1995) to psychomotor tests (Carretta and Ree 1993) to computer-based (but not VE) assessments (Carretta and Ree 1993) have all been used with varying levels of success. The single most important criticism of each of these approaches is that they are designed to be predictive of future performance and as such are more often than not abstractions of aspects of the larger task(s) for which the individual is being selected. An alternate approach would be to provide selectees with a method that provides a direct indication of their performance abilities. This distinction, essentially between a test being predictive of performance ability versus indicative of performance ability, has a great impact on selection. A meta-analysis performed within the aviation domain, where much of selection research has focused, found that typical predictive validities (most often reported as either the correlation coefficient, r, or the multiple correlation coefficient, R, and representing the degree to which a given predictor/set of predictors and performance metrics are related) for such assessments range from a low of 0.14 to a "high" of about 0.40 (Martinussen 1996). Yet, when a simulation component is added to this mix, these values have been shown to improve considerably, pushing correlations toward the 0.60 level (Gress and Willkomm 1996).

A potential deterrent with using VEs as part of a selection toolkit is the high cost associated with developing both the system and the performance measures that need to be integrated with it. However, when considered as one part of a comprehensive performance-enhancement program, this concern vanishes. The same effort and cost devoted to developing the system for selection can typically, with minimal additional input, be modified (e.g., via altered scenarios) to meet identified training goals and objectives. It is, therefore, necessary to explore some of the basic requirements for using VEs as training tools to understand how one technology can truly be applied for these multiple purposes.

A constant thread in training research is the notion that in order for training to be effective, the basic skills being taught must show some degree of transfer to real-world performance.

Over 100 years ago, Thorndike and Woodworth (1901) laid down the most basic training–transfer principle when they proposed that transfer was determined by the degree of similarity between any two tasks. Applying this heuristic to VE design, one might conclude that the most basic way to ensure perfect transfer is to ensure that the real-world performance elements that are meant to be trained should be replicated perfectly in a VE. This notion of "identical elements" could easily create a serious challenge for system designers even by today's technology standards, as VEs are still not able to perfectly duplicate the wide range of sensorial stimuli encountered during daily interactions with our world (Stoffregen et al. 2003). Countering this somewhat simplistic design approach is Osgood's (1949) principle that greater similarity between any two tasks along certain dimensions will not guarantee wholesale, perfect transfer. The challenge, as noted by Roscoe (1982), is to find the right balance between technical fidelity and training effectiveness.

This suggests that when developing training systems, it is important to take two factors into consideration. The first is how one can measure training transfer, and the second is how one can assess the cost/benefit relationship associated with making the decision to use VEs to provide training. The most basic metric for assessing transfer is the percent of transfer (Wickens and Hollands 2000) in which the amount of time saved in learning the real-world task is expressed in terms of how much time a control group, denied such training, required to learn the task (Equation 28.1):

$$\%\text{Transfer} = \left\{\frac{\text{Control time - Transfer time}}{\text{Control time}}\right\} \times 100 \quad (28.1)$$

A quick inspection of this metric suggests that it is overly simplistic. Consider a situation in which the percent transfer is high, yet the total amount of time spent training in the transfer platform (e.g., VE) may be greater than that spent by a control group to achieve similar levels of performance. Such an outcome is hardly cost-effective. Consequently, in parallel to a basic quantification of transfer, another metric, the training effectiveness ratio (TER) (Povenmire and Roscoe [1973]) focusing on training efficiency is needed (Equation 28.2).

$$\frac{\text{TER} = \text{Amount of time saved learning task by transfer group}}{\text{Time spent in transfer platform}} \quad (28.2)$$

All things being equal, these two measures should perfectly quantify VE utility as a training tool. Yet, a third factor, cost, almost always factors in. Indeed, cost is often the single most critical driving factor in determining whether to supplement a training program with VE tools. In terms of training effectiveness, cost can be quantified using the training cost ratio (TCR) (Wickens and Hollands [2000]), as shown in Equation 28.3.

$$\frac{\text{TCR} = \text{Training cost in real platform}}{\text{Training cost in transfer platform}} \quad (28.3)$$

When making the determination to use a VE to provide some (or, less likely, all) of a given set of training, one must consider the interplay between these measures. Specifically, the relationship between training effectiveness, as expressed through the TER, and training cost, as expressed through the TCR, will drive this decision. A good rule of thumb, provided by Wickens and Holland (2000), is

$$\text{TER} \times \text{TCR} > 1.0, \text{VE Training is effective} \quad (28.4)$$

$$\text{TER} \times \text{TCR} < 1.0, \text{VE Training is ineffective} \quad (28.5)$$

A slightly different way of interpreting this was provided by Roscoe (1982), who suggested that, given that the higher the level of technical fidelity the more costly the system, there is a region of design space within which cost/benefit is optimal; move away from this region in either direction and you run the risk of paying a lot for a system that delivers less than effective (and perhaps even negative) training.

This brief overview should not leave one with the impression that the decision to use—or to not use—VEs for training is simple. Assessing the TER × TCR function is no easy matter. Simply put, the cost of performing the study needed to capture the effectiveness of a training device can far outstrip the perceived immediate impact of incorporating the device into a training curriculum. Often, the type of system being developed requires a significant investment in time, money, and labor to be evaluated. Consider a situation in which a new flight simulator is being considered for purchase. To determine both the TER and the TCR, one must conduct an actual transfer study, which involves the following:

1. Removing a set of trainees from their curriculum for experimental purposes
2. Developing reliable performance metrics
3. Providing both the experiment group and the control group with adequate time in the real-world (e.g., aircraft) environment and the experiment group time in the VE
4. Dealing with typically low-effect sizes, which forces experimenters to use large sample sizes

Yet, just as the TER × TCR function could guide when to use and not use VEs, it is possible to pull some general principles from the literature. For example, cognitively oriented training, which often features problem solving or decision making as a key training goal, may oftentimes be satisfied by using simple, relatively inexpensive visualization systems (Gopher, Weil, and Bareket 1994; Morris and Tarr 2002; Stone 2002; Figueroa, Bischof, Boulanger, and Hoover 2005; Milham et al. 2004). Contrastingly, motor skill–based training, which often requires complex interactions between users and their environments, frequently requires more costly solutions. When considering whether or not to "go virtual," a useful solution would be to first determine the general category of skill to be trained (Cognitive or Motor; cf., Anderson

[1987]); estimate the TER and TCR from sources as broadly ranging as basic science studies, published costs of similarly desired systems, and one's own best estimates; and then develop a basic decision matrix to establish a range of TER × TCR values.

28.6.2 Virtual Environment as an Entertainment and Education Tool

VEs have reached beyond their original applications, primarily as military training tools, and have extended into a wide variety of entertainment applications. From interactive arcades to cybercafes, the entertainment industry has leveraged the unique characteristics of the VE medium, providing dynamic and exciting experiences in a multitude of forms. VE entertainment applications have found their way into games, sports, movies, art, online communities, location-based entertainment, theme parks, and other venues (Badiqué et al. 2002; Nakatsu, Rauterberg, and Vorderer 2005). By exploiting the unique interactive characteristics of VEs compared with more traditional entertainment media (e.g., film, play), VE technology provides a more immersive medium for entertainment through the use of simple artificial virtual characters (i.e., avatars), engaging narrative and dynamic control to create an immersive interactive experience.

Interestingly, the utility of virtual games has been found to have a cultural differential. Rauterberg (2009) found that while in Western countries game content is focused on violence, in Asia, they are exploring intensive game usage and its impact on the intellectual development of children. Yet, this is likely changing, as evidenced by the recent focus on educational games in the West (cf., the eEducation Roadmap developed by the National Aeronautics and Space Administration [NASA] eEducation and the Federation of American Scientists, which explored the research challenges associated with the design of immersive environments for education; Laughlin, Roper, and Howell [2007]). This report suggests that it is essential to understand how best to exploit the unique features of synthetic gaming environments by characterizing which features of these systems are important for learning and why. Specific research challenges that the report indicates must be met to realize the full potential of immersive game-based learning environments that enhance education including the following:

- Developing an understanding of effective learning strategies based on the needs of individual learners and how to use this information to design an individualized, immersive learning experience
- Determining how best to take advantage of the benefits offered by immersive gaming technologies to facilitate educational inquiry (i.e., enhancing the frequency and quality of questions posed by learners) and effective methods for delivering answers to the questions posed
- Determining how best to deliver feedback and guidance and use real-time assessment to adapt the immersive learning environment to the needs of individual learners such that they proceed to mastery in the most effective and efficient manner
- Determining how to design effective collaborative VEs that reflect current understanding of physics, chemistry, biology, mathematics, and other disciplines that permit collaborative exploration-based pedagogy

Until recently, the high cost of the component technologies comprising VEs precluded their becoming anything more than a research test-bed for well-funded laboratories or an exclusive tool for high-end consumers, like commercial airline companies or the military establishments of entire countries. Yet, after nearly 5 decades of research and development, VEs have finally begun to realize their potential and are making their way into both entertainment and educational applications. It is likely only the imagination that limits future such applications of VE technology.

28.6.3 Virtual Environment as a Medical Tool

> What makes VR application development in the assessment, therapy, and rehabilitation sciences so distinctively important is that it represents more than a simple linear extension of existing computer technology for human use. VR offers the potential to create systematic human testing, training, and treatment environments that allow for the precise control of complex, immersive, dynamic three-dimensional (3-D) stimulus presentations, within which sophisticated interaction, behavioral tracking and performance recording is possible. (Rizzo, et al. 2006, p. 36)

Much has been written about applications for VE within the medical arena (cf., Moline 1995; Satava and Jones [2002]). Although some of these applications represent unique approaches to harnessing the power of VE, many other applications, such as simulating actual medical procedures, reflect training applications, and therefore will not be discussed anew here. One area of medical application for which VE is truly coming into its own is medical rehabilitation. In particular, two areas of rehabilitation, behavioral/cognitive and motor, show strong promise.

28.6.3.1 Behavioral/Cognitive Rehabilitation Applications

In terms of behavioral rehabilitation applications, VE applications have been gaining prominence in behavioral science research over the past several years. For example, VE cue reactivity programs have been successfully tested for feasibility in nicotine-(Bordnick et al. 2005), opiate-(Kuntze et al. 2001), and alcohol-(Bordnick et al. 2008) dependent individuals, and those with eating disorders (Gutiérrez-Maldonado, Ferrer-García, Caqueo-Urizar, and Letosa-Porta 2006). VE applications have also shown promise in modifying exercise behavior (Fox and Bailenson 2009), retirement savings behavior (Ersner-Hershfield, Bailenson, and Carstensen 2008), and managing pain (Dahlquist et al. 2010; Gold, Belmont, and Thomas 2007; Hoffman et al. 2008). Perhaps the fastest-growing application for VEs in behavioral rehabilitation is in the area of exposure therapy (Fox, Arena, and Bailenson 2009; Gregg and Tarrier 2007; Parsons and Rizzo 2008; Powers and Emmelkamp 2008). For example, VE applications have been used to treat acrophobia (the fear of heights; Coelho et al. 2006), agoraphobia (fear of open spaces; Botella et al. 2007), arachnophobia (fear of spiders; Cote and Bouchard 2005); aviophobia (fear of flying; Rothbaum et al. 2000), combat-related posttraumatic stress disorder (Reger and Gahm 2008), panic disorder (Botella et al. 2007), public speaking anxiety (Harris, Kemmerling, and North 2002), and social phobia (Roy et al. 2003). The reason for this broad use of VE technology for exposure therapy is likely due to the ideal matching between VE's strengths (presenting evolving information with which users can interact in various ways) and such therapy's basic requirements (incremental exposure to the offending environment). Importantly, compared with previous treatment regimens, which oftentimes simply required patients to mentally revisit their fears, VEs offer a significantly more immersive experience. In fact, it is quite likely that many of VE's shortcomings, such as poor visual resolution, inadequate physics modeling underlying environmental cues, and failure to fully capture the wide range of sensorial cues present in the real world will be ignored by the patient, whose primary focus is on overcoming anxiety engendered by her or his specific phobias. On a practical level, VEs enable patients to simply visit their therapist's office, where they can be provided an individually tailored multimodal treatment experience (Rothbaum et al. 1996; Emmelkamp et al. 2001; Anderson, Rothbaum, and Hodges 2003).

Beyond behavioral rehabilitation, VE applications are being developed for the study, assessment, and rehabilitation of various types of cognitive processes, such as perception, attention, and memory. For example, VE applications are being used as perceptual skill trainers, such as for elderly drivers who have degraded visual scanning behavior (Romoser and Fisher 2009) and for rehabilitating stroke victims who suffer from Unilateral Spatial Neglect, where an individual fails to perceive stimuli presented to the contralesional hemi-visual field even though they are not "blind" to this area (Katz et al. 2005). In terms of attention, attention deficit hyperactivity disorder is an example of a cognitive dysfunction that has been addressed via VE rehabilitation applications (Parsons et al. 2007). Brooks and Rose (2003) suggest that VE rehabilitation applications can be used both in terms of assessment of memory impairments and memory remediation (e.g., use of reorganization techniques), where it has been found to promote procedural learning of those with memory impairments; importantly, this learning has been found to transfer to improved real-world performance. Examples of memory remediation in VEs include its use to enhance the ability of stroke victims to remember to perform actions in the future (Brooks et al. 2004) and its use in enhancing the performance of an individual with age-related impairment in memory-related cognitive processes (Optale et al. 2001). VEs have also been shown to uncover subtle cognitive impairments that might otherwise go undetected (Tippett et al. 2009). In general, VE applications can provide precisely controlled means of assessing cognitive impairments that are not available using more traditional evaluation methods. Specifically, VEs can deliver an assessment environment, where controlled stimuli can be presented at varying degrees of perception/attention/memory challenge, and level of deficit can be assessed. This level of experimental control allows for the development of both cognitive impairment assessment and rehabilitation applications that have a high level of specificity and ecological validity.

28.6.3.2 Motor Rehabilitation Applications

Many of VE's qualities that make it an ideal tool for providing medical training, such as tactile feedback and detailed visual information (Satava and Jones 2002), also make it an ideal candidate for supplementing motor rehabilitation treatment regiments for such conditions as stroke (Deutsch and Mirelman 2007; Yeh et al. 2007), cerebral palsy (Bryanton et al. 2006), and amblyopia (i.e., lazy-eye) (Eastgate et al. [2006]). Specifically, Fox, Arena, and Bailenson (2009) suggest that VEs have three features that make them uniquely suited to facilitating motor rehabilitation, including the ability to review one's physical behavior and interactively exam one's progress, see one's own avatar from a third-person perspective in real time, and safely recreate real environments that cannot otherwise be experienced (e.g., crossing a busy intersection). In determining how best to apply VE in physical rehabilitation treatment regimens, Holden (2005) suggested considering three practical areas in which VE is strongest: repetition, feedback, and motivation. All three elements are critical to both effective learning and regaining of motor function. The application of VE, in each case, provides a powerful method for rehabilitation specialists to maximize the effect of a treatment regimen for a given session and, because they may reduce the time investment required by therapists (one can simply immerse the patient, initiate the treatment, and then allow the program to execute), to also expand the access of such treatments to a wider population.

Since VE is essentially computer-based, patients can effectively have their attention drawn to a specific set of movement patterns they may need to make to regain function; conducting this in a "loop" provides unlimited ability to repeat a pattern while using additional visualization aids, such as a rendered cursor or "follow-me" types of cues, to force the patient into moving a particular way (cf., Chua et al. [2003]). As well, it is a relatively simple matter to digitize movement information, store it, and then, based on comparisons to previously stored, desired, movement patterns, provide additional feedback to assist the patient. In terms of motivation, treatment scenarios can be tailored to capture specific events that individual patients find most motivating: a baseball fan can practice her movement in a baseball-like scenario; a car enthusiast can do so in a driving environment.

There are certain caveats that must be considered when exploiting VE for rehabilitation purposes, most significantly the potentially rapid loss of motor adaptations following VE exposure. Lackner and DiZio (1994) demonstrated that certain basic patterns of sensori-motor recalibrations learned in a given physical environment can diminish within an hour, post-exposure, although subsequent findings (DiZio and Lackner 1995) suggest that there are certain transfer benefits that are longer-lasting. Brashers-Krugg, Shadmehr, and Bizzi (1996) provided additional evidence that sensori-motor recalibrations of the type likely to be required for rehabilitation have postexposure periods, in excess of 4 hours, during which their effects can be extinguished. Most concerning Cohn, DiZio, and Lackner (2000) demonstrated that such recalibrations, when learned in VE, have essentially no transfer to real-world conditions post exposure. Clearly, more research is needed to understand the conditions under which such transfer effects can be made most effective within the clinical setting.

28.6.4 Virtual Environment as a System Acquisition Tool

In many areas of research and development, rising costs, with their associated increasing consequences of failure, have all but forced scientists and engineers to focus only on developing those products that have an almost guaranteed chance of succeeding in the marketplace. Although this may seem like an ideal situation—after all, who would want to field technologies that won't work?—the net result is an increasing aversion, among companies and their financial backers, to shoulder much risk. Consequently, much-needed breakthrough technologies may be ignored in favor of "sure-thing" technologies, which more often than not do little to push ahead technology barriers.

The United States Department of Defense (DoD), seeking to reverse this trend while maintaining a level of control over risk, developed the process of simulation-based acquisition , a methodology that introduced the use of modeling and simulation (M&S) within the product-development process (Sanders 1997; Zittel 2001). Most recently, these M&S solutions have become increasingly integrated into 4D interactive tools that enable human-in-the-loop testing of design and operational principles (Sanders 1997). As one example that cuts across DoD and industry, consider the development of the Joint Strike Fighter (JSF). While more common M&S solutions, such as the ability to simulate individual components digitally before manufacturing them (through the CAD/CAM process), formed a core component of the development process, more advanced M&S solutions, such as VEs, have enabled developers to include users throughout the development process to answer such questions as (1) how users (e.g., pilots) would implement the fighter in combat, using virtual war-gaming techniques; (2) how well individual pilots could handle a given JSF design; and (3) how the JSF would alter the nature of warfare (Zittel 2001).

This is just a small glimpse of the potential applications for VE technology, the limit of which is bound only by our imagination. Recently, VEs have even been suggested as having potential value in simulating reenactments of criminal situations to enhance courtroom practices (Leonetti and Bailenson 2010). It will be interesting to see the vast variety of future VE applications that evolve.

28.7 CONCLUSIONS

Clearly, VE technology has evolved significantly over the past 5 decades. Yet, despite significant revolutions in component technology, many of the challenges addressed over this time period, such as multimodal sensori-interaction, scenario generation, and sickness and aftereffects, have yet to be fully resolved. At the same time, our understanding of the potential such tools have to offer has advanced considerably. No longer for simple amusement, this powerful technology can provide educational value, assist in treating core physical and cognitive maladies and even help design better interactive systems. As the uses for which VEs are ideally suited continue to be defined and refined, one can anticipate that current development challenges will be resolved, only to find new ones waiting to take their place.

29 Privacy, Security, and Trust

Human–Computer Interaction Challenges and Opportunities at Their Intersection

John Karat, Clare-Marie Karat, and Carolyn Brodie

CONTENTS

29.1 INTRODUCTION

In this chapter, we discuss three topics—privacy, security, and trust—which all have a variety of meanings in human contexts in a multidisciplinary view of the world. This presents a challenge in talking about any of them in isolation, and also in addressing questions of deciding what human–computer interaction (HCI) research might be relevant to each. To help set the context for this chapter, we will make use of a unifying scenario. As the discussion progresses, we will identify HCI research views that have been most useful in developing a productive research agenda for the field. The scenario below is drawn from our work in bridging the gap between business and technology perspectives in the area. As in our research work, we use the scenario to highlight issues rather than to offer an accurate picture of an existing situation or details of an idealized proposed solution.

29.1.1 Medical Scenario as Context for Privacy, Security, and Trust Issues

Patient Moves to New City, Selects and Sees New Doctor, Later Goes to Hospital for Tests, Receives Referral to Specialist, Communicates with Family, Friends, and Business Associates in United States and Europe

Mary Simpson and her husband have moved from Boston to New York and started a new job in the financial sector. In her new job, Mary collaborates with people in New York and colleagues in Europe. Before leaving Boston, she requested and obtained a copy of her medical records, containing both paper records and pointers to electronic information from her physician. As part of getting settled into the new community, she selects a new doctor based on referrals from people at work. The group practice that the doctor is part of is particularly forward-looking and thorough. The group practice has created a privacy policy and formulated procedures for collection, use, and storage of their patients' medical data. To do this, they have reviewed the Health Insurance Portability and Accountability Act guidelines and written a policy and set of procedures to cover the different situations that arise. Although some data are kept in hard copy files, much of the patient record is kept electronically in a commercial patient record system called MedicalFiles.

The group practice's privacy policies cover their operational rules for disclosing information to healthcare professionals within the practice and in other organizations who are coordinating in the care of patients in the group practice, disclosure of information to insurance companies and national health center organizations, and the privacy policy preferences that the patients can set up for allowing access to the patient view of the medical file called MyMedicalFile. Similarly, the group practice has a set of security policies that it follows for both the hardcopy and electronic patient data. The database administrator for the group practice implements both the privacy and security policies for the MyMedicalFile electronic patient record system and coordinates with the office manager on the implementation of privacy and security policies for hardcopy data within the group practice. The database administrator uses commercial security and privacy software with the MedicalFile application. The security software protects against unauthorized access. The privacy software controls access to patient data for different purposes and logs the access information. The doctor's office has data retention policies for individually identifiable health information (IIHI) data and conducts periodic audits to ensure the accuracy of IIHI data in medical summaries and billings to insurance companies. The retention policy covers patients who move away or have died.

The MedicalFile application is hosted on the web server and provides a MyMedicalFile view for patients to view information about their medications, their medical summaries, and their laboratory test reports, and also to make appointments. Mary makes an appointment to see the doctor. At the time of the appointment, she brings in her previous medical records including laboratory reports, doctor's summaries, and hard copies of reports such as mammograms or x-rays, with pointers to electronic records. Mary's data are collected by the doctor's staff and with the new information she provides during the initial visit with the doctor, the information forms her patient record file in this group practice. Mary's patient record is a combination of paper, x-ray, and electronic IIHI. Mary is informed about the privacy policy regarding her data and consents to it. She is also informed about how to access her online data in the patient record system. Before Mary leaves the office, the office staff submits her bill to her insurance company.

A few months later Mary becomes ill and wants to see the doctor regarding her illness. She goes online to make an appointment to see the doctor. She visits the doctor, and he orders a number of lab tests. Some of these tests are done in the doctor's medical office by the nurse on staff. Others are scheduled by the nurse to be done at a nearby hospital with which the doctor is affiliated. Mary completes the tests to be done in the medical office at the end of the visit. Again, Mary's bill for seeing the doctor is completed and submitted to her insurance company before she leaves the doctor's office.

Mary visits the hospital on an outpatient basis and completes the tests. Her insurance is billed by the hospital. A few days later, her test results are forwarded by the hospital to the patient record system maintained by her doctor's practice. The data are encrypted during this process for security and privacy reasons. Mary is able to see her test results through her MyMedicalFile view of her online patient record. No one else in Mary's family can view her results in the online medical record as she has not authorized her family through the policy preferences she controls in the MyMedicalFile system to have access to the data. Because she trusts him and for convenience, Mary decides that she will change her profile to allow her husband access to her test results in the future. Any unauthorized attempts to view Mary's records are noted and logged.

Mary is an active user of a social networking tool and communicates with her friends, family, and colleagues through the tool about her health issues. She has previously set up different groups with different levels of access to her information. She uses these groups to ensure that only the personal and professional information she wants to share is disclosed to personal friends, family, and business associates in the United States and in Europe. During this ongoing medical situation, she provides updates to her family, friends, and colleagues as appropriate. It is helpful for her to get the information out to people in this way. Although Mary phones her closest family member and friends, the use of the social networking tool with the proper security and privacy profiles allows her to let all the appropriate people know her situation without making a large number of phone calls to people with much different geography.

In reviewing the results, Mary's primary physician determines that the tests have revealed that Mary has cancer. There are a number of possible treatment alternatives for the type of cancer that Mary has. Mary's doctor wants to have Mary see a specialist, an oncologist, for another opinion about how to proceed based on the test results. He talks with Mary about this during an office visit to review her test results with her. Mary agrees to see the specialist before a treatment plan is defined. Before going to see the specialist, Mary searches the web for information about her medical condition.

Mary's doctor completes the referral to the specialist, and the staff at her doctor's office makes the appointment for Mary to see the specialist. As part of the privacy policy of the group practice, the specialist is granted access to review Mary's most recent test results in the online patient medical record as the doctor is part of Mary's healthcare team now. Mary's primary physician also has his staff forward specific elements of her data in an anonymized manner to a national database conducting medical research on the disease she has.

29.1.2 Policy as a Central Issue in Security, Privacy, and Trust

It should be clear from the scenario above that security, privacy, and trust are influenced by rules that are specific to a context. When Mary allows her husband to see her medical history, she intends to create a rule that gives him access to her records. She trusts that he will use the information appropriately. She might even trust that the system would not allow her records to be tampered with by people not authorized by the doctors to do so. We will consider these types of rules—rules that guide the operation of various systems—to be *policies*. Broadly speaking, policies might be "built into" systems or they might be "set" by system administrators or even end users. When they are built in, they become difficult to change or modify. This can be appropriate when the policies are fixed across time and user population, or it can be problematic if the context calls for flexibility. Such policies have a particularly important role in security and privacy systems. Because the context can be quite dynamic (different people can view sharing their information differently, and new intrusion threats can develop that security systems need to respond to), policies are generally authored by users with some intention. Thus, policy management (which includes how policies are authored, modified, evaluated, and implemented) becomes an important issue to be considered within security, privacy, and trust contexts.

29.1.3 Relationships among Privacy, Security, and Trust

What do we mean when we say that we trust a computer system? Although trust is a complex concept with many different meanings in the behavioral science literature, it can be seen as having a fairly specific meaning when applied to a person's interaction with a technology system. Trust in a system is the extent to which a system behaves as the user expects. Put another way, it is a measure of how much users believe that the system will do what they ask it to do without causing any harm. This view suggests that people can enter an interaction with a system with some ideas about what the interaction will involve, and that their trust in the system can either increase or decrease with experience. Trust becomes important, particularly for people or organizations that rely on people wanting to use their websites or products, because without trust in a system, people will find other ways to conduct their business. Parts of the expectations people have about systems are related to the intended function or purpose of the system. They trust that automatic teller machines (ATMs) will correctly distribute money and debit their accounts appropriately. They expect that merchandise ordered through a website will arrive safely at their homes. But, there are also expectations about the handling of information they exchange with the system. They assume that transactions are secure—that they know who they are dealing with and that information only reaches the intended target. They also assume that their privacy is respected—that promises the owners of the system make about how the information will be used or shared are kept. This intersection of trust, security, and privacy is becoming increasingly important as information technology (IT) becomes a more pervasive part of our lives.

There can be many aspects and influences on the trust placed by a user in a computer system. We will not try to address them all in this chapter, but will focus on two important contributing factors associated with the "risks of harm" one might have in interacting with a system. Generally speaking, when someone interacts with a system, they assume that doing so will not cause them any harm. They expect, that is they trust, that the interaction is truthful and without hidden consequences. If they interact with a website, they assume that it represents communication with a specific person or organization. If they disclose information to the site, they assume that the disclosure will only reach the intended target and that only appropriate use will be made of the information.

We will consider security as the degree to which a system can protect information it contains. There are many factors associated with security in systems that interact with humans. Perhaps the most important of these is authentication—how a system and a user can be confident of each other's identity.

If the user and system each have confidence that they know the identity of the other, we generally assume that neither will attempt to do harm to the other. Although research in system security is often aimed at minimizing risks associated with malicious attacks on systems, for HCI, we will focus on the trade-offs between rigorous authentication and ease of interaction.

The concept of privacy extends beyond security to examine how well the use of information that the system acquires about a user conforms to the explicit or implicit assumptions regarding that use associated with the personal information (PI). There is an important distinction that we would like to draw when discussing privacy from an HCI view. In general, studies have looked at privacy from two different perspectives. From an end-user perspective, privacy can be considered as restricting access to their PI, or it can be viewed as controlling use of PI. In the former, the user expresses a “wish to be left alone”; in the latter the wish is to “use my information according to expressed wishes.” Although much has been said about the end of privacy in the pervasive computing world—meaning that so much is known about each of us that it is futile to worry about privacy—this view is an attempt to highlight the difficulty people face in trying to remain anonymous (the first consideration above). Although electronic surveillance is increasingly common, this does not mean that people have to give up their rights to control the use of information collected about them. It is our assumption that collection of more and more data about us is a trend that will continue. But we also assume that legislation will support people’s rights to ensure that appropriate use is made of data collected. In considering privacy, we will generally assume that security in a system is adequate. Thus, we will view data protection failures associated with unauthorized access to information to be security failures or breaches, and those associated with noncompliance to stated privacy policies to be privacy breaches. We will explore the privacy issues in more detail below. For the purposes of this chapter, a simple but useful definition of privacy is

> The ability of individuals to control the terms under which their PI is acquired and used (Culnan 2000, p. 21).

In summary, security involves technology to ensure that information is appropriately protected. It involves users in that security features such as passwords for access control or encryption to prevent unintended disclosure, often place requirements on users to function correctly. Password schemes must be hard to guess but should be easy to remember. Encryption mechanisms must prevent unintended decryption but be transparent (or nearly so) to intended senders and recipients. Privacy involves mechanisms to support compliance with some basic principles. Basically, these suggest that people should be informed about information collection, told in advance what will be done with their information, and given a reasonable opportunity to approve of such use of information. Trust is seen as increasing when it is perceived that security and privacy are provided for. Without trust, it is perceived that people will be less likely to use systems.

As a part of our team’s line of research in these areas, we identified connections between the concepts of privacy, security, and trust as they applied to interaction with organizations that collect PI. This work (Karat et al. 2005) used a contextual design method, which enabled us to identify themes presented in data and to understand the relationships among them. One theme involved the relationship of privacy to other concepts. Many of the participants we talked with discussed how privacy related to other concepts such as security, personalization, trust, and education. Figure 29.1 shows how each of these concepts relates to privacy. Good security enables and is a building block for privacy, and the interviewees noted that as they focus on managing privacy in their organizations, they have found ways to enhance their security as well. The trust that data subjects have in an organization is paramount, and providing privacy protection is a critical means of ensuring that trust. Privacy education is important both for the organization and their external users. Many interviewees stated that privacy education of their employees is an ongoing priority now and that they believe the privacy of data subjects’ PI cannot be effectively protected until employees (the data users) believe it is important and follow through in their daily actions. Many have initiated training programs and have frequently asked questions (FAQ) documentation available for employees to access to understand how to handle PI correctly. The interviewees in the current research study stated that their customers would only provide PI on the condition that it would be protected and not misused and this is a critical element in personalization. Privacy is woven into organizations’ business processes. Interviewees stated that they are reexamining their business processes to protect the PI of their employees, customers, constituents, and patients. They are finding redundancies in the collection of PI and are realizing financial benefits from streamlining their processes privacy management.

The privacy and security functionality of the applications that users experience must also be usable to gain the user’s trust. There are unique challenges in making these capabilities usable. We will explore these issues before discussing the research in privacy, security, and trust.

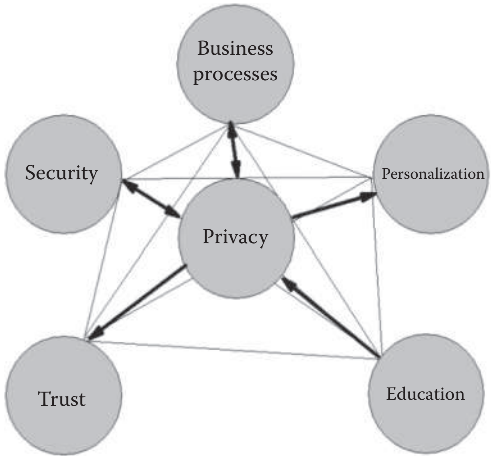

FIGURE 29.1 The relationships between privacy and other concepts.

29.2 HUMAN–COMPUTER INTERACTION AND USABILITY IN THE PRIVACY, SECURITY, AND TRUST DOMAINS

Although the core usability goals of understanding the user, their tasks, and the context of use apply across a wide range of domains, there are unique aspects of privacy and security that present challenges and opportunities when designing security and privacy functionality. First, a key issue to consider is that the use of security and privacy solutions is not the user's main goal. Users value and want security and privacy functionality and they are not likely to trust systems that do not provide them, but they regard them as only secondary to completing their primary tasks (e.g., completing an online banking transaction, ordering medications). The central conflict in the minds of many is that security mechanisms are seen as making operations harder, whereas usability is focused on making operations easier. The user would like the solutions to be as transparent as possible, but users do want to be in control and understand what is occurring. Therein lies the HCI challenge. Thus, the display of information and the interaction methods related to security and privacy solutions need to be accessible if and when desired by the user.

Second, as more of people's interactions in daily life involve the use of computing technology and sensitive information, disparate types of users must be accommodated. Security solutions in particular have historically been designed with a highly trained technical user in mind. The user community has broadened extensively as organizational business processes have come to include new types of roles and users in the security and privacy area. Many compliance and policy roles in organizations are handled by legal and business process experts who have limited technical skills. Moreover, the end-user base includes virtually everyone in the population. The functionality provided by the system for people with different roles must accommodate the skill sets of each. Security and privacy are requirements for doing business as an organization and must be done well, or the organization may lose the user as a customer or worse.

Third, the risk of the negative impact of usability problems is higher for security and privacy applications than for many other types of systems. Although complexity is at the very heart of many security and privacy solutions, from an HCI point of view that complexity is really the enemy of the success of security and privacy. If the system is so complex that the various users groups (e.g., technical users, business users, and end users) cannot understand it, then costly errors will occur. There is a saying in the HCI field that: "If the user cannot understand functionality, it doesn't exist." In the case of security and privacy, badly designed functionality may put users at more risk than if they used less sophisticated solutions. So, the increased risk of errors in this domain provides an even greater incentive to include HCI work in system research and development. The user issues in the domain provide unique technical challenges to architects to design the solutions to be simple and effective.

Fourth, organizations and their users will need to be able to easily update security and privacy solutions to accommodate frequent changes in legislation and regulations. Additionally, different domains (e.g., health care, banking, government) and geographies will have unique requirements. Systems must be designed to enable easy and effective updates to them. Although this list is not exhaustive, these challenges provide a unique focus and strong incentive to include HCI in the system lifecycle. We discuss the valuable role that HCI can play in more detail below.

29.3 VIEWS ON PRIVACY

The rapid advancement of the use of IT in industry, government, and academia makes it much easier to collect, transfer, and store PI around the world. This raises challenging questions and problems regarding the use and protection of PI (Kobsa 2002). Questions of who has what rights to information about us for what purposes become more important as we move toward a world in which it is technically possible to know just about anything about just about anyone. As stated by Adams and Sasse (1999, p. 41): "Most invasions of privacy are not intentional but due to designers' inability to anticipate how this data could be used, by whom, and how this might affect users." Deciding how we are to design privacy considerations in technology for the future includes philosophical, legal, and practical dimensions—any or all of which can be considered as within the domain of the field of HCI.

Privacy can and does mean different things to different people. This chapter primarily focuses on a view of privacy as the right of an individual to control PI use rather than as the right to individual isolation. Organizations commonly provide a description of what kind of information they will collect and how they will use it in privacy policies. In some areas (e.g., the collection and use of healthcare information in the United States or movement of PI across national boundaries in Europe), such policies can be required, though the content of the policy is not generally specified in legislation. Although there has been considerable consensus around a set of high-level privacy principles for IT, it is not likely that a single privacy policy can be created to address all information privacy needs. For example, there will likely be considerable differences in privacy legislation in different regions of the world. Similarly, organizations in different fields (e.g., healthcare, banking, government) need to tailor policies to their domains and needs. This chapter focuses on privacy policy, although privacy is not entirely about "setting rules and enforcing them" (Palen and Dourish 2003, p. 129). To implement privacy within an organization, the coordination of people, business processes, and technology is required (Karat et al. 2005). Still, we do believe that such policies are essential when interacting with technology and organizations in that they enable people to better understand the boundaries between public and private information and technology.

It is interesting to note that while privacy policies are not new to most organizations, very little has been done to implement the policies through technology (Smith 1993). There are emerging standards for privacy policies on websites (Cranor 2002), but these address machine-readable policy content without specifying how the policy might be created or implemented. The reality is that there is very little capability to have technology actually implement access and disclosure limitations that we might expect from a policy statement like: "We will not share your information with a third party without your consent." The emerging focus is on how organizations could create a wide range of policies, and how technology might enable the policies to be enforced and audited for compliance. Karat et al. (2005) focus on technology to enable usable privacy policy authoring and enforcement, rather than trying to directly address what privacy rights people should have or how to de-identify information such as video stored in systems (e.g., Senior et al. [2003]). Privacy is an important social issue and technology that can enable flexible, reliable, and verifiable privacy policy enforcement to preserve individual rights.

The situation with respect to privacy in organizations is described in a Forrester report (Hagan 2000). This research reveals a mismatch between consumer demands for privacy and enterprise practices in industry. According to this report, although customer concerns about privacy remain high, the majority of executives (58%) believe privacy issues are addressed extremely well by their companies. Most executives do not know whether their customers check the privacy policies or not and few see the need to enhance their privacy practices. Research in the Asia-Pacific region complements these results (Office of the Federal Privacy Commissioner of Australia 2000). With these results in mind, we suggest that privacy protection must extend across the network into enterprise processes, and that there is a need to audit data collection and sharing mechanisms. We agree that technology design generally does reflect concerns of society in general (Ackerman and Mainwaring 2005), and believe that we are experiencing a shift toward a greater concern for privacy in IT design. Currently, end users of social networking applications such as Facebook and search engines such as Google are pushing back on these organizations and demanding new customer defined boundaries for the use of their PI (Helft and Wortham 2010; Opsahl 2010).

Central to our view of privacy is the notion that the parties involved in information exchanges have implicit or explicit policies with regard to the use of the information. This applies both to the person whom the information is about and to the organization collecting and using the information. In the privacy literature on organizations, although some attention has been given to the generally implicit policies of end users whose PI is being collected and used (often called data subjects), the main focus is on the policies of the organization collecting the information. Smith (1993) described such organizational policies, and also noted the lack of technology in enforcing the policies. He described the rather unstructured ways in which organizations develop privacy policy—a characterization that has changed little in the nearly 20 years since his research was published in spite of the increased legislation of the past few years. Future research must address both the needs of data subjects and organizations by addressing the gap between policy and practice.

In the medical scenario described above, there are a number of privacy questions related to Mary's healthcare episode. Who can access Mary's medical data and for what purposes? Who authorizes the access? How can Mary easily and effectively manage the disclosure of information to people so that she is comfortable and in control? What steps are available to monitor and assure that Mary's privacy is being protected as intended in the health care and insurance environments she interacts with and in the personal and professional areas of her life? Section 29.3.1 will review HCI research on privacy with these questions in mind.

29.3.1 Human–Computer Interaction Research on Privacy

Rapid advances in technology are pushing us closer and closer to Mark Weiser's (1991) vision of a ubiquitous computing world. Technology has permeated every facet of our daily lives—from enabling us to shop online with a few clicks of the mouse, to recommending movies appropriate for our interests (Good et al. 1999), to helping us share documents with colleagues on the team (e.g., Horstmann and Bentley 1997), to allowing us to estimate when a collaborator may be available for communication (e.g., Begole et al. 2002), to reminding us of relevant tasks based on our current context (e.g., Dey and Abowd 2000), and so on. The benefits of these technological developments promise to improve quality and experience of life by providing people convenience and efficiency. To effectively provide these benefits, systems need to capture, store, and analyze information that may be deemed sensitive by the individuals concerned. The quantity of information varies from system to system, and the associated sensitivity can vary from individual to individual and context to context. As a result, to fully achieve their potential such systems must first overcome various social hurdles. In particular, user perceptions regarding potential violations of privacy have emerged as a key factor that affects technological acceptance and adoption (Herbsleb et al. 2002; Want et al. 1992). For example, the ambitious Total Information Awareness initiative proposed by the U.S. government was abandoned before proceeding beyond the planning stages due to its inability to satisfactorily address privacy fears raised by citizens concerned with civil liberties (Associated Press 2003). As rampant increases in viruses, worms, spam, spy-ware, and ad-ware threaten to erode user confidence, it has become increasingly important that a system empower users to appropriately manage privacy.

The motivation in studying these issues within the field of HCI lies in the interest in designing computing systems with privacy in mind at the outset. Although researchers have acknowledged the existence of privacy concerns in a wide variety of technological domains: e-mail (e.g., Bellotti 1996), e-commerce (e.g., Egelman et al. 2009; Ackerman, Cranor, and Reagle 1999), media spaces (e.g., Mantei et al. 1991), data mining (e.g., Thuraisingham 2002), homes of the future (e.g., Little, Sillence, and Briggs 2009; Meyer and Rakotonirainy 2003), designing effective solutions to address these concerns is challenging. One of the reasons is that relatively few empirical studies have been conducted with the sole aim of studying privacy issues. In addition, empirical investigations of privacy pose numerous methodological challenges. To start with, privacy has proved hard to define due to its highly nuanced and context-dependent nature. Thus, individual differences in perceptions and interpretations of privacy could lead to researcher-introduced bias. For example, in a review of 23 privacy surveys, Harper and Singleton (2001) point out that some surveys may suffer from manipulative questioning on the one hand and that unprompted surveys may reveal a low level of user privacy concerns on the other hand. It is also possible that certain privacy issues remain undetected because the researcher(s) did not recognize them as such. Moreover, cultural differences in expectations and behaviors regarding these issues tend to be quite profound (Milberg et al. 1995), making it difficult to generalize findings across cultures, or to study settings that involve individuals from multiple cultures. Differences in privacy laws in different countries could make it difficult to isolate actual intention from mere legal compliance. Further, methodologies for studying privacy may themselves be deemed too privacy invasive, causing users to deviate from normal practice and/or to withhold revealing sensitive aspects. As a result, relying on self-reported attitudes and behavior alone may not provide a valid view of normal practices (Spiekermann, Grossklags, and Berendt 2001).

With this overview of the privacy and HCI area as context, we will now examine a selection of key privacy research in two topic areas: user control of PI and organizational requirements in managing privacy. Although this is not an exhaustive review, it will illustrate the HCI issues in the area of privacy.

29.3.2 User Control of Personal Information

29.3.2.1 End-User Views of Privacy

It is important to Mary that her physician's group practice takes great care to protect the privacy of her medical data within their practice and in dealings with other medical specialists involved with her care and with insurance organizations processing claims for health care services. As an end user of the online medical file application, she has decided not to share access to her medical file with other family members except her husband. In the business and personal parts of her life, she has carefully determined what information to disclose to groups through verbal interactions and as an end user of web-based work environments and social networking services.

Researchers have conducted many studies on end-user preferences regarding privacy on the web and the HCI factors that are necessary to satisfy the user's desire for privacy. Jensen and Potts (2004) found that while most surveys of user concerns about privacy show high rates of behaviors such as reading the privacy policy or taking concrete actions to protect their privacy, informal analysis of log-file data suggests that the actual rates of these user behaviors are much lower. Jensen, Potts, and Jensen (2005) found that users place inappropriate trust in the presence of trust indicators such as the TRUSTe mark or a privacy policy on the site, assuming quality in the presence of these trust indicators rather than understanding that the level of their trust should be dependent on the content of these policies. The users were willing to divulge PI when it was not warranted. Jensen and Potts (2004). recommend that HCI professionals work to increase awareness of the privacy issues related to the policy issues associated with the trust indicators, as unscrupulous online vendors could use the trust indicators to mislead users to accept privacy policies and divulge private information that they would not otherwise willingly do. Buffett et al. (2004) have created a technique for enabling a user to compute the value of the consequences of exchanging PI on the web. The paper provides a demonstration of the effectiveness of the technique in improving a user's expected utility in a simple privacy negotiation.

Little, Sillence, and Briggs (2009) have carried out some interesting scenario-based work to investigate a variety of social impact issues, including privacy concerns for pervasive technology. They observe that developments in ubiquitous and pervasive computing herald a future in which computation is embedded into our daily lives. Such a vision raises important questions about how people, especially families, will be able to engage with and trust such systems while maintaining privacy and individual boundaries. Their work includes the development of approaches (e.g., the use of illustrative videos) and tools (e.g., a Pre-Concept Evaluation Tool for use in design and implementation of ubicomp systems) for investigating such issues. Over 300 UK citizens participated in 38 focus groups. The groups were shown videotaped scenarios depicting pervasive applications in a number of contexts, including shopping. The results covered family concerns over who controls information, who sees information, who benefits from the use of information, and who is responsible for data control. The data raises a number of important issues from a family perspective in terms of access, control, responsibility, benefit, and complexity. Also findings highlight the conflict between increased functionality and the subtle social interactions that sustain family bonds.

Cranor (2005) leads the W3C standardization work in the area of the Platform for Privacy Preferences (P3P) policies. P3P policies provide end-users information about the privacy policies of a site before they interact with it. Dr. Cranor and a team at AT&T Labs designed and developed the Privacy Bird, a browser help object that provides summary information about the agreement or lack thereof between the end-user's privacy preferences and the privacy policy of the website with which the person is considering interacting. Research continues to improve the usability of the Privacy Bird in communicating to users about website privacy policies and in capturing user privacy preferences. At the current time, there is no verification possible that organizations are operating according to their stated P3P policies. An important area for future research is the challenge of linking the P3P policy to the internal operational privacy policies and their implementation in organizations, and then enabling compliance audits of policy execution.

Peer-to-peer (P2P) systems enable users to easily share files, by downloading data simultaneously from multiple sources and sharing many different file types. Good and Krekelberg (2003) illustrate HCI problems with P2P file-sharing systems such as KaZaA. KaZaA, the most popular and widely used P2P tool in 2003, had an average of 120 million downloads worldwide and 3 million users online at any given time during the course of the study. Good et al. conducted a user study of KaZaA and found that a large proportion of users unwillingly share personal and private files, leaving them at risk of being taken advantage of through unknown exposure of PI. The majority of the users in the study were unable to correctly determine the files they were sharing. Many thought they were sharing no files when they were actually sharing all the files on their hard drive.

The area of ubiquitous computing provides many new capabilities for users to use in communicating with the outside world. Users can communicate using a number of different mobile, pervasive devices, and they have many choices in terms of managing their privacy in these new computing contexts. Researchers have conducted a series of studies in this domain. In the first study, Lederer, Mankoff, and Dey (2003) conducted a questionnaire-based study on the relative importance of the inquirer and the situation in determining a user’s decision regarding the preferred accuracy of PI disclosed through the ubiquitous device. They found that users were more likely to provide the same level of accuracy in the disclosure of PI to the same inquirer in different situations rather than to different inquirers in the same situation. In later research, Hong et al. (2004) developed a privacy risk model for designing privacy-sensitive ubiquitous computing systems and present two case studies that illustrate the use of the privacy risk model in the design of applications. The goal in the research was to refine the concepts of privacy to concrete issues that could be addressed by users using different applications. They found through the case study research that although there were many variables to manage, people did not want privacy management to be complicated or take very much time. People, on occasion, also wanted the ability to provide inaccurate or false information. Hong and Landay (2004) create a toolkit for developers called Confab that facilitates the development of privacy-sensitive ubiquitous applications. Confab includes a framework and customizable privacy mechanisms. The tool also includes extensions for managing location privacy. The goal of Confab is to enable application developers to address the range of trust and privacy requirements of end users of ubiquitous computing systems.

In terms of providing solutions for users to manage their privacy in the future, the European Union is sponsoring research on a system called PRIME (PRivacy and Identity Management for Europe). The goal of the PRIME system is to support the user in controlling the PI about himself that is disclosed to others through interactions with individuals, systems, and organizations (Pettersson et al. 2005). The Pettersson et al. (2005) paper describes three alternative user interface paradigms for privacy-enhanced identity management and illustrates how key legal privacy principles from the European Union Directives are associated with these designs. In this publication on the first year of research in this effort, the team reports some results of initial usability evaluations of mock ups of the three paradigms. The final project report was delivered in 2008 and covered research on graphical user interface, authorization models, cryptography mechanisms, communication infrastructures, and user-side and services-side identity management (PRIME 2008). Some of the concepts were incorporated in prototypes, others are to be considered in follow-up projects the PRIME partners are involved in.

29.3.2.2 Personalization

Mary enjoys the ease and efficiency with which she can log on to her personalized view of the medical file application to make appointments with health care providers and review her medication information and medical summaries. Personalizing interaction involves the use of information about the user to alter the content presented to provide value to the user (Karat, Karat, and Brodie 2004). In their empirical studies, Karat et al. found that the most critical element in the willingness of users to adopt and use personalization systems was user control of personal data. Users want to be in control of their privacy and appreciate the benefits of personalization when they have control over the use of their personal data. A case study of the personalization research (Karat and Karat 2010a,b,c) illustrates the central role that explicitly stated privacy policies have in the success of personalization in an e-commerce web application. End users wanted to know that they had control of all data kept in their profile and the ability to review and edit it at any time. Also, end users strongly endorsed a privacy and personalization policy to collect only the minimum amount of PI necessary for the application to provide the valued personalization functionality to the end user. Once end-user concerns regarding privacy were satisfied, then additional variables related to the particular personalization feature available, user characteristics, and the business context of a task influenced the value of personalization to the user.

Cranor (2004) complements this line of research with an analysis of privacy risks associated with personalization and presents a set of design guidelines to reduce privacy risks in personalization systems. Teltzrow and Kobsa (2004) completed a meta-analysis of 30 consumer studies of user privacy preferences regarding personalization systems and found that consumer demands and current practice diverge significantly regarding control of PI. The vast majority of businesses neither allow control over what information is stored or ability to access it for verification, correction, or updates.

29.3.2.3 Anonymity

Anonymity and anonymization in IT includes the ability of a user to maintain privacy while completing transactions on a network and the ability for a user to keep the data they provide from identifying them personally. In the medical scenario, Mary is willing to provide her medical data to the national database conducting research on the disease she has, given that it is provided in an anonymized manner.

Sweeney (2002) and Malin and Sweeney (2004) have demonstrated that minimal amounts of information believed to be anonymous can be used to personally identify an individual. Since data are aggregated from a myriad of databases in the networked world in which we live, users may falsely believe that they can remain anonymous by providing only minimal bits of information in transactions here and there over time. When the data are aggregated though, the person can be identified fairly easily based on three minimal pieces of information. Users may not think about the types of data from different sources that might be combined and analyzed to identify them, and thus there is a false sense of privacy. This research also makes it clear that there is a grey area in terms of what data elements might be labeled as PI versus personally identifying information—it depends on the other data available in context.

In researching anonymizing networks, Dingledine and Mathewson (2005) conclude that in order for users to be able to preserve their privacy on networks by completing transactions without revealing communication partners, it is critical that the system chosen is usable so that other users can successfully use the system as well. Anonymizing networks are successful at hiding users among other users. An eavesdropper may be able to determine who is using the network, but cannot identify who completes a particular transaction. Moreover, the larger the group of users on the network, the more anonymous the participants become. The catch phrase in this area is "anonymity loves company" (Reiter and Rubin 1998, p. 70).

29.3.3 Organizational Requirements in Managing Privacy

The topic of organizational requirements in managing privacy includes several related subtopics as follows:

1. The three pillars of people, technology, and business processes
2. The ongoing training and education of personnel
3. Policy technology as an essential component of privacy solutions
4. Ongoing business process refinement in a new world of information sharing
5. Compliance audits: Monitoring of privacy policies in operation

29.3.3.1 Three Pillars of People, Technology, and Business Processes

The successful implementation of a privacy program in an organization is supported by people, technology, and business processes (Karat and Karat 2010a,b,c). A privacy program cannot succeed in a modern day organization with only one of these pillars, and will fail if any one of these foundations is compromised. All three are required and they are the minimum resources necessary to handle an organization's privacy program. In the medical scenario, Mary learns about and trusts the privacy policies used by the health care group practice within their group, and the policies about sharing her data with other medical specialists involved with her care, the insurance organizations handling her claims, and the national health care center studying her disease. She feels a level of comfort in knowing about the policies, understands that the MedicalFile application enforces the policies through technology, and is pleased that the group practice monitors and audits the policies in practice.

29.3.3.2 Ongoing Training and Education of Personnel

The employees or members of an organization must have the opportunity to learn the privacy policies of the organization regarding the use of all data that people in the organization collect, use, manage, store, access, view, share, disseminate, and destroy. The workings of an organization fundamentally rest with the people in the organization; they are the heart of it. All data handling and processes do not happen automatically, and organizations can only go so far in controlling the data that employees see as part of manual and automated business processes. The people are the first and last line of defense in the organization. If they understand the intent of the organization's privacy policies, they can go above and beyond to ensure that the intent of the policies is executed in day-to-day transactions in the organization. Also, all the people who interact with the organization must have an easy and efficient means of learning about the organization's privacy policies and the implications of the privacy preferences they select in interactions with the organization. The training and information available to people within and outside the organization is an ongoing process that requires updates as external and internal requirements and situations change.

29.3.3.3 Policy Technology as an Essential Component of Privacy Solutions

As mentioned previously, the adoption of technology has brought mankind closer to the vision of a ubiquitous computing world (Weiser 1991). As data are collected, stored, used, disseminated, and destroyed around the world, it is essential that end users and organizations define and agree to the policies for the handling of the data and that these policies conform to legislation at all levels of government in the geographies in which data are involved. Organizational privacy policies, particularly for governments and multinational corporations handling data around the world, can be complex. For particular pieces of legislation in the United States, for example, a privacy policy may consist of thousands of policy rules. Therefore, there is a pressing need for usable policy technology that enables organizational users to author policies, analyze, deploy, and audit privacy policies in operation.

The privacy technology must be architected and designed with these requirements in mind, so that it is easy for the intended users to work with, integrates with an organization's business processes, and can be modified and audited as desired is essential (Karat et al. 2005).

29.3.3.4 Ongoing Business Process Refinement in a New World of Information Sharing

Privacy policy technology must be able to keep pace with the fast pace of change in organizations today and in the future. For example, external events, new legislation, or inventions within the organization may significantly change the products and services that an organization provides, and these changes will necessitate updates and modifications to the privacy policies deployed by the organization. As the organization's mission changes, the business processes and applicable privacy policies must be updated as well.

29.3.3.5 Compliance Audits: Monitoring of Privacy Policies in Operation

For the ongoing management of the organization, there must be the ability to complete compliance audits of the operation of the privacy policies in the day-to-day execution of the organization's business (Karat et al. 2005). Compliance audits of the enforcement of the privacy policies in the organization's operations will enable the organization to grow and learn about gaps in policies and emerging changes requiring new business processes. The basic purpose of the audit is to determine whether the privacy policies are working as intended in operation. Audits can uncover exception processing that may be the result of gaps in policies, internal fraud and abuse, or changes in the external environment that necessitate changes in business processes and the associated privacy policies for them. Compliance audits of policies close the loop in the policy lifecycle from policy definition to compliance audits.

HCI research focused on the organizational view of privacy includes the Server Privacy Architecture and Capability Enablement (SPARCLE) Policy Workbench (Karat et al. 2005; Karat and Karat 2010a,b,c), privacy policy research across the domains of health care, finance, and government (Brodie et al. 2008), policy refinement research in the Open Collaboration Research project on privacy and security policies (Bertino et al. 2009; Karat et al. 2009; Ni et al. 2008), and privacy research in the health care domain by Adams and Blanford (2005). Karat et al. (2005) used user-centered design methods with 109 target users to identify organizational privacy requirements, and then designed and tested a prototype system for users to author privacy policies, implement the policies, and conduct compliance audits of them. The prototype was a Wizard-of-Oz version of a system, meaning that users were able to have an immersive and dynamic experience with the system capability that seemed real, although there was no functional code behind the screens. Empirical results show that organizational users value highly a set of capabilities that enables policy officers to use natural language to author the policies, with the option of beginning with a template. Users found a visualization of the policies very valuable for communication, review, and identifying necessary modifications to rules, and reaching consensus on policies across the organization. The implementation capability enabled the experts to approve the nominated mappings between rule elements and data base fields and applications in the organization's configuration. The compliance audit capability enabled the users to run general audits to verify that the policy was complying with regulations and was being enforced operationally as stated in the policy, and to run specific inquiries based on individual requests for information about use of PI by the organization. The organizational users who were the participants in the evaluation study rated the prototyped functionality as being of very high value to them.

Karat et al. (2006) conducted an empirical study to determine whether the two methods of authoring rules that were prototyped by Karat et al. (2005) (natural language with a guide or structured list) enabled users to create higher quality rules than an unguided natural language control method (using a word processing window). Empirical results demonstrated that both prototyped authoring methods yielded higher quality rules than the control condition. Users, with no training in use of the methods, were able to create privacy rules covering about 80% of the required rule elements described in scenarios when using either the natural language with a privacy rule guide tool or a structured list tool compared with covering about 40% of the required elements in scenarios using the unguided natural language control condition.

Research and development on the SPARCLE Policy Workbench continued and the general rule authoring utility for the privacy domain became functional, with working code that was successfully tested with the privacy policies of banking/finance, health care, and government organizations (Brodie, Karat, and Karat 2006; Karat, Brodie, and Karat 2005). Users could create new policies with SPARCLE, import existing text versions of policies, or cut and paste sections of policies to form a new policy. Then SPARCLE used natural language processing technology to parse and identify the rule elements. Users reviewed and modified the rules, and when they were happy with the policy, the policy was transformed into XACML code (the OASIS international standard for the format of security access control rules with a privacy profile) for input to the enforcement engine. The team continued to design and create other components in the end-to-end solution for privacy and believed that the policy workbench could be generalized to the security domain and possibly others. The functional SPARCLE prototype was transferred into development and the first SPARCLE-based product called Secure Perspective was available commercially in 2007 (IBM Secure Perspective 2007). The initial product focused on security policies due to market and other considerations. Other product releases supporting various platforms and functionality were released in 2007 and 2008, respectively.

Another policy research effort focused on both the privacy and security domains and involved collaboration between IBM Research, Carnegie Mellon University, and Purdue University (Bertino et al. 2009; Karat et al. 2009; Ni et al. 2008). In this research, the combined team worked on the architectural framework for privacy and security policies and investigated issues in the refinement of policy from high-level statement in natural language to the policy execution layer. Once policies are defined, they need to be transformed to tie the intent of the policy to the system objects and run in real time (Karat et al. 2009). This transformation will move a policy rule from a natural language statement that is understandable by people such as the following:

> Healthcare staff can forward patient medical information for the purpose of national medical research if the information is anonymized.

to a rule format for processing by the organization's computer systems:

```
If request(upload(DBname)) && BName==NIH_Records
then Set DB = anonymize(PatientDB,NameAttribute,
AddressAttribute); upload(DB,DBname)
```

Policy rules may be written using a variety of formats. A new format being researched is privacy-aware role based on access control (Ni et al. 2008). After policies are authored and prior to the privacy policy rule enforcement system going live, a set of policy rules can be analyzed to determine any conflicts or redundancies with other privacy policies already deployed or part of the new set being created (Bertino et al. 2009). Research investigated HCI design ideas related to system feedback to the user on how to resolve identified policy conflicts and redundancies in policy sets.

Adams and Blanford (2005) addressed the gap between organizational and user perspectives of security and privacy in the healthcare domain. They conducted ethnographic evaluations of 93 clinical staff, managers, library staff, and IT department members in two hospitals. They found contrasting perspectives on security and privacy within the groups. They use the concept of "communities of practice" to identify security and privacy issues within organizations, acknowledging the importance of knowledge gained through a work community in day-to-day work practices and formal learning. The "community of practice" acts as a link between the individual and the organization. In their research, one hospital was able to improve communication and awareness across the organization through a community and user-centered approach to the design and development of an organizational privacy and security application. In the second hospital, a clash between the formal rules and the perspective of the local community of practice were at the heart of an identified security problem. The authors highlight the importance of designing security and privacy practices within the context of communities of practice.

TABLE 29.1
Design Factors in Usable Privacy Solutions

Networked World

- There is technology and data collection in most aspects of everyday life in the developed world.

Privacy Legislation

- Requirements for privacy vary by geography and across cultures. Organizations and end users must become knowledgeable.

End-User Views of Privacy

- People perceive and define privacy intrusions differently, and privacy solutions must be designed to support varying definitions and choices.
- End users must be informed of the risks of choices involved in different anonymity enabling situations.
- User control of data to be disclosed is critical for using personalization.
- Regarding pervasive devices, users want control over access to them but want it to be easy to use, fast, and flexible.
- Regarding social computing, user must be clearly informed about data at risk of disclosure.
- For the end user, managing privacy policies is not generally his or her main task; it is a necessary step in completing tasks or activities of value to the user. Managing privacy needs to be simple and efficient.

Organizational Management of Privacy—Requirements, Approaches, and Perspectives

- Authors of privacy policies, who have the knowledge of organizational practices, must be able to tie written policies to implementation through technology, with verification through compliance audits.
- Need views into policy applications for employees within organizations, and for end users who interact with them.
- Automated transformation of policies from natural language to executable code is desirable, with clear links between the transformation levels.
- Policy refinement must include ability to complete policy analysis on current and future policies. The end user and organizational users would benefit from information about possibilities for resolving conflicts and redundancies in privacy policies.
- Need to be able to demonstrate the impact of a policy and ensure that implementation will execute the policy intent of the organization.
- Policy architecture must allow for simple and fast updates of organizational privacy policies based on changes in end-user preferences, legislation, external events, and changing business situations.
- The intent of privacy policies needs to be understandable across cultures.
- There is a critical need to understand community of practice issues in an organization in creating privacy policies.

29.3.4 Summary of Human–Computer Interaction Privacy Research Results and Recommendations

A body of HCI research that can inform the design of usable privacy mechanisms is growing (see Table 29.1). This review of research has covered topics related to the networked world in which we live, the end-user's view of privacy and concern for anonymity while interacting over networks, desire for personalization, and the impact of social networking technologies on privacy. The research on organizational views of privacy has investigated how to provide people technology to

- Create privacy policies that people can understand
- Enable an organization to implement the privacy policies in their computer systems

- Provide simple and efficient ways to update policies as changes occur
- Enable auditing of privacy policy enforcement events for compliance with organizational and legislative requirements

In our roles as usability professionals, it is incumbent on us to consider the issues of privacy in the design, review, approval, development, and use of computing systems by end users and organizations.

The HCI field will be enriched by considering privacy more fully, and this research will cross-pollinate in several areas. For example, cross-cultural studies of privacy can inform the growing interest in HCI in cross-cultural interfaces and coordination. Kumaraguru and Cranor (2005) report a study that demonstrates an overall lack of awareness of privacy issues and less concern about privacy in India than has been found in similar studies conducted in the United States.

29.4 VIEWS ON SECURITY

It is broadly recognized that one of the major challenges to the effective deployment of information security systems is getting people to use them correctly. As far back as the 1970s, usability with specific reference to security mechanisms was identified as a key principle in the design of secure systems (Saltzer and Schroeder 1975). Even beyond the domain of electronic information systems, there are many examples of the fact that overly complex security systems actually reduce effective security. For example, Kahn (1967), cited by Anderson (1994), suggests that Russian military disasters of the Second World War were partly due to the fact that Russian soldiers abandoned the official army cipher systems because they were too hard to use, and instead reverted to simpler systems that proved easier to crack. Ellison and Scheiner (2000, p. 4) sums up the situation: "Security measures that aren't understood by and agreed to by everyone don't work." However, as with many areas in the design of complex systems, recognizing that there is a potential problem does not necessarily create a rush of work to resolve it. Work on making security usable—and balancing the complex relationship between "secure" and "easy to use" is just beginning to become a major topic.

Networked computer systems are increasingly the site of people's work and activity. Millions of ordinary citizens conduct commercial transactions over the Internet, or manage their finances and pay their bills online. Companies increasingly use the Internet to connect different offices, or form virtual teams to tackle mission-critical problems through entirely "virtual" interaction. For example, interaction between citizens and local and federal government agencies can increasingly be conducted electronically; and the 2004 national elections in Brazil and (to a much more limited extent) the United States saw the introduction of electronic voting, which will no doubt become more widespread.

However, these new opportunities have costs associated with them. Commercial, political, and financial transactions involve disclosing sensitive information. The media regularly carry stories about hackers breaking into commercial servers, credit card fraud, and identity theft. Many people are nervous about committing PI to electronic information infrastructures. Even though modern PCs are powerful enough to offer strong cryptographic guarantees and high levels of security, these concerns remain.

The need for secure systems is broadly recognized, but most discussions of the "problem of security" focus on the foundational elements of information systems (such as network transmission and information storage) and the mechanisms available to system developers, integrators, and managers to ensure secure operation and management of data. Security, though, is a broader concern and a problem for the end users of information systems as much as for their administrators. Participation in activities such as electronic commerce requires that people be able to trust the infrastructures that will deliver these services to them.

This is not quite the same as saying that we need more secure infrastructures. De Paula et al. (2005) suggest that it is important to separate theoretical security (the level of secure communication and computation that is technically feasible) from effective security (the level of security that can practically be achieved in everyday settings). Levels of effective security are almost always lower than those of theoretical security. A number of reasons for this disparity have been identified, including poor implementations of key security algorithms insecure programming techniques (Wagner et al. 2000; Shankar et al. 2001), insecure protocol design (Schneier and Mudge 1998), and inadequate operating systems support (Bernaschi et al. 2000).

One important source of the disparity, though, is problems around the extent to which users can comprehend and make effective use of security mechanisms. Approaches that attempt to make the provision of system security "automatic" or "transparent" essentially remove security from the domain of the end user. However, in situations where only the end user can determine the appropriate use of information or the necessary levels of security, then this explicit disempowerment becomes problematic.

Perhaps the best consolidation of usability issues for security comes from Sasse and Flechais (2005). They observe that currently users often disclose (or write down) passwords, fail to encrypt confidential messages, switch virus checkers off, and generally engage in behavior counter to "good security," and ask why this is so common. They conclude that most users

1. Have problems using security tools correctly
2. Do not understand the importance of data, software, and systems for their organizations
3. Do not believe that the assets are at risk
4. Do not understand that their behavior puts assets at risk

Whitten and Tygar (1999) identify a "weakest link property," stating that attackers need only to exploit a single weak point in system security. Frequently, the human user proves to be this weakest link—not from malicious intention but from inability to reasonably do the right thing. Sometimes, this is a matter of education—people need to be made aware of what to do and why to do it. But some of the blame and burden on making our systems more secure rests in making security systems more usable.

29.4.1 Usability of Security Software and Mechanisms

In a series of studies, researchers at University College, London, have explored some of the interactions between usability and security (Adams and Sasse 1999). They focused on user-visible elements of security systems, such as passwords. Although many information systems professionals regard users as being uninterested in the security of their systems (and, indeed, likely to circumvent it by choosing poor passwords, etc.), Adams and Sasse's investigations demonstrate that users are certainly motivated to support the security of the system, but often unable to determine the security implications of their actions. The specific problems that they identify with passwords have also led to interesting design alternatives (Brostoff and Sasse 2000; Dhamija and Perrig 2000).

In some cases, the complexity of making security work is as much a matter of interface design as anything else. Whitten and Tygar (1999) present a usability analysis of PGP 5.0, demonstrating the difficulties that users have in completing experimental tasks (in their user study, only 3 out of 12 test subjects successfully completed a standard set of tasks using PGP to encrypt and decrypt e-mail.) The problems that they uncovered were largely problems of interface design, and in particular, the poor matching between user needs and the structure of the encryption technology provided to meet these needs.

Zurko and Simon (1996) explore similar concerns in their focus on "user-centered security." Their work addressed their perception that the inscrutability of conventional security mechanisms makes it less likely that users will use them effectively. The approach they outline focuses on graphical interfaces and query mechanisms to MAP, an authorization engine. Although this approach is clearly helpful, it is limited to a particular area of system security, and lacks the real-time feedback.

A classic research paper by Karat (1989) demonstrates the valuable contribution that HCI can make in the design of security solutions. Karat, as the HCI lead on a security project, worked in collaboration with the security technical staff to create a security application to be used by branch office personnel in IBM. She joined the team that was already underway on the creation of a new security application whose goal was to eliminate the recurring need for security authorization while performing discrete but related tasks that composed a business process for the employees. The current system impacted user productivity, and due to human memory load issues in its design, added a level of risk regarding the security of the application, and data that needed to be resolved. Dr. Karat conducted a usability evaluation of the initial design of the solution by the security technical staff. Results showed that only 20% of the target users could successfully sign on to the system, and those users required over 3 minutes to do so. She identified four key usability problems in the design of the system. Working with the security technical staff and developers, she was able to improve the design of the user interface to the security application while the security staff identified a technical solution to finesse a key complexity issue in the underlying system. Together the team created a successful solution. Usability tests of the final design showed that 100% of the target users were able to sign on successfully and begin the selected transaction on application within 7 seconds. The new application was deployed on time and under budget because the usability problems were discovered early and resolved. There was high user satisfaction with the security application, and the need for a help desk in the transition period was eliminated. The cost-benefit analysis on the use of HCI skills on the project demonstrated a 1:10 ratio; for each $1 dollar spent on usability, $10 in costs were eliminated from project development and application deployment (see Karat 1994, 2005 for discussion of usability cost-benefit methodology and data).

29.4.2 User Control over Security

How might Mary see her role in the protection of the systems that collect and house her medical information? At one level, Mary wants what we all want. She wants to know that the systems are "secure"—that they have safeguards against misuse, that those she trusts protect those systems, and that she does not have to do much to ensure the security. If Mary asks for a copy of her information, she expects that the system will recognize her and grant the request. If someone Mary does not know asks for her information, she would expect that the system would not grant the request without checking with her. She might expect that if her doctor's laptop computer was lost or stolen, her information would not be easily retrieved from it. In the language of systems security, these can be seen as issues of access control and data encryption. In some cases, we try to remove the need for humans to ensure system security, in others they are a necessary component.

One area at the intersection of usability and security that has received some attention is the role of access control in interactive and collaborative systems. For example, Dewan and Shen (Dewan and Shen 1998) have explored the use of access control and meta-access control models as a basis for describing and controlling degrees of information access and management in collaborative systems. This is not simply a technical matter since the structure and behavior of these "internal" components can have a significant effect on the forms of interactivity and collaboration they can support (Greenberg and Marwood 1994). As with privacy, policies play an important role in security through access control. There is no single answer to how access should be controlled in a system. Context determines the access control that is appropriate and this control is communicated through human-authored policies.

Many collaborative systems involve privacy issues and need to provide users with control over the disclosure of information. This has spurred a number of researchers to explore the development of privacy control systems that are tailored to the needs of end users. For instance, Dourish (1993) describes the relationship between three different security mechanisms for similar multimedia communication systems, each of which reflects assumptions and requirements of the different organizations in which they were developed. Bellotti and Sellen (1993) draw on experiences with multimedia and ubiquitous computing environments to identify the source of a number of potential privacy and security problems. Their primary concepts—disembodiment and dissociation—are both visibility problems, related to the disconnection between actors and actions that renders either actor invisible at the site of action, or actions invisible to the actor.

Based on their investigations of privacy problems in online transactions, Ackerman and colleagues propose the idea of privacy critics—semiautonomous agents that monitor online action and can inform users about potential privacy threats and available countermeasures (Ackerman, Cranor, and Reagle 1999). Again, this mechanism turns on the ability to render invisible threats visible.

One important related topic is control over the degree of security available. One of our criticisms of traditional security systems has been their “all or nothing” approach. However, there has been some work that attempts to characterize degrees of security provision, as embodied by the idea of “quality of security service” (Irvine and Levin 2001). This builds on earlier work establishing a taxonomy of security service levels (Irvine and Levin 1999). The fundamental insight is that organizations and applications need to trade-off different factors against each other, including security of various forms and degrees, to make effective use of available resources (Thomsen and Denz 1997; Henning 1999). Although this work is directed toward resource management rather than user control, it begins to unpack the “security” black box and characterizes degrees and qualities of security.

For end users, perceived security can be defined as the level of security that users feel while they are shopping on e-commerce sites. Yenisey, Ozok, and Salvendy (2005) report a study that aimed to determine items that positively influence this feeling of security by users during shopping, and to develop guidelines for perceived security in e-commerce. An experiment allowed users with different security assurances to shop on simulated e-commerce sites. The participants were divided into three groups, shopping for cheap, mid-range, and expensive products, respectively. Following the shopping environment, a virtual shopping security questionnaire was presented to the users. Generally, there were no significant differences in item ratings between the groups of different shopping item values. A factor analysis procedure determined two main factors concerning perceived security in e-commerce. The perceived operational factor includes: the site’s blocking of unauthorized access; emphasis on login name and password authentication; funding and budget spent on security; monitoring of user compliance with security procedures; integration of state-of-the-art systems; distribution of security items within the site; website’s encryption strategy; and consolidation with network security vendors. The perceived policy-related factor includes: the website’s emphasis on network security; top management commitment; effort to make users aware of security procedures; the website’s keeping up-to-date with product standards; the website’s emphasis on security in file transfers; and issues concerning the web browser.

29.4.3 Research Topics for Human–Computer Interaction in Information System Security

The computer science research community commonly views security and privacy as related topics (e.g., the IEEE Symposium on Security and Privacy is a major research forum). In this literature, privacy gets much less attention that the wide range of security topics. This can be seen as related to an effort to make system secure against human error (or attack) as much as possible. There are some areas of secure systems research that have given more attention to HCI issues. We summarize some of these in Section 29.4.3.1.

29.4.3.1 Secure Design and Administration

Yee (2002) provides guidance for designing and evaluating usable secure software aimed at protecting the interests of the legitimate user. Starting with the work of Saltzer and Schroeder (1975), he divides his guidelines into two general categories—guidelines for authorizing others to access valuable resources and guidelines for communication between the system and the user. For authorization, he suggests associating greater risk to the user with greater effort or less visible operations so that user’s natural tendencies leads to safe operations. For communication, he suggests enabling users to express safe security policies that fit their tasks. The guidelines are not empirically derived, but are gleaned from the experiences of security software designers.

Kandogan and Haber (2005) have applied ethnographic approaches to the study of a particular class of users involved in the protection of systems—security administrators. The issues are somewhat different for populations whose job responsibility includes the security of systems used by others when compared with the situation in which users are acting as their own “security administrators.” However, they represent another important category of user in the area of creating usable security systems. In the ethnographic tradition, they examine their users in typical work situations (e.g., detecting and addressing a security attack) and look at how well their tools help them to do their job. One important result of their work is the realization that administrators simply have too much to look at in the course of their daily work, and that they specifically need tools that help them understand vast amounts of dynamic data. Their work focuses on developing visualization tools to assist in this situation.

Balfanz et al. (2004b) present guidelines for usable security systems developed over a course of research that has focused on the intersection of security and usability. The guidelines include advice to focus on designing both security and usability into the system rather than attempting to retrofit either into existing systems. It seems that the lessons learned in HCI work with regard to the need to consider it early and often during design also apply to security (security engineering is an important topic in that field, much as usability engineering is in HCI). Additional guidelines also call for a focus on the user by looking for high-level building blocks that can be used to create user-oriented solutions, rather than assuming users will be skilled at assembling their own tools for effective security. They point out that the security community has long held the belief that security is more important than user needs, and that it is users who must adapt to requirements to assure system security. An empirical study (Balfanz et al. 2004a) showed how hard it can be for security researchers to accept the difficulty of using some of their own systems. When they evaluated the time it took to secure a wireless network using a tool they had developed, they were surprised to find that it took users over 2 hours on average. The authors mention that the reaction in the security community was often that the "empirical data must be wrong." Although these views are changing with the emergence of usable security research groups like this one, we should not expect the difficult trade-offs to be quickly resolved.

Maxion and Reeder (2005) provide a study in which a system specifically designed to assist users in avoiding errors (Salmon) is compared with the standard operating system interface for making file-sharing decisions. Salmon was found to increase successful task completion by 300% (the standard interface used misleading terminology that caused users to feel that they were sharing files when in fact they were not). Users also spent less time searching for information using Salmon and had a greater proportion of their time on essential task steps rather than security overhead. In their study, they demonstrate that attending to error avoidance in interface design can facilitate usable security.

29.4.3.2 Authentication Mechanisms

Security systems are designed to let authorized people in (the permission problem), and to keep unauthorized people out (the prevention problem). This involves three distinct steps: (1) identification, (2) authentication, and (3) authorization (Renaud 2005). The identification step asks a person to identify himself—usually by means of a token or an identification string such as an e-mail address or account number. Once the identification token has been provided, the person has to provide some evidence of his identity (authentication). This can be done by presenting something they know (e.g., password), something they recognize (e.g., graphical passwords), something they hold (e.g., a certificate), or something they are (e.g., biometrics). For the first three, authentication depends on the user and the system sharing a secret, which for security purposes should be difficult for someone else to guess, and for usability purposes should be easy for the user to remember. The trade-off between these two purposes can be difficult to resolve, and contributes to discussions of "how much security" rather than a view of security as something that is either present or not. In the case of biometrics, the system records a digital representation of some aspect of a person's physiology or behavior at enrollment, and this is confirmed at authentication time.

Many authentication scenarios can be strengthened (in a security sense) through the use of public key cryptography. For example, a user can have a smart card that contains a public key and a matching private key. Instead of a password, the user's public key can be placed on file at a remote computer system (authentication server). To authenticate the user, the remote system sends the user a random challenge. The user "signs" the challenge with his private key and sends the result back to the remote server, which verifies the signature with the public key. In this way, the remote server can verify that the user has possession of the private key without having to receive it. Instead of having the public key on file at the remote system, the smart card can submit both the signed challenge and a public key certificate that has been signed by a third party. In this case, the use of public key technology is called public key infrastructure.

Whatever methods are used, at each stage of an authentication process, we can ask "is it secure?" The real areas of vulnerability are the input mechanism and the user. In the case of knowledge-based authentication, the user must be able to keep the secret and the secret must be hard to discover.

29.4.3.3 Passwords

Random passwords are currently the most popular user authentication mechanism. As such, they also represent the most common research target for work in the security and usability arena. One might consider them the "white rat" for HCI work, similar to menu structures or word processor designs of earlier HCI eras. Yan et al. (2005) conducted research to examine some of the commonly held beliefs about the security and usability properties of various password generation guidelines. In their work, they confirmed that passwords generated by typical advice (e.g., use of a random sequence of letters and numbers) can be difficult for people to remember, but that more cognitively friendly advice (such as select mnemonic-based passwords) can be much easier to remember without sacrificing the theoretical security levels of random passwords. They also explored additional security screening capabilities—such as screening for "weak choices (e.g., obvious dates/places)," and found that such filtering could work well with other advice provided to users. Contrary, the beliefs held within security communities, they did not find that theoretical analysis necessarily corresponded to actual system security. For example, encouraging the use of truly random passwords resulted in more frequent writing down and carrying passwords than encouraging the use of mnemonic passwords.

Others have taken up the challenge of providing usable passwords through nontext password schemes. For example, Monrose and Reiter (2005) provide an analysis of graphical passwords. As with text passwords, graphical passwords might be selected by the user (possibly enhancing usability but perhaps decreasing security) or selected by the system (enhancing security at the cost of usability). Although there is certainly ample evidence that people exhibit powerful memory for images (e.g., Mandler 1991), it is not completely clear that this translates easily into a superior password mechanism. Results from Monrose and Reiter demonstrate that graphical password schemes can suffer from drawbacks similar to those of textual schemes. People tend to select memorable graphical passwords enabling them to be more easily attacked, and random graphical figures can be more secure but also more difficult to recall.

Wiedenbeck et al. (2005) have experimented with an interesting variant of graphical password. In their PassPoint system, users are provided with an image in which they establish a password by selecting a series of points on the image (the number of points selected and the order in which they are selected are factors in the complexity—and thus the potential security features of the password). Their experimental work indicates that such a system is promising from a usability perspective—people can learn the systems easily and remember their sequences over time. However, performance with such a system was not as good as with a comparison textual password system. It took more time to learn the passwords, and more time to enter them even with practice. The extent to which such performances differences might be due to novelty associated with graphical systems compared with textual systems remains unclear, and is in need of further research before we might expect them to replace the textual passwords we have so much experience with. As De Angeli et al. (2005) report in their work on the graphical authentication systems, successful design of password systems is a complex task and requires considering and weighing a number of factors (such as the trade-off between security and usability).

Recently, Everitt et al. (2009) tackled some of these broader graphical password issues in the first study of multiple graphical passwords to systematically examine the effect of frequency of access to a graphical password, the effects of interference resulting from interleaving access to multiple graphical passwords, and the effect of patterns of access while training multiple graphical passwords.

In this work, Everitt et al. show that field studies of graphical password systems are likely to overestimate ease of access if they do not study the realistic use of multiple graphical passwords. With regard to interference, participants in their study who accessed four different infrequent passwords each week had a failure rate more than 10 times greater than participants accessing a single infrequent password. Everitt et al. only used facial recognition, and it is possible that other schemes (e.g., other location or graphic-based schemes) might be less susceptible to interference. Still, developers of graphical password systems should consider the guidance to study ease of access under more realistic training and use conditions.

Inglesand and Sasse (2010) have also answered this call to more realistic evaluation of password policies and practices. Their work presents a study that re-examined password policies and password practice in the workplace. Staff members in two organizations kept a password diary for 1 week, which produced a sample of 196 passwords. The diary was followed by an interview that covered details of each password, in its context of use. The authors found that users are in general concerned to maintain security, but that existing security policies are too inflexible to match their capabilities, and the tasks and contexts in which they operate. As a result, these password policies can place demands on users that impact negatively on their productivity and, ultimately, that of the organization. Inglesant and Sasse (2010) conclude that, rather than focusing password policies on maximizing password strength and enforcing frequency alone, policies should be designed using HCI principles to help the user to set an appropriately strong password in a specific context of use.

Some of the trade-offs between security and usability, and some of the tension between the approaches of the two communities can be seen in some recent research lines. Davis, Monrose, and Reiter (2004) provide a study that looks at how user selection of passwords in graphical password schemes might increase the likelihood that passwords can be attacked. For text passwords, user selection is the norm, and there is no evidence that allowing users to select passwords (following some guidelines for length and character type) makes the resulting passwords any more vulnerable to brute force attack than the theoretical maximum set of passwords for the set of characters involved. Several new approaches for password selection—including a number that involve allowing the user to select a sequence of images—have been developed to help with password memorability (see Real User Corporation [2002] for a commercially available example). Although there has been research on several of these approaches to indicate that they provide passwords that are more memorable than text passwords, and have similar theoretical protection (entropy), there has not been much research into how effective they are in actual use. The research reported by Davis et al. suggests that people do not select as randomly, and instead form passwords with a limited set of possibilities (perhaps analogous to forming passwords with strings that might be easily associated with an individual such as birthdates). Overall, many questions remain regarding how to optimize both security and usability at the same time in the area of knowledge-based passwords.

29.4.3.4 Biometrics

As we have discussed, authentication in computer systems has suffered from the limited number of types of mechanisms available for a system to know who it is interacting with. With advances in technology, we have new opportunities (beyond traditional mechanisms such as passwords) for systems to recognize us. Biometrics refers to a means of identification that can be uniquely associated with an individual (e.g., voice patterns, fingerprints, and hand geometry). Biometrics involves the comparison of live anatomical, physiological, or behavioral characteristics to a stored template of a person (Coventry 2005). Physiological biometrics that have been investigated include those based on fingerprints, hand and/or finger geometry, and the patterns of retinas, veins, irises, and faces. Behavioral biometric techniques that have been advanced include those based on voice, signature, and typing behavior (Peacock, Ke, and Wilkerson 2005). Other techniques that are not yet as well developed include recognition of characteristics such as ear shape, gait, laughter recognition, facial thermograms, and lip shapes.

To begin, it is important to distinguish between the use of biometrics for identification and verification. For identification, the task is to identify an individual out of a population of all possible users. As the population of possible users grows, the demands on identification can also grow (either in terms of performance or accuracy of the recognition system—challenges similar to speech recognition for large vocabulary unconstrained speech). For verification, the task is to verify a particular identity by matching a characteristic to a stored template for the individual. The computational task is much simpler for verification than for identification (where only fingerprints, retinal scanning, and iris scanning have been proven successful for large populations). For the most part, we will talk about the use of biometrics for verification in this chapter.

Coventry (2005) provides an excellent illustration of how biometrics might be used and what some of the current trade-offs are for a common application—ATMs. For all techniques, there are usability issues that can be cited as barriers to implementation and acceptance. Fingerprint identification is relatively well developed, but sensors placed in public places are subject to environmental issues (such as dirt or latent prints) and user training issues (they can be sensitive to where the finger is placed on the reading device). Retina scans have attractive potential, but are currently quite invasive and difficult to develop for a full range of users (they require placing the eye close to a sensor location). Speaker verification can be subject to background noise problems, and relatively complicate user registration requiring more input than a single word or phrase. Signature verification is attractive because of its long use and association with financial authorization, but current technology is not yet seen as reliable. Typing verification is seen as having some potential, but lacking the reliability necessary for large population verification.

Biometrics researchers have determined that real-life users are the biggest variable in system performance. Ashbourn (2000) has suggested several user characteristics for evaluating biometric systems. These include a users general acceptance of the biometrics concept used (i.e., Is the idea of having a system read such characteristics acceptable?), general knowledge of the technology (i.e., Does the user understand what is being done?), knowledge of the particular biometric characteristic (e.g., Does the user understand that if fingerprints are being read, the finger should be centrally placed on the sensing device?), experience with the sensing device, environment of use (e.g., public or private), and transaction criticality. Although biometrics technologies are rapidly improving, inherent performance limitations remain and are extremely difficult to work around, except perhaps by combining multiple technologies or providing for a bypass.

29.4.3.5 Other Security Approaches

One other way of authentication by "something I have" is through the use of smart cards—here referring to a portable device (or card) with processing power and authentication information contained on it. Smart cards essentially add an integrated circuit to familiar plastic credit cards enabling the use of cryptographic services like random number generation and public key cryptography (Piazzalunga, Salvaneschi, and Coffetti 2005).

Just (2004) examines the design of challenge-question systems, looking for ways to improve the usability/security characteristics of these. Beckles, Welch, and Basney (2005) look at the usability of security mechanisms in grid computing contexts.

Encryption of data is a well-established mechanism for protecting information. Rather than storing or transmitting data that can be read "in the clear" (i.e., data that is stored in standard code schemes such as ASCII), information is encrypted using a key, and then must be decrypted using a key. Although this contributes to achieving some security goals (e.g., if an encrypted file containing sensitive information is lost or stolen, it would be a considerably harder task to make use of the information than if a plain data file were lost or stolen). There is a "usability cost" for this added security—users might have to indicate when and how files are to be encrypted or decrypted. Unfortunately, the complexity of this process has been found to cause user difficulties, variously resulting in inability to use security mechanisms appropriately (Whitten and Tygar 1999; Caloyannides 2004; Guttmann 2003). Work continues at addressing the issues associated with cryptographic approaches to security (e.g., Balfanz, Durfee, and Smetters 2005).

29.4.3.6 Security Policy Management

Much of the research related to policy management mentioned above in the Privacy Research Section also applies to Security Policy Management. To the extent that privacy policies can be viewed as a specific case of an access control policy, issues in authoring, conflict resolution, visualization, and other issues clearly overlap. There are additional complexities for privacy policies in that they include an additional element (purpose of use of the resource in question). These complexities drive implementation challenges that, to date, have not been fully addressed. For example, how would a system know that Mary's doctor was using her medical information for authorized purposes and not for unauthorized use? At some level, this is a concern for security policies as well. In the security literature, little attention is paid to the notion of purpose. Authorization policies specify who can do what with a resource, but do not really address the use beyond the system concept of the action involved. If a doctor is authorized to make a copy of a medical test, then it becomes outside of the domain of the security system to follow how the information is used. Having policies that can travel with information and can be interpreted by other systems is an approach to such problems, but it is a complex unresolved issue (e.g., who would pay to re-architect existing systems to accommodate such a solution?).

Another issue for security policies is that there are many different policy types. Although standards exist that cover privacy policy formats, they describe a single policy type (e.g., a XML format for a general access control policy). For security policies, there are many different types—access control, firewall, network, and so on. If people are going to manage sets of different policy types, it might be useful to design similar methods for the basic functions of authoring, analyzing, and visualizing such policies. Recent policy research has focused on providing usable tools for policy template authors (Johnson et al. 2010a,b). A policy template is a policy format that enables users to create policies that covers their activities using a form provided by the organization. The template makes policy creation efficient by creating a form that will handle the range of acceptable policies and that reduces the chances of creating policies that are considered out of bounds. The policy template may be prepopulated with the policy attributes (elements of the policy) that are considered within the organization's mission.

29.4.3.7 Usability Challenges Specific to Security: Attack Defense

Much of what we present above should seem familiar to the usability practitioner in the sense that security considerations should be considered as part of the overall system use context. The choice of authentication technique in general should consider the various trade-offs in the techniques available. Biometric techniques can be considered if users are likely to accept them and if they cover the population of expected users. If passwords are used, they should be easy for users to recall and enter, but difficult to be guessed or stolen. There are some specific issues that arise because of the nature of security as a protection against attack. The fact that it is not just the user, but also that other parties with intention to do harm that must be considered, makes considering usability issues complicated in new ways.

For the majority of usability work, the goal is to make the users' primary task understandable, efficient, and effective. For security considerations, we encounter a different situation—the fact that there are people who might be trying to deceive the user and commit fraud (Conti, Ahamad, and Stasko 2005). Of considerable recent interest in the security arena is the battle against "phishing"—the misrepresentation by someone of an identity or website intended to draw the user into interactions that can be harmful to the user. A phishing attack succeeds when a user is tricked into forming an inaccurate model of the interaction and when the user takes actions contrary to their intentions. Attacks often begin with e-mails sent to potential victims, purporting to be from an individual or organization that the user has some legitimate reason for interacting with.

The issue of phishing has been viewed as a model problem for illustrating usability concerns in security (Dhamija and Tygar 2005; Miller and Wu 2005). There is an Anti-Phishing Working Group, which has been collecting and describing phishing attacks since 2005 (Anti-Phishing Working Group 2005). Analysis of the reasons why phishing attacks are so often successful points to a number of interesting usability aspects. For example, operating systems and windowing platforms that permit general purpose graphics, also allow attackers to mimic the appearance of legitimate sites. Users tend to habituate on commonly occurring warnings about submitting data over unencrypted connections, and can easily fail to notice when they are actually entering information to an insecure site. Because organizations can invest heavily in having their names and logos associated with trust, attackers can take advantage of this association by simply convincing the user that they represent a trusted organization. Because security is generally a secondary goal for users, there is only so much attention end users are willing to expend to ward off attempts at fraud.

End users are not alone in trying to prevent attacks on systems. For people working in organizations in which there are system administrators, the usability problem is partly moved from the end user to the administrator. Here, the focus shifts to making tools for users whose primary activities include monitoring the health of the overall system. Security is one of their main tasks. Intrusion detection (ID)—the problem of detecting computer attacks in a timely manner is one of both great difficulty and utmost importance. Finding specific evidence of attack activity in the enormous number of potentially relevant alerts, packets, operating system events, and user actions presents an almost overwhelming task for an ID analyst. Visualization tools and techniques can be used to increase the effectiveness of ID analysts by more fully exploiting their visual cognition abilities. Recent work has identified promising avenues for research in visualization for ID (e.g., Goodall et al. 2005). Goodall et al. present a user-centered visualization based on understanding of the work of ID and the needs of analysts derived from the first significant user study of ID. Consistent with good information visualization practice, their tool presents analysts with both "at a glance" understanding of network activity, and low-level network link details. Results from preliminary usability testing show that users performed better and found easier those tasks dealing with network state in comparison with network link tasks.

29.4.4 Summary of Human–Computer Interaction Security Research Results and Recommendations

We would all like our information to be secure; that is, we would like our systems to be resistant to access or modification from individuals whom we do not authorize to have access to them. This requires that users be aware of security mechanisms even though they would generally prefer not to. The design challenge is to make security appropriately usable—that is, to make it as easy to use as possible for the

TABLE 29.2
Design Factors Impacting Usable Security

Automatic Security versus User-Controlled Security

- Security is not generally the main user task focus for personal information management (PIM).
- "Risk Management" is not a topic that end users explicitly understand.

Authentication Mechanisms

- Access to resources is controlled by knowledge of who the user is.
- Identification relies on authentication through one (or more) mechanisms.
- Mechanisms have usability/security trade-offs.
- Can be "something I know" or "something I have."

Passwords

- Usually textual, but can be other such as graphical.
- A form of "something I know" authentication and users will forget passwords.
- Users will select passwords that are not optimally secure.

Biometrics

- A form of "something I have" authentication.
- Not all users might have a characteristic (e.g., fingerprint).
- Recognition technology is involved, so errors and attacks are possible.

Attack Considerations

- Complete design requires consideration of possible attacks.
- Anti-phishing approaches.
- Visualization for system administrator tools.

Policy Management

- Complete design requires consideration of how policies are authored, evaluated, maintained, and executed.
- Policies have much in common with rule-based system issues—they can be hard to maintain, people can have difficulty knowing what they do, and so on.

intended users, whereas making it as difficult as possible to circumvent for the potential attacker. This means that security administration and user involves trade-offs that need to be evaluated in the design of a system. Absolute security is a myth—we need to understand that it is appropriate levels of security we are looking for.

Some of the aspects of security that researchers have investigated are mentioned in Section 29.4.3 and summarized in Table 29.2. We think that serious consideration of the trade-offs between usability and security has just begun, and that much work remains. Although initial approaches have involved hiding security controls from users, we believe that this needs to be done in balance with giving the user the ability to control the level of security required.

29.5 VIEWS ON TRUST

As with privacy and security, trust is a term that can be used in many ways, and this contributes to confusion and difficulty in making progress in advancing IT systems. Trust is related to privacy and security, but differs from these concepts in that it is not an objective measure. Trust is based on the perception that the person, organization, or system one is dealing with is reliable and will act in a predictable manner. In our scenario, Mary has to make many decisions in which trust is a factor. In this discussion, we will explore factors that have been found to influence trust of online commercial entities, government organizations, and social networking sites. In particular, we will discuss the relationship between trust and risk, the factors influencing the development of trust, the relationship between trust and social networks, trust and personalization, and trust and intercultural collaborations. For the purposes of this discussion, we will assume that the privacy and security protections discussed earlier in this chapter are in place.

The relationship between trust and IT systems is complex and multifaceted. For example, users can have different perspectives on how much they trust their systems, trust the organizations they are interacting with through their systems, and trust in the provided security mechanisms that are intended to protect their privacy. There are many definitions of trust and none of them satisfies every use. These definitions vary across academic domains and with context. When dealing with e-commerce and other computer applications, the user is deciding not only to trust the individual or organization, but also the technology implementation provided by the individual or organization. Kuhlen (1998, p. 3) defined trust as "allowing us to act as if we have perfect knowledge about the reliability of that entity even if we do not." Marsh and Dibben (2003, p. 466) defined trust as concerning "a positive expectation regarding the behavior of someone or something in a situation that entails risk to the trusting party." Jøsang and Presti (2004, p. 1) defined trust as "the extent to which one party is willing to depend on somebody or something, in a given situation with a feeling of relative security, even though negative consequences are possible."

Given the many attempts at privacy definitions and the recognition of the importance of trust to the success of all types of online enterprises (Hoffman, Novak, and Peralta 1999), researchers have also attempted to model trust. Schultz (2006) proposes a model of trust and trustworthiness. This model explores how an individual's trust in another entity's trustworthiness evolves over time depending on the outcome of different and repeated situational contexts. Grabner-Krauter, Kaluscha, and Fladnitzer (2006) built a model based on characteristics of the context, the truster, and the trusted party or object. They point out that trust only is required when there is risk, and that an individual's willingness to trust and other personal characteristic affect whether or not they will develop trust. Additionally, they point out that several characteristics of the trusted party, such as dependability, predictability, benevolence, and integrity, also affect the development of the trust relationship.

There is one area of online activity in which users trust decisions increasingly can have immediate consequences if the wrong decision in made—determining if an e-mail is from a legitimate source or is a phishing attack. Kumaraguru, Acquisti, and Cranor (2006) proposed a trust model that is tailored to capture differences in expert and nonexpert recognition of these potential phishing attacks. Their model includes representations of the context or state of the world, signals that the user can detect from the target e-mail, actions that the user may take, and the user's well-being. They found that security experts were much better at detecting a range of signals from the e-mails that indicate potential phishing attacks and using this information to avoid actions that would be counter to their well-being.

All of the definitions and models share the concept that trust is about allowing us to feel comfortable allowing another entity, such as an organization or an organization's computer system, to take one or more actions for us even though there is risk that we could be harmed in some way. In other words, in the online world, the trusting party believes that the trusted organization has implemented privacy and security so that it will protect the PI of the individuals interacting with it.

29.5.1 Trust and Risk

One element that all the definitions and models have in common is that trust cannot exist without risk (Grabner-Krauter, Kaluscha, and Fladnitzer 2006; Schultz 2006). If a situation is without risk, then there is no need for trust. As Patrick, Briggs, and Marsh (2005, p. 81) pointed out, "Trust is intimately associated with risk," and people evaluate the degree of risk in many situations both online and offline. For example, Mary must evaluate risk at several points in our scenario. Mary's medical records contain sensitive PI and sharing them with a new doctor's office staff does presents risks. She must worry about both whether the staff in the medical office will treat any knowledge they learn about her appropriately and whether the records will be secure in their computer system. In our scenario, she reads and consents to the privacy policy before giving her medical records to her new doctor. Although the use of the doctor's MyMedicalFile system is very convenient for patients, it also raises privacy and security risks since it makes parts of Mary's medical records available over the Internet. If the security measures that the practice has put in place were somehow breached, unauthorized people might have access to these records. Mary must also consider the risks of using a social networking site to communicate with friends and family. Again, although this service provides convenient methods for Mary to disseminate information and receive the emotional support she needs from friends and family, it is possible that she will face negative consequences if people she did not intend see her information on this site. In all of these cases, Mary must decide whether she trusts the other entities and their IT systems to enforce her privacy choices and to provide effective security to protect her information.

In the online world, decisions like those Mary faced in our scenario require different skills to judge the trustworthiness of the entities she is dealing with than in the physical world. People can become victims of phishing attacks and identity theft if they trust too much. However, as Friedman, Kahn, and Howe (2000) point out, there are costs to trusting too little. Many opportunities can be missed if users do not take advantage of the online information and services available to them. Friedman et al. discussed several issues that make online trust and risk decisions more difficult than face-to-face transactions such as the anonymity of online transactions, the difficulty in assessing the reliability and security of technology, and misleading statements and images. Patrick, Briggs, and Marsh (2005) referenced work by Chaiken (1980) that described two strategies used by individuals depending on the perceived level of risk involved. Where people are not highly involved with the decision, they often make decisions based on appearances, and when they are more deeply involved, they use strategies that are more systematic (Chaiken 1980). This suggests that the degree to which users believe they are at risk will determine the strategies they use to assess the credibility of a website or system and the organization behind it. This model is similar to the three-stage model proposed by Sillence et al. (2004). In the first stage of their model, users make quick decisions based on appearance, which is similar to Chaiken's description of when people are not highly involved. In the second stage, Sillence et al. (2004) described the user perceptions of the credibility of the information, which is similar to the systematic strategies that Chaiken described when people are more involved.

29.5.2 Factors Influencing Trust

In our scenario, Mary decides to trust the doctor's office and its associated technology and the social networking site she used and the websites that she consulted for information. An important research question is what leads an individual user to trust or not trust a website or an online service. Brodie, Karat, and Karat (2004) showed that greater degrees of transparency and control regarding the use of PI do increase website visitor trust in the domain of IT equipment. In addition, to control one's own data and the transparency of its use, researchers have found that individuals' familiarity with a website and the perceived credibility and quality of the site also affect trust. Fogg et al. (2001) found that website visitors' perceptions of the credibility of a website were most influenced by the degree to which it was connected to a known organization in the real world and whether it seemed well designed and implemented.

Building on this research, Fogg et al. (2003) conducted a study with 2500 participants to understand factors that influence the perceived credibility of a website. They found 18 factors that influenced credibility. The biggest factor by far was the design of the appearance of the website. This was followed by the information design or structure, information focus, perceived motivation of the website owner, perceived usefulness of the information, accuracy of the information, name recognition and reputation of the website, the tone of the writing, the identity of the sponsor, functionality on the site, customer service, past experience with the site, clarity of the information, performance on a test, readability, and affiliations (Fogg et al. 2003). They attribute the importance of the design look of the site to the fact that it is very prominent when a visitor looks at a website. This supports Fogg's theory that credibility is based on noticing a feature and then interpreting its quality to create judgment (Fogg 2003). This theory is posited as a reason why there are apparent differences in findings relating to the affect of privacy guarantees (i.e., privacy statements and privacy seals) on websites (Palmer, Bailey, and Faraj 2000; Turow 2003). Palmer et al. found that privacy seals and statements did contribute to user's trust of website, whereas Turow found that website visitors do not read privacy statements or understand the meaning of seals and that there is a need to educate the public regarding privacy issues and the web.

Lumsden (2009) looked at the factors that effect initial trust in a commercial website and found that the important factors for trust were similar to those found by other researchers. These included the presence of security certifications such as Verisign, customer recommendations and testimonials, privacy and company policy statements, and contact information. When particular security features of the site were highlighted for the user (i.e., use of Secure Sockets Layer), these were also rated highly, but otherwise not. This suggests that many users do not notice them without aid. They found that although the perceived professionalism of the site design was important, it was more important when the appearance and quality of the products being sold were harder to judge online. For example, they found it was more important on clothing websites than bookseller sites.

Given that familiarity is a factor in establishing trust, Zhang and Ghorbani (2004) have identified several factors that influence familiarity, including: the individual's knowledge of similar services (prior experience), the number of times she has visited the particular website before (repeated exposure), the length of each visit to the website (level of processing), and the interval of time between visits (forgetting rate) (Zhang and Ghorbani 2004). Corritore, Kracher, and Wiedenbeck (2003) have created a model using similar factors as influencing trust in the online world. In this model, trust is determined by both external factors and the user's perception of the application or website. The external factors include the user's propensity to trust and prior experience in similar situations and their perception of the credibility of the website, how easy it is to use, and the degree of risk involved. All of these researchers' findings suggest that Mary's decision to trust the website was based on the degree to which she felt she had control of the information about her, the professionalism of the doctor's office, its website, the social networking service she used, and the informational websites, the reputation of each organization, and past experiences she has had.

Hartmann, De Angeli, and Sutcliffe (2008) studied the effect of positive and negative framing of information provided a priori to users on the usability, service quality, and look and feel of websites. They found that although all the participants were given the same information, they responded more positively if the information was put in stated in a positive way ("90% of users experience the website as easy to use") rather than a negative way ("10% of users experience difficulty using the website"). The results of this study suggest that positive recommendations Mary received regarding the doctor from friends and colleagues may have also contributed to her trust decisions.

After Mary received her diagnosis, she decided to research her condition online before her first appointment with a specialist. For each website that Mary considered, she had to decide whether the information provided was credible and trustworthy. In this case, she was not as worried about someone trying to steal her PI, but on whether or not to trust information that might affect her health decisions. Briggs, Simpson, and De Angeli (2004) looked at trust in a different type of informational website—advice websites. They have developed a model of how people determine whether or not to trust the advice they receive from websites. The authors developed a 22-point scale designed to break down trust into a set of judgments that can be measured. This list includes: whether the user perceives the information to be prepared by an expert or a knowledgeable source, whether comments from other users were available on the site, if the site was owned by a known and respected company, if they had to wait a long time on the site, if different options were suggested by the site, if the site was perceived as hard to use, whether the user felt involved in how the site constructed the advice offered, if the site was perceived to be interactive, if the advice was tailored to the user, if the reasoning was explained to the user, if there was an opportunity to contact a human, if the advice appeared to be impartial, if the advice was perceived to be good and the user trusted it, and if the site behaved in a predictable way (Briggs, Simpson, and De Angeli 2004). This study supported an earlier study that found trust was influenced by the perceived credibility of the source of the information, whether the site was personalized so that information was tailored to the individual, and whether the site is operated in a predictable way (Briggs et al. 2002). Although many have found that trust affects the use of personalization, Briggs et al. found that the presence of personalization can contribute to trust if it allows the visitor to feel that the site is tailored to their needs.

Sillence et al. (2004) had similar results when studying trust of information on health-related websites. They have proposed a three-stage model of trust in which visitors make initial, rapid assessment of a website based on the design and appearance of the site and then do a more systematic evaluation in which the credibility of the site and the degree to which it appears to be personalized to their situation becomes more important. The participants were looking for information written by or for people in situations similar to their own. The third stage of this mode addresses the maintenance of the trust relationship over time and is left as future work in this paper.

One currently popular source of information on the web is Wikipedia. This wiki provides information on a very large range of topics including illnesses and other health-related issues. Information on the site can be suspect because it is provided by members of the general public who may or may not have expertise on the subject. Suh et al. (2008) have developed an interactive visualization to show the information creation and revision history of each article to help users better determine the quality of the information. The initial results showed the users felt this tool gave them important information about the quality of information within Wikipedia. Pirolli, Wollny, and Suh (2009) followed up on the previous research by studying the effect of their visualizations on both people who tended to be more or less skeptical of Wikipedia. They found that both groups trusted the information appropriately more often when using the visualization.

Patrick, Briggs, and Marsh (2005) provide a thorough overview of many issues related to trust, including credibility of information on a website, familiarity with the website, and external factors such as prior knowledge and disposition to trust. They also describe how trust is developed slowly over time, but a bad experience or even a processing error can destroy that trust very quickly. They review a number of privacy models that have been operationalized using questionnaires including Bhattacherjee's model that describes how familiarity leads to trust and to a willingness to do business with a site (Bhattacherjee 2002) and Corritore et al.'s model that is described above (Corritore, Kracher, and Wiedenbeck 2003). Patrick, Briggs, and Marsh then conclude with design guidelines for promoting trust based on the literature that they review (Patrick, Briggs, and Marsh 2005).

Many researchers who have studied the development of trust in the online world have identified the transparency, reputation, and perceived intentions of organization and their associated websites and the ability of users to control access to their information. One active area of research that can help to address these user concerns is the use, analysis, and enforcement of organizational policies. These policies can enhance an organization's ability to provide high quality and enforceable security and privacy controls. However, if the website users do not understand or are unaware of the policies or they are not enforced by the organization, they will not help to build trust. Karat and Karat (2010a,b,c) describe research into a natural language policy authoring system to allow organizations to write policies in natural language and transform it into machine-readable formats. Karat et al. (2009) build on this work by describing research into a policy framework that has the potential to reduce these concerns by transforming policies from the human understandable natural language form to the executable policy that can be executed by an enforcement engine.

Johnson et al. (2010a,b) further builds on this research with a template-based policy authoring approach with the goal of creating enforceable and understandable policies. The templates allow both policy creators and implementers to have a better understanding of the natural language policy and to ensure that the final executable policy better adhere to the original intent of the natural language policy. From a trust perspective, this research has the potential to benefit two different groups in two different ways.

First, in this research different policy creation roles were identified ranging from policy template authors who take a broad, high-level view of the organization though to specific low-level policy authors who are responsible for policies in a small portion of the organization. Many of the policy template authors that participated in the study reported concern regarding lower level policy authors who may inadvertently create policies that do not meet the intended standards of the high-level policy management. In other words, the policy template authors do not trust the policy authors to be able to consistently create policies that meet the organization's standards. The use of templates have the potential to help address this trust issue by providing guidance and limits on the policies that individual policy authors can create.

Second, policies created with well-understood templates would allow end users to also understand the policies that are in effect and to build appropriate trust models. In our scenario, this technology would, for example, allow Mary to better understand the privacy policy that she agreed to at the doctor's office or the social networking site and feel more comfortable using the MyMedicalFile system and the social networking site.

29.5.3 Trust and Social Networking

One area of online user activity that requires trust decisions is the use of social networking sites such as Facebook, LinkedIn, and MySpace. Given these sites growing popularity, this area warrants its own analysis and discussion. Social networking sites offer users many advantages. They provide easy methods of networking with new and existing colleagues from a professional standpoint and convenient ways of finding, connecting, and communicating with old friends. In our scenario, Mary uses an online networking site to let colleagues, friends, and family who live in many different geographies know about her medical condition. This has the potential to be a powerful means of support for Mary through her illness, but it does come with associated risks. These risks range from someone gaining enough information to commit identity theft or even target a person for a crime in the physical world to people seeing PI about Mary that she did not intend for them to see and using this information against her perhaps by limiting her career advancement based on fear of her cancer returning.

There have been many accounts of negative results from sharing too much PI on social networking sites without proper thought to either privacy settings or the information posted on the sites. Acquisti and Gross (2006) reported on disciplinary actions taken against college students when pictures on Facebook showed them violating their dormitory's alcohol policy. They studied the use of Facebook by college undergraduates, graduate students, facility, and staff. At the time this paper was presented in 2006, Facebook was mainly used by college and high school students. They found that the majority of their participants reported that they were concerned about privacy and did understand how to control access to the data using the controls provided by Facebook, but their behavior differed from their stated concerns in the amount of information they disclosed. They also found that there was a sizeable minority who did not understand how to use the privacy profile functionality within Facebook to control access to their data.

Strater and Lipford (2008) also reported many potential negative consequences to revealing too much information through social networking sites, including embarrassing situations and blackmail, physical and online attacks, and the use of data by law enforcement for the investigation of crimes. They also studied students at a major university. They found that students either made everything open and planned to protect privacy using self-censorship or set all their profiles to be friends-only so that they could control the audience. New users seemed very aware that many people could be looking at their data and therefore often had an appropriate degree of trust in the system, but as time went on this changed. As users used the system to correspond only with friends through Facebook, they came to feel that the audience for their data was limited to only their friends. This has the potential to create an inappropriate degree of trust in the system. The researchers also found that many students only set their profiles once and then rarely went back to update it. They also often did not understand the implications of all the settings so they were revealing more information than they intended to.

Stutzman and Kramer-Duffield (2010) studied students at a major university in the United States who chose to use friends-only privacy settings on Facebook. First, they consider many implications of the use of the friends-only setting. Although this setting provides control of a user's audience, it does limit the power of a social networking site by greatly reducing the potential to develop new relationships with people one does not know in the physical world. Secondly, there are still ways that information about an individual may be available to a wider audience than the user realizes if others post information about them or post pictures in which they are tagged. The only method for controlling this type of disclosure is through negotiations with ones' friends. In this research, they also studied what characteristics were associated with the use of the friends-only networks. Females who had large networks and who were likely to discuss and negotiate privacy issues with friends and who were aware that casual acquaintances on campus may be looking at their information were most likely to use friends-only privacy settings. They also noted that the students were not so aware or concerned about outsiders (e.g., potential employers, law enforcement, school administration, etc.) viewing their information. The researchers highlight the need for greater education regarding privacy and the use of the privacy profiles in social networking sites such as Facebook.

Although many researchers are considering the privacy and trust implications of the use of social networking sites, most have simply proposed increased education to help users understand how to control their privacy settings and create an appropriate level of trust. Mannan and van Oorschot (2008) have proposed an approach that allows users to control access and increase their trust in a user-friendly manner. They suggest that many of the social network site users already have a "circle of trust" established with their instant messaging (IM) contact list. They suggest that this list could be utilized to automatically limit access to the same list. One major advantage of this scheme is that it would require little set-up work on the part of the social network user. It is clear that over time privacy perceptions by both individuals using social networking sites and the social networking sites themselves are changing even as usage grows. The default policy of at least one of the major social networking sites has been becoming less private over time (Opsahl 2010), although it is not clear that users are aware and sensitive to these changes. Research must continue to evolve in this growing and changing area.

29.5.4 Trust and Personalization

Another important area in dealing with online entities in which trust has important implications is personalization. In the last decade, many e-commerce companies have invested in personalizing the e-commerce websites to encourage business. However, personalization is only useful if users are willing to share data with the website, and this has not always been the case. This requires that users trust that owners of the website will not misuse their data. Hagan (2000) found that website visitors often show their distrust of Internet websites by disabling cookies on their computers and entering incorrect information into online forms. Many researchers have studied what aspects of an application or website affect user's willingness to use personalized features of websites. The Office of the Federal Privacy Commissioner of Australia (2000) conducted a large study of the factors that affect whether individuals are willing to share information with a business or other organization. They found that it is important to individuals that they understand how their data will be used and that they have control over who has access to it. Welty and Becerra-Fernandez (2001) examined how information technologies can reduce transaction costs and increase trust by increasing the symmetry of information available to both sides of the transaction in a business-to-business setting. Likewise Brodie, Karat, and Karat (2004) showed that greater degrees of transparency and control regarding the use of PI do increase willingness to share data to get access to personalized features of websites in the IT domain. Karat and Karat (2010a,b,c) further expand on this research by discussing that in addition to transparency and control of data, functionality that made the customer more effective in their own job also increased potential trust. They found that e-commerce website customers were more willing to share personal data when provided with functionality that was truly useful to them. Examples of these technologies include tracking previous customer purchases and providing compatibility information on potential new purchases, providing automatic support alerts, and tracking transactions. These findings suggest that website users' trust of an e-commerce website increases when the website allows the user to control their own PI on the site and provides value to them in their jobs or other time-critical areas of their lives.

Cranor (2003) discusses several risks that potential e-commerce customers perceive when using a personalized website. These include unsolicited marketing, potential price discrimination based on a profile, and personalization functionality, making inferences about them that are either incorrect/frustrating or correct but that the user would rather not have known by others. There are many different entities that potential website users may not want to have access to these inferences including the company itself, other users of their computer, hackers who steal information from the e-commerce company, and law enforcement. Cranor suggests several approaches to addressing these concerns including pseudonymous profiles in which users' real names are not stored, encrypted, client-side profiles so that not only is the information not stored on the enterprise's server, it is also not readable by other users of the client computer, tasked-based personalization that is deleted at the end of one session, and user control of data. Although each of these approaches has implementation costs and limitations, they provide a set of methods that could be useful depending on the specifics of the website and the situation.

Overall, trust and personalization have a complex relationship in which the presence of personalization functionality that can provide website visitors with information tailored to their situations and needs has been found to lead to a greater degree of trust on a website. At the same time, website visitors must trust the website and the organization behind it enough to share PI if the functionality is going to be effective and provide value both to the user and organization. Research has shown that website visitors are willing to share more PI when they understand how and by whom their data will be used and when they have the ability to control how it is used, which suggests that these are important factors for designers to keep in mind when designing their websites.

29.5.5 Trust and Intercultural Collaboration

Another area that deserves special discussion is the need for trust in intercultural collaborations. In the modern world, teams are often separated by large geographic distances and cross country and language borders. These distances and differences can lead to misunderstandings because team players do not always share cultural understanding to the same degree as do teams that are co-located and from the same culture. These misunderstandings can negatively impact trust that may be developing between culturally diverse partners. Many researchers have studied how to identify cultural differences that may affect productivity to improve trust issues and facilitate collaboration in many different domains. Dalberg et al. (2006) have developed a framework for identifying risks due to cultural differences on large software development projects within the European Union. The goal of their research is to understand areas that might lead to misunderstandings, inefficiencies, and loss of trust during large projects. Their framework considers the strengths and weaknesses of each team to assess risks based on contextual, cultural, and collaboration process dimensions.

Quinones et al. (2009) studied intercultural collaboration among students from different universities located in the United States, Brazil, Israel, and Turkey working on a building project to understand how their different mental models affected the team dynamics. They identified many differences in understanding that led to bad feelings and lack of trust between team members. These included differences in the perspective on the meaning of a deadline as a hard and fast time to be finished by the U.S. students versus something a bit more flexible by the Brazilian students and differences in the willingness to share some PI before starting the business of a meeting between U.S. students and Israeli students. This research went a step further than the previous project in that it concluded with recommendations for the development of collaborative tools to address these issues.

Karat et al. (2009) extend intercultural collaboration research by developing a policy framework that can be used to create tools to address the issues found. They describe research into context-sensitive policy management for collaborative mission planning. Although the current research is centered in the military domain, the teams involved have studied planning in a range of commercial domains and the proposed policy framework is generalizable to many other domains. They have combined research techniques such as Contextual Inquiry and Cultural Network Analysis to understand how policies are created and implemented from the high-level natural language level to the low-level implementation. The goal is to create a policy framework that not only performs the necessary transformations, but also detects potential conflicts between partners and even within a single organization's policies and suggests possible resolutions to those conflicts. A context-sensitive framework of this type has the potential to identify possible misunderstandings before they become serious and help to resolve them and, therefore, foster trust between the culturally diverse organizations.

29.5.6 Summary of Human–Computer Interaction Trust Research Findings and Recommendations

Trust is necessary to function in an uncertain world. The Internet continues to grow in importance in our lives. Although the traditional e-mail, IM, and informational websites continue to be important, other Internet services are growing in usage every day. These include e-commerce, social networking, and tools that allow widely distributed teams to collaborate across time, distance, and cultural differences. Trust is an important consideration in users' acceptance of all of these online services. Although this online functionality provides a great deal of value to society, it does come with serious risks and it is important that users develop an appropriate level of trust. Although there has been a great deal of research on why and when people trust in the online world, there is more to do. HCI researchers and practitioners can help by continuing to build an understanding of what leads individuals to trust a website or an application and to drive the research into new technologies that can help to allow users to develop appropriate trust models of the online websites and functionality that they use. Table 29.3 contains a summary of the factors

TABLE 29.3
Factors Influencing Online Trust in Reviewed Research

<table>
<tr><th colspan="4">Online Trust Issues Spanning All Research Areas</th></tr>
<tr><td colspan="4">• Perceived credibility of the website or application
• User familiarity with a website or application
• Predictability of the behavior of the website
• External factors (propensity of the user to trust and users’ prior experiences in similar situations)
• Ease of use
• Perceived degree of risk in dealing with the site
• Use of policy templates can address policy template creators’ concerns regarding low-level policy authors creating high-quality policies
• Policy framework and templates allow end users to better understand policies in place</td></tr>
<tr><th>Advise Websites</th><th>E-Commerce/Personalization</th><th>Social Networking</th><th>Intercultural Collaboration</th></tr>
<tr><td>• Perceived quality of information provided
• Professionalism of the site design
• Reputation of entity</td><td>• Professionalism of the site design
• Reputation of entity
• Site personalized to provide value to user
• Ability to control information shared with site
• Degree of transparency regarding use of shared information</td><td>• Ability to control information shared with site
• Degree of transparency regarding use of shared information
• User perception of information audience</td><td>• Identify and resolve misunderstandings
• Assist with cultural education</td></tr>
</table>

identified in the research cited in this chapter that have been found to influence trust in the different areas of the online world to date. HCI practitioners and website designers need to understand the factors that influence trust and use this knowledge as they design websites and applications.

29.6 CONCLUSIONS AND DIRECTIONS

The intersection of HCI, privacy, security, and trust is emerging as a critical area for research amid the backdrop of recent world events. Information is being improperly disclosed in ways that causes real harm to people through identity theft. Organizations are concerned about theft of proprietary data and documents. Citizens are becoming increasingly concerned about the use of the vast amounts of data that organizations and governments have about them, and are increasingly concerned about how that information might be used. The rapid advancement of the use of IT in industry, government, and academia makes it much easier to collect, transfer, and store sensitive information of a variety of types around the world. IT Professionals are faced with technical challenges that result from inadequate consideration of security and privacy issues in architecting current information systems, which, if not addressed, will result in a significant deterioration of the trust that people have in IT. And while there certainly is considerable research in this area, particularly on the security side, it is becoming increasingly clear that really making our systems secure and enabling appropriate attention to privacy issues will require more than just a technology focus. Although usability has been identified as a major challenge to moving the results of security and privacy research into use in real systems, it is not clear that this challenge has reached the interdisciplinary researchers needed to carry out the complex agenda of work.

We see privacy as a complex social issue concerned with individuals’ rights to know what information is collected about them and how it might be used. We do not see a solution for appropriate use of information through identification of a single policy or approach for information privacy, but argue as others have that consideration of privacy and tools to enable it need to develop hand in hand (e.g., Iachello and Abowd 2008). Technology is forcing us to rethink how we think about privacy—how much of it we want and how we can control it. This is not a simple user productivity issue, nor is it an issue we expect to see “resolved.” We fully expect that we will see rapid changes in this arena over the next decades.

We see security as an issue that will also evolve rapidly as technology develops. As we rely more and more on technology in our daily lives, we need to know that the technology functions as expected and is not subject to malicious modification in behavior. This will continue to be dealt with as both a technical issue in which guidance is to minimize the human role in the development of secure systems, and as a socio-technical issue in which the users of the technology play an important role in keeping the systems secure. The role of HCI research in security is less clearly defined than it is for privacy in that it is easier to consider our information privacy “requirements” and to imagine technology that would enable those requirements than it is to consider our information system security “requirements” and the technology that would enable those.

Trust differs from privacy and security in that it is more about individual’s perception of the risks of a situation than about measurable objectives regarding the protection of data and systems. Historically, this difference has driven trust research directions toward understanding trust issues in the online world and to the development of trust models that explore the characteristics of both users and systems that either trust or do not trust technology and the organizations providing it. In recent years, HCI researchers have begun to broaden the trust research in many areas of the online world by creating recommendations and prototypes of technologies to help address the trust issues and allow users to develop an appropriate level of trust in systems, the organizations behind the systems, and even other end users that they may interact with through the technology. In the future, more HCI research is needed to ensure that trust-enhancing technologies that are created and implemented really meet users' needs in these areas. As many researchers have pointed out, trust in online services is necessary for the success of all facets of the online world, from e-commerce to social networking to e-medicine and e-government.

Deciding how we can design usable and effective privacy and security technology capabilities for the future includes legal, cultural, business, social policy, human performance, and practical dimensions. Since at its core, the goals of HCI and user-centered design are to understand the user, the user's tasks or goals, and the social and physical context in which the user is interacting with the system, all of these dimensions can be considered as within the scope of creating usable and effective privacy and security solutions.

HCI research in privacy, security, and trust are critical areas of focus in today's world. Communication and collaboration is occurring between researchers, academics, and practitioners with expertise in one or more of the areas of privacy, security, trust, and HCI. This emerging community is beginning to work together to incorporate HCI in the design and development process for usable and effective privacy and security solutions. This chapter has reviewed and synthesized the research on HCI and privacy, security and trust, calling out many key areas in need of future research. Please join the emerging professional community focusing on the worthy effort to create usable and trusted privacy and security solutions for end users and organizations worldwide.

Application-/Domain-Specific Design

30 Human–Computer Interaction in Health Care

François Sainfort, Julie A. Jacko, Molly A. McClellan, and Paula J. Edwards

CONTENTS

30.1 INTRODUCTION

U.S. health care expenditures reached $2.3 trillion in 2008 and is 16% of the U.S. Gross Domestic Product (BlueCross/BlueShield Association 2008). Despite such large spending, many Americans remain uninsured and do not have access to health care services. According to the Congressional Budget Office, about 43 million people, or 17%, of the nonelderly population are uninsured (Congressional Budget Office, 2007). Furthermore, while our country has the most formidable medical workforce in the world and develops and uses the most modern medical technologies, the World Health Organization (2000) rated the quality and performance of the U.S. healthcare systems as being worse than most of its counterparts in the Western world. In 2006, the United States was the biggest spender in terms of health care per capita but ranked 39th for infant mortality, 43rd for adult female mortality, 42nd for adult male mortality, and 36th for life expectancy (World Health Organization).

Chassin, Galvin, and the National Roundtable on Health Care Quality (1998) documented three types of quality problems: (1) overuse, (2) underuse, and (3) misuse. The results of an extensive review of over 70 publications covering years 1993 through 2000 provide "abundant evidence that serious and extensive quality problems exist throughout American medicine resulting in harm to many Americans" (Institute of Medicine 2001, p. 24). In its first report, To Err is Human, the Institute of Medicine (2000) reported serious and widespread errors in health care delivery that resulted in frequent avoidable injuries to patients. The Institute of Medicine (IOM) (2001) suggested four key underlying reasons for inadequate quality of care in the U.S. health care system: (1) the growing complexity of science and technology, (2) the increase in chronic conditions, (3) a poorly organized delivery system, and (4) constraints on exploiting the revolution in information technology. Since the IOM report was issued, health care reform has been highly debated. Current U.S. health care reform proposals focus on extending insurance coverage, decreasing the growth of costs through improved efficiency, and expanding prevention and wellness programs (Murray, Phil, and Frenk 2010). To improve quality of care, the American Recovery and Reinvestment Act (ARRA) of 2009 allotted $19.2 billion for Health Information Technology (HIT) including financial incentives to use electronic health records (EHRs) and grants and loans for HIT solutions (American Recovery and Reinvestment Act of 2009).

Reengineering the delivery of health care services through innovative development, application, and use of information and medical technologies can result in tremendous cost savings, improved access to health care services, and improved quality of life for all citizens. Health care professionals in the United States have recognized that both the information revolution and the biological revolution will offer tremendous opportunities—and challenges—for (re)designing the health care system of the future. They are aware of the need to better utilize new information and communication technologies and incorporate computing power into care delivery and clinical practice. They are also aware that the widely publicized biological revolution (which includes advances both in genetics and biomedical engineering) will soon bring a large number of screening and diagnostic tests as well as new treatment strategies and disease management tools. It is clear that the combination of biotechnology, computing power, information and communication technologies, distance technology, and sensor technology will make future delivery of health care in the United States unrecognizable from the care we deliver today.

Despite these acknowledgments regarding the need for HIT, implementations in the last decade have proceeded slowly. It is estimated that only 17% of U.S. physicians and 8–10% of U.S. hospitals have a basic EHR system, and even less have or use comprehensive HIT systems that reach their full potential (Blumenthal 2009). Reasons contributing to this slow adoption of modern information and communication technology in health care include the perceptions that it is too expensive, very unusable, and quite divergent from current practice (Schoen et al. 2000). HIT implementations have altered the concerns of health care staff. Now that they are interacting with increased HIT systems in the workplace they are now concerned with the flexibility of the systems, if the systems were "fit for purpose," and have varying levels of confidence and experience with information technology (IT) (Ward et al. 2008). The literature further indicates that proper education and training are required to achieve user acceptance of HIT systems.

In addition, the current generation of HIT systems do not typically come "ready-to-use" off the shelf. It is extremely difficult, if not impossible, for health care provider organizations to have the range of expertise, in house, that is needed to design, adapt, and implement technologies to meet an organization's needs. In fact, many health care organizations are often not even fully aware of their own needs, do not know which technologies are available for what, and do not know how modern information and communication technologies can be effectively used to improve and simplify care delivery. In many cases, IT adoption among health care providers has been driven by Federal and state regulations and requirements rather than well-recognized internal needs and growth opportunities—for example, in Subtitle A—promotion of HIT, the ARRA sets the goal for the utilization of an EHR for each person in the United States by 2014 (American Recovery and Reinvestment Act 2009).

Health informatics is a field that can be widely defined as the generation, development, application, and testing of information and communication principles, techniques, theories, and technologies to improve health care delivery. It includes the understanding of data, information, and knowledge used in the delivery of health care and an understanding of how these data are captured, stored, accessed, retrieved, displayed, interpreted, used, and made more efficient. Although health informatics intersects with the fields of clinical-, biomedical-, medical-, and bio-informatics, it is different in the sense that it focuses on health care delivery, and hence is centered on the patient (and/or consumer), the clinician (or health care professional, or "provider"), and, more importantly, the patient-provider interaction. Human-computer interaction (HCI), from the perspective of both the patient/consumer and the provider, is essential to the success of "health informatics." In this chapter, we first review the characteristics of the healthcare industry in the United States. We then review information systems used by consumers, patients, and providers and raise HCI issues and challenges associated with both perspectives. Then we propose a framework for evaluating health care applications and conclude with a discussion of future opportunities and challenges for HCI in health care.

30.2 CHARACTERISTICS OF THE HEALTH CARE INDUSTRY

30.2.1 Health Care Industry

As previously discussed, the Institute of Medicine (2001) put forth four key underlying reasons for inadequate quality of care in the U.S. health care system today: (1) the growing complexity of science and technology, (2) the increase in chronic conditions, (3) a poorly organized delivery system, and (4) constraints on exploiting the revolution in information technology. In addition, a growing trend toward consumerism has become a major force in shaping the future organization of the health care industry. These five trends, detailed further in the following discussion, continue to shape the future of health care in the United States.

30.2.1.1 Complexity of Science and Technology

The sheer volume of new health care science and technologies—the knowledge, skills, interventions, treatments, drugs, and devices—is very large today and has advanced much more rapidly that our ability to use and deliver them in a safe, effective, and efficient way. Government and private investment in pharmaceutical, medical, and biomedical research and development has increased steadily. The health care delivery system has not kept up with phenomenal advancement in science and technology and proliferation of knowledge, treatments, drugs, and devices. With current advances in genomics (offering promise in diagnosis and, possibly, treatment), sensor technologies (offering promise in automated detection, measurement, and monitoring), nanotechnologies (offering promise in diagnosis, treatment, and control), and information and communication technologies (enabling remote delivery, telemedicine, e-health, and patient empowerment), the complexity of science and technology in health care is only going to increase.

30.2.1.2 Chronic Conditions

As noted by the Institute of Medicine (2001), "because of changing mortality patterns, those age 65 and over constitute an increasingly large number and proportion of the U.S. population" (p. 26). Therefore, there is an increase in both the incidence and prevalence of chronic conditions (defined as conditions lasting more than 3 months and not self-limiting). The National Committee for Quality Assurance (NCQA) found that chronic diseases lead to an estimated 45 million sick days and $7.4 billion in lost productivity each year (2007).

In a landmark study, Hoffman, Rice, and Sung (1996) estimated that American patients with chronic conditions make up 80% of all hospital bed days, 83% of prescription drug use, and 55% of emergency room visits. The presence of chronic disease has become the principal health burden in many developing countries as well. Chronic diseases were responsible for 50% of the disease burden in 23 developing countries in 2005 and will cost those countries $84 billion by 2015 if nothing is done to slow their growth (Nugent 2008). Compared with acute illnesses, effectively treating chronic conditions requires disease management and control over long periods of time, collaborative processes between providers and patient, and patient involvement, self-management, and empowerment.

30.2.1.3 Organization of the Delivery System

The health care delivery system in the United States is a highly complex system that is nonlinear, dynamic, and uncertain. The system is further complicated by a large number of agents who are multiple stakeholders, each with multiple, sometimes conflicting, goals, aspirations, and objectives. As a result, the entire system leads to a lack of accountability; it is as frequently misaligned reward as well as incentive structures, and it suffers from inefficiencies embedded in multiple layers of processes. The health care "product" or "service" is often ill defined or difficult to define and evaluate. The processes involved in delivering health care services are complex, ill specified, and difficult to measure, monitor, and control. Health outcomes are difficult to measure, manage, and analyze. The system experiences growing cost pressures, faces potential insurance premium increases, and is extremely fragmented. Wagner, Austin, and Von Korff (1996) identified five elements needed to improve patients' outcomes in a population increasingly afflicted by chronic conditions as follows:

- Evidence-based, planned care
- Reorganization of practices to meet the needs of patients who require more time and/or resources, and closer follow-up
- Systematic attention to patients' need for information and behavioral change
- Ready access to necessary clinical knowledge and expertise
- Supportive information systems

Regarding this last point, the Institute of Medicine (2001) pointed to the fact that

> Healthcare organizations are only beginning to apply information technology to manage and improve patient care. A great deal of medical information is stored on paper. Communication among clinicians and with patients does not generally make use of the Internet or other contemporary information technology. Hospitals and physician groups operate independently of one another, often providing care without the benefit of complete information on the patient's condition or medical history, services provided in other settings, or medications prescribed by other providers. (p. 30)

In the 10 years since that IOM reporting, progress has been made in applying information technology to manage and improve patient care, but widespread adoption across the industry has still not been achieved. Thus, fragmentation of patient information and gaps in care coordination across providers treating the same patient continue to be a significant problem.

30.2.1.4 Information Technology

The revolution in information technology holds great promise in a number of areas for consumers, patients, clinicians, and all organizations involved in the delivery of health care services. A report by the National Research Council of The National Academies (2000) identified six major information technology applications domains in health care: (1) consumer health, (2) clinical care, (3) administrative and financial transactions, (4) public health, (5) professional education, and (6) research. There have been notable technological advances in health care. For example, in the second edition of this handbook, it was noted that while some applications were currently in use (such as online searches for medical information by patients), many other applications were in early stages of development (such as telerobotic remote surgery). Since then, the world's first telerobotic remote surgery service was established (Anvari, McKinley, and Stein 2005), and surgical teleproctoring is an accepted technique for guiding remote general surgeons by a surgical subspecialist when patients are in need of an emergency subspecialty operation (Ereso et al. 2010).

Although the Internet (and intranets) has been a driving force for changes in the information technology landscape in the past decade, many health care applications are not web based. Applications such as administrative billing systems, EHRs, and computerized physician order entry (CPOE) systems frequently remain on legacy systems, and lack integration with other applications. The current generation of EHR and CPOE systems had begun to provide web access to these systems; this access is sometimes provided via third-party applications like Citrix, which introduce usability issues related to single-sign-on access and performance.

With respect to consumers/patients and providers, the Committee on the Quality of Health Care in America identified five key areas in which information technology could contribute to an improved delivery system (Institute of Medicine 2001):

- Access to medical knowledge base
- Computer-aided decision-support systems (DSSs)
- Collection and sharing of clinical information
- Reduction in medical errors
- Enhanced patient and clinician communication

The ensuing and ongoing infusion of information technology into the delivery of health care has yet to fully achieve success in these five key areas, despite the fact that it has been 10 years since they were first identified. One factor contributing to delays in adoption is poor usability of these systems and the disruption they cause to clinical workflows. Exacerbating this problem is a limited supply of IT personnel knowledgeable in both IT and clinical workflows and challenges who can help to identify and address these usability and workflow issues to avoid potential safety issues, improve efficiency of IT use, and ultimately increase technology acceptance by clinicians.

30.2.1.5 Consumerism

Consumerism in health care can be defined as an "orientation to new care delivery models that encourage and enable greater patient responsibility through the intelligent use of information technology" (Cohen et al. 2010, p. SP37). The Internet and other developments in information and communication technologies are contributing to greater consumerism with stronger demands from individuals for information and convenience. People are more demanding; they want timely and easy access to medical information, the latest in technology, and the latest in customer service. However, getting access to one's own health data in a format that is easy to understand is nearly impossible, even for those who have some knowledge about health matters, are well educated, and do not have physical, perceptual, or cognitive disabilities (Jacko 2011). Researchers and providers are beginning to recognize that patients need access to tools that can lead to empowerment and shared decision making regarding their own health care. In addition, because of increased fragmentation and specialization in medical care, patients need to take a more active role in managing their health and health care to ensure that the various providers involved in providing their care (i.e., primary-care physician, specialist, pharmacist, etc.) have the information they need to provide appropriate, quality care. Cohen et al. (2010, p. SP37) state that although consumerism holds promise, the following four principles should be followed to deliver improved outcomes and lower costs: "(1) keep the consumer at the center of innovation, (2) keep it simple, (3) link products and services to a broader 'ecosystem' of care, and (4) encourage health in addition to treating illness."

However, there are many technical, organizational, behavioral, and social challenges and barriers to an increased use of information technology by individuals in managing their own health/health care. These challenges not only include the design of optimal, effective, flexible human–computer interfaces but also issues of privacy/security of information, health literacy, and challenges associated with health information exchange (HIE). Those are discussed in Section 30.2.2.

30.2.2 Health Care Regulatory Environment in the United States

The health care industry has experienced unique legislative milestones (Kumar and Chandra 2001). Among them, three in particular have had far-reaching implications for the field of health informatics: (1) the Health Insurance Portability and Accountability Act (HIPAA); (2) health information and other business data security; and (3) The Health Information Technology for Economic and Clinical Health Act (HITECH Act). The HIPAA Act was passed and signed into law in 1996 and is designed to improve the portability of health insurance coverage in group and individual markets, limit health care fraud and abuse, and simplify the administration of health insurance. The act has serious, impending implications for health care providers and information managers. Of all its mandates, administrative simplification is perhaps the most critical for health care information managers, who are faced with everything from establishing standardized financial and clinical electronic data interchange (EDI) code sets to adopting, assigning, and using unique numerical identifiers for each health care provider, payer, patient, and employer. Both HIPAA and the growing role of the Internet-based technologies in delivering health care create an even greater and critical concern for data security and privacy.

The HITECH Act, enacted as part of the ARRA of 2009, provides an unprecedented investment in HIT to improve American health care delivery and patient care. The provisions of the HITECH Act are

> specifically designed to work together to provide the necessary assistance and technical support to providers, enable coordination and alignment within and among states, establish connectivity to the public health community in case of emergencies, and assure the workforce is properly trained and equipped to be meaningful users of EHRs. Combined, these programs build the foundation for every American to benefit from an EHR, as part of a modernized, interconnected, and vastly improved system of care delivery. (Office of the National Coordinator for Health Information Technology, 2011)

The interconnected programs that were funded by the HITECH Act are as follows:

- Beacon Community Program
- State HIE Cooperative Agreement Program
- HIE Challenge Grant Program
- HIT Extension Program
- Strategic Health IT Advanced Research Projects Program
- Community College Consortia to Educate HIT Professionals Program
- Curriculum Development Centers Program
- Program of Assistance for University-Based Training
- Competency Examination for Individuals Completing Non-Degree Training Program

Under the HITECH Act, privacy and security of personal health data (PHI) remain of paramount concern. Covered entities are required to report any breach of health information affecting 500 or more individuals to the Secretary of the Department of Health and Human Services (HHS) within 60 days of discovery. These breaches are posted on the HHS website for consumers to access. As of March 14, 2011, a total of 241 breaches have been listed since September 22, 2009 affecting a total of 8,225,193 individuals (United States Department of Health and Human Services 2011).

30.2.3 Meaningful Use of Electronic Health Records

The HITECH portion of ARRA specifically mandated that incentives should be given to Medicare and Medicaid providers, not for EHR adoption, but for "meaningful use" (MU) of EHRs. This distinction is important from the perspective of HCI because "meaningful use" is nearly impossible without highly usable technologies and systems. In July 2010, the U.S. Department of HHS released that program's final rule, thus defining stage 1 MU. Furthermore, that the proposed draft criteria for stages 2 and 3 of MU aggressively raise the requirements for EHR use to improve advanced care processes and health outcomes (United States Department of Health and Human Services 2011). The MU objectives and measures focus on five health outcome priorities: (1) improving quality, safety, efficiency, and reducing health disparities; (2) engaging patients and families in their own care; (3) improving care coordination; (4) improving population and public health; and (5) ensuring adequate privacy and security protections for personal health information.

Many of the criteria focus on clinician utilization of specific EHR functionality, thus HCI considerations that impact clinician acceptance and use of EHRs are critical to achieving the MU program goals. Also, the need for optimizing the interaction between patients/caregivers/families and (health) information technology is clear in the MU objectives and measures, particularly in the objectives and measures relating to engaging patients and families in their care. Notably, the evidence base and rationale provided for the proposed new MU objectives cite landmark studies and clinical trials (e.g., Gustafson et al. 1999; Mark et al. 2008; Ralston et al. 2007; Riggio et al. 2009; Rosenberg et al. 2008; Gustafson et al. 2001) that demonstrate the inherent value of providing patients and their families with highly usable tools and technologies that enable them to actively engage in their own health and health care.

30.2.3.1 Transaction Standards and Coding Sets

The U.S. Department of HHS has adopted national standards for electronic administrative and financial healthcare transactions. This is one of the most positive attributes of Title II of HIPAA, also known as administrative simplification, as it eliminates the conflicting transaction standards, coding sets, and identifiers used by the various players in the industry. Initial transaction and code sets were implemented in October 2002, with a revised code set standards defined and implemented by October 2003. The standards relating to enrollment, referrals, claims, payments, eligibility for a health plan, payment and remittance advice, premium payments, health-claim status, and referral certifications and authorizations. By developing national standards, it is anticipated that EDI of healthcare data will significantly reduce administrative costs. The Workgroup on Electronic Data Interchange (2000) estimated that EDI can reduce administrative costs by $26 billion per year by streamlining precertification, enrollment status, and reimbursement processes. Code Sets have also been defined in which variations are not permitted. Code Sets are based on the following standards:

International Classification of Diseases, Ninth Revision (ICP-9) Volumes 1 and 2—Diagnosis Coding
International Classification of Diseases, Ninth Revision (ICP-9) Volume 3—Inpatient Hospital Service Coding

International Classification of Diseases, Tenth Revision, Clinical Modification (ICD-10-CM) (To be implemented October 1, 2013)

International Classification of Diseases, Tenth Revision, Procedural Coding System (ICD-10-PCS) (It is a successor to Vol. 3 of ICD-9-CM as well as a clinical modification of the ICD-10) (To be implemented October 1, 2013)

Current Procedural Terminology (CPT 4; Fourth Edition, maintained by the American Medical Association [AMA].)—Physician Service Coding

Current Dental Terminology (CDT; it is a code set developed and maintained by the American Dental Association [ADA].) 2011/2012—Dental Service Coding

Healthcare Common Procedure Coding System (HCPCS; based on CPT. It is pronounced "hick picks.")—Other Health-Related Coding

DRG—Diagnosis Related Groups

NDC—National Drug Coding

HIPAA also establishes unique identifiers for health care providers, health plans and payers, employers, and eventually patients/individuals. Currently, the patient/individual identifier is pending as no consensus could be reached.

30.2.3.2 Privacy and Security

Administrative simplification also addresses patient privacy and security. Privacy standards exist for disclosure of patient identifiable information (including demographic data), training of healthcare workforce, individual's rights to see records, procedures for amending inaccuracies in medical records, maintenance of privacy when patient information is exchanged among business associates, designation of a privacy officer, procedures for complaints, sanctions for infractions, duty to mitigate, and document compliance. As a component of disclosure, covered entities (providers, payers, and clearinghouses) must make reasonable efforts not to use or disclose more than the minimum amount of protected patient information necessary to accomplish the intended purpose of the use of disclosure. Wide adoption and use of electronic medical record (EMR) systems will present technical challenges to preventing disclosure of this information. In the past, accessibility of paper-based patient records to clinicians was restricted in part by the chart's physical location (i.e., in medical records storage, on the nursing unit in a hospital). However, EMR makes these charts available to a much large number of clinicians in a wider range of physical locations, making it more difficult to prevent inappropriate uses of this protected information by authorized users of the EMR.

While the privacy rule of HIPAA pertains to all Protected health information (PHI), the security rule deals specifically with electronic protected health information. Security standards require establishment of administrative procedures (policies and procedures), physical safeguards (physical access to computers), technical security (individual and network computer access), and electronic signature (optional, but if used, it must be digital). Implementation requirements of the privacy and security standards have received a tremendous amount of debate. Although most feel the intent of the standards is good, the cost implications have left many advocating for a longer implementation period. The Department of HHS previously estimated the total cost to implement Subtitle II to be approximately \$17–\$18 billion over the next 10 years. The Mayo Clinic collected startup cost data for HIPAA implementation prospectively from January 1, 2001, through April 14, 2003. Their costs included direct (policy revisions) and indirect costs, training, forms revision and printing, privacy curriculum, workforce training, privacy expenses and IT costs, totaling \$4,663,672 (Williams et al. 2008).

In addition to the cost of implementation, the privacy and security requirements present usability challenges as well, for example, security steps required for patient access to a patient portal can be time-consuming and cause some patients not to register and use these online tools. Additionally, striking the right balance between protecting patient information but ensuring that clinicians can access it in emergency medical situations continues to be debated in both large provider organization and state and community HIEs. Requirements for auditing access to PHI also have significant IT system performance implications, and those performance issues can translate to user dissatisfaction. Thus, more attention to usability issues related to privacy and security requirements is needed.

30.3 HEALTH INFORMATICS

As defined earlier, health informatics comprises the generation, development, application, and testing of information and communication principles, techniques, theories, and technologies to improve the delivery of health care with a focus on the patient/consumer, the provider, and, more importantly, the patient–provider interaction. Although a number of systems using a number of platforms and technologies have already been developed and are currently being developed, the field itself is still in its infancy. In addition, current systems have been designed to fit within the existing health care delivery system and thus are only marginally or superficially impacting the way health care is being delivered. The true potential of health informatics is yet to be experienced and will radically transform the way health care is being delivered and managed in the future. Sections 30.3.1–30.3.6.3 provide background information on current health care applications with an emphasis on two types of users: (1) the consumer/patient and (2) the clinician/provider.

30.3.1 Informatics from a Consumer-Centered Perspective

Consumer health information has been defined as "any information that enables individuals to understand their health and make health-related decisions for themselves or their families" (Harris 1995, p. 210). Patrick and Koss (1995) listed a variety of organizations and entities that produce and/or disseminate consumer health information including health-related organizations (involved in provision of, or payment for, health care services and supporting services), libraries, health voluntary organizations (i.e., American Heart Association, American Cancer, American Lung, etc., and 60,001 other health interest societies), broadcast and print media, employers, government agencies, community-based organizations (i.e., churches, YMCA, agencies for the elderly), networked computer health information providers—"virtual" communities. Methods of dissemination are diverse and include informal channels, printed text, broadcast electronic media, dial-up services (telephone), nonnetworked computer-based information (i.e., CD-ROM, Kiosk technology), and networked interactive computer-based information.

The field of Consumer Health Informatics (CHI) is focused on supporting the consumer needs for health information. The goal of CHI is to develop web-based applications for consumers to be able to efficiently obtain and understand information found online. CHI also analyzes individual needs for health information, accessibility of information, and the integration of consumer preferences into online applications (Eysenbach et al. 2005). CHI applications range from smoking cessation to asthma/COPD websites. Select CHI applications have been found to successfully engage consumers, enrich traditional clinical interventions, and improve health outcomes (Gibbons et al. 2009).

Harris (1995) discussed a number of problems with health information including how to interpret conflicting or differing information; how to judge reliability; how to choose among many alternatives; and how to deal with the vast quantities of information, much of which is superficial or even inaccurate. Over 80% of Americans have searched for health information online, yet only 15% of those say they "always" check the source and date of the information they find (Fox 2006). This indicates that the majority of information seekers online are not paying attention to quality indicators that are available.

30.3.2 Interactive Health Communication

Historically, print and broadcast dissemination of health information has led to a number of problems such as the timing relative to need, single directionality (difficulty of following up, clarifying, and understanding), timeliness and relevance vis-à-vis updates, and uniqueness to individuals (Patrick and Koss 1995). As early as 1995, Harris asserted that electronic sources of health information had the potential to be more timely and complete as other media and could become more accessible to all citizens. Consequently, the use of interactive health communication or CHI has emerged as a dominant theme.

Web 2.0 applications are becoming increasingly popular for clinicians, students, and health care consumers. Hughes et al. (2009) found that despite concerns over validity of information, over half of the physicians they followed utilized Web 2.0 applications. Wikis, blogs, and podcasts are most popular because of their ease of use, collaboration, and rapid deployment of information sharing (Boulos, Maramba, and Wheeler 2006). Unfortunately, wikis can be edited by anyone, which means that the information provided to the consumer is not always reliable and accuracy is difficult to assess. Blogs and podcasts are created by individuals, and therefore somewhat easier to gauge for accuracy depending on the source. The Cleveland Clinic, and any other health systems, has libraries of reliable health and wellness videos available as vodcasts, or video podcasts (e.g., http://my.clevelandclinic.org/health_edge/vodcasts.aspx). Topics range from tips on how to change your diet to the difference between a cold and sinusitis. Although some initial applications of Web 2.0 technology are promising, more research is needed to ensure security and reliability of information for health care consumers.

30.3.3 Consumer/Patient Web-Based Applications and e-Health

An estimated 122 million Americans seek health information online (Tu and Cohen 2008). In 1999, the Benton Foundation (1999) estimated there were 10,000 or more health-related websites. However, this number has grown tremendously to meet increasing consumer demand for health care information. In early 2011, the Google directory of health-related websites (http://www.google.com/Top/Health/) listed over 19,000 websites related to diseases and conditions alone and thousands of other sites addressing topics ranging from pharmacy to alternative medicine to public health. This variety of information available demonstrates that consumers and patients desire a range of information and services including getting disease treatment information, obtaining report cards on physicians or hospitals, exchanging information with other patients, interacting online with their physicians, and managing their own health benefits. The sheer volume of information on the Internet exceeds most expectations yet raises problems: efficient search for information, information retrieval, information visualization, human-information processing, understanding, and assimilation. Authors of Internet information need to determine how to best structure the information for use by others. E-Health can be described as the transition of health care processes and transactions into the Internet-delivered electronic superhighway. Potential problems exist that are specific to patients seeking electronic health-related information (Sonnenberg 1997), including the lack of editorial control of information, conflict of interest for website sponsors, and unfiltered information presenting an unbalanced view of medical issues. However, referring primarily to self-help groups, Ferguson (1997) believed that the problem of obtaining bad medical information online is not very different from obtaining bad medical information at cocktail parties, in the tabloids, in magazine ads, and so on. In addition to the content of information, there are technological problems that may affect both access and use of health information on the Internet: slow modems, poor institutional Internet connections, firewalls that interfere with Internet traffic, malfunctioning message routers, and heavy Internet usage in the immediate geographic area (Lindberg and Humphreys 1998). Most current concerns about interactive health communication center on the fact that these applications have the potential to both improve health and to cause harm; thus, highlighting the need to ensure their accuracy, quality, safety, and effectiveness (Robinson et al. 1998).

30.3.4 Personal Health Records

The personal health record (PHR) is an example of an interactive technology that is designed for consumer engagement. The U.S. health care system can be fragmented and often creates passive patients with high-cost dependency on the health care system. The use of PHRs can change this by transforming the consumer's role while improving the delivery of health care and also facilitating research. The Center for Information Technology Leadership (CITL), a nonprofit research center, released findings on the value of PHRs, concluding that PHRs could save $19 billion annually on a national level by focusing on prevention, early intervention, self-management, and evidence-based care (Kaelber et al. 2008). CITL reported that PHRs, web-based systems that allow patients to populate and maintain their medical data, continuity of care documents, prescription medication lists, health histories, hospital discharge summaries, can also enable consumers to elect to share their information with third parties to facilitate wellness. PHRs empower patients to use their data to better manage their health care and health care costs. The nonprofit Partners Center for Connected Health released a report concluding that EMRs will not reform health care without consumer engagement, stating: "True health care reform will require a more patient-centered approach and a broader policy palette, including incentives for providers to adopt more population health management tools and for patients and consumers to take more ownership of their health" (Kvedar 2008). The goal is for PHRs to serve as integrated tools for health management (Masterson 2008). Some health care organizations have begun offering PHRs to their patients at no cost. Through the PHR, patients are provided access to a portal that enables, for example, viewing and archiving laboratory results, scheduling appointments, and securely messaging their physicians.

30.3.5 Health Informatics from a Provider-Centered Perspective

Providers and health care provider organizations have long used health-information systems to support both administrative and clinical functions of health care delivery and management. However, despite the fact that health care is one of the most information-intensive industries; it has very few state-of-the-art information management systems. Health care is fragmented, with hundreds of thousands of payers, hospitals, physicians, laboratories, medical centers, pharmacies, and clinics, each with its own legacy of systems, hardware, software, and platforms. EDI and connectivity issues have become critical. Numerous information systems have been developed and implemented, the most noteworthy being integrated EMRs/EHRs and CPOE systems. The following is a discussion of some important clinical applications.

30.3.5.1 Electronic Medical Records

EMRs are increasingly being adopted in both primary-care and inpatient-care environments. EMRs provide functions to document all clinical processes and patient-related information relevant to the delivery of patient care. EMRs are advocated and used to improve the quality, accessibility, and timeliness of patient medical information. However, because EMRs replace traditional patient charts, they affect a wide range of clinical users and clinical processes. As such, they face a number of barriers to adoption, including cost, a lack of tested systems, problems with data entry, inexperienced vendors, confidentiality concerns, and security concerns (Wager et al. 2000). In a systematic literature review of articles published between 1998 and 2009, eight categories of barriers to EMR adoption were identified. Those categories are: (A) Financial, (B) Technical, (C) Time, (D) Psychological, (E) Social, (F) Legal, (G) Organizational, and (H) Change Process (Boonstra and Broekhuis 2010). Understanding barriers to implementation and successful interventions should allow an increasing number of organizations to implement EMRs.

In addition, EMRs may have barriers that are specifically related to the practice of medicine. For example, physician use of an EMR while with patients could affect patient perceptions of quality of care or quality of physician–patient interactions. Although some past studies examining this issue have not shown this to be the case (i.e., Legler and Oates 1993), a survey of pediatric-care primary physicians using EMR indicated that they felt it reduced eye contact with patients and increased the duration of patient visits (Adams, Mann, and Baushner 2003). Thus, the impact of these technologies on physician-patient interactions is not clear at this point.

A key factor that will contribute to whether EMR systems become more rapidly adopted in primary-care practices is whether or not physicians themselves perceive the systems as improving quality (of the medical records, patient care, and overall performance). Anderson and Balas (2006) surveyed U.S. primary-care physicians and found that nearly 75% indicated that HIT could reduce errors; 70% felt HIT could increase their productivity; over 60% indicated that HIT could potentially reduce costs and help patients assume more responsibility.

Another study examined this issue using qualitative methods in five community-based practices that had used EMR for at least 2 years and did not use a duplicate record system (Wager et al. 2000). Results indicated that many physicians and staff members perceived benefits, such as increased access, an ability to search the system, and improved overall quality of medical records. However, there were several disadvantages mentioned, including the frequency of downtime and the time necessary to develop customized templates. A more recent survey found additional concerns such as physician over-reliance on potentially inaccurate information, nurses focusing more on EMR use protocol than reviewing order accuracy, neglected orders in the system, and physicians ignoring alerts because they were used to false alarms (Holden 2010).

In a study examining the quality of worklife of family physicians, Karsh et al. (2001) collected quantitative data about EMR to compare perceptions of medical records between physicians using EMR and those not using EMR. Specifically, they assessed whether or not the use of EMR was related to perceptions of improved quality of medical records. The results showed that physicians who used EMR perceived their medical records to be more up to date and accessible. Physicians who used EMR were also more satisfied with the overall quality of their medical records systems. However, there were no differences in perceptions of whether medical records could be modified to meet individual needs. This suggests that EMR can have positive impacts on medical records. (It is possible, though, that the positive responses were caused not by positive traits of the EMR, but rather because of cognitive dissonance.)

The results of Karsh et al. (2001) study supported those of qualitative studies of physicians who use EMR. Wager et al. (2000) found that physicians in primary practice who had used EMR for at least 2 years believed EMR to have many benefits over paper-based systems, including increased access and availability of patient information to multiple users, the ability to search the system, improved overall quality of patient records, improved quality of documentation, increased efficiency, facilitated cross-training, and improved communication within the practice. Thus, it is clear that EMR has the potential to improve the quality of patient records and therefore, possibly, the quality of care. However, to fully capitalize on such systems, they need to be designed to maximize usability, connectivity, and portability while guaranteeing privacy and security.

30.3.5.2 Electronic Health Records

Although the terms EMR and EHR are often used interchangeably in the market and by government officials, they are not equivalent terms. The National Health Alliance for Information Technology (2008) penned the following definitions to describe the differences: "EMR: An electronic record of health-related information on an individual that can be created, gathered, managed, and consulted by authorized clinicians and staff within one health care organization. EHR: An electronic record of health-related information on an individual that conforms to nationally recognized interoperability standards and that can be created, managed, and consulted by authorized clinicians and staff across more than one health care organization."

EHRs are currently in their infancy because they are dependent on the ability to exchange health information through a Regional Health Information Organization, state or community HIE or through the proposed National Health Information Network. The ability for EHRs to be implemented and integrated across communities or regions will be reliant on the establishment of clinical information transaction standards for EMR. The investment in HITECH, for example, the Beacon Program, gets us closer to achieving this goal.

Underlying all of this is the ability and willingness of providers to actually use the system. Edwards et al. (2008) evaluated a pediatric EHR system using a predictive evaluation method prior to EHR implementation at a major pediatric health system in the Southeastern United States. The method resulted in many system improvements and enabled avoiding usability problems at time of system rollout. This case study demonstrated both the need to conduct usability evaluations for large commercial software implementations and the utility of using heuristic walkthrough as a tool for accomplishing this.

30.3.6 Health Information Exchange

An HIE is used to "electronically capture and distribute administrative and clinical information between health care stakeholders while maintaining the meaning of the information exchanged via a common language" (Krohn 2008, p. 7). With the incentives and funding provided in the ARRA act to promote HIE adoption and use, implementing HIEs is receiving increased attention. Some of the benefits that can be achieved through HIE include the following:

- Improved care coordination at transitions in care
- Improved patient safety
- Improved communication among providers caring for the same patient
- Increased hospital and ambulatory provider efficiency and reducing administrative costs
- Improved care quality
- More effective use of health care resources (e.g., reducing duplicate laboratory tests)
- Improved population health

However, early HIEs have struggled due to a number of challenges. These challenges include financial sustainability, physician adoption, privacy/security concerns, data sharing policies, lack of technical standards, and workflow challenges. The e-Health Initiative has identified 234 active HIEs in the United States, 199 of which responded to the annual 2010 Survey of HIE. The majority of respondents reported a reduction in staff time and redundant testing, and increases in functionality with respect to the MU rules (e-Health Initiative 2010). In addition, 44 of these initiatives now allow patients to view their health data, which is up from 3 in 2009.

Current HIEs are working through these challenges, but clear best practices have yet to emerge. With HIEs, achieving the benefits is directly related to the degree of adoption and data sharing across the community, so HCI methods need to be applied to maximize the use and, consequently, benefit of HIEs.

30.3.6.1 Computerized Physician Order Entry Systems

CPOE systems have substantial potential for improving the medication ordering process because they enable physicians to write orders directly online. They have the potential to ensure complete, unambiguous, and legible orders; they assist physicians at the time of ordering by suggesting appropriate doses and frequencies, by displaying relevant data to assist in prescription decisions, by checking drugs prescribed for allergies, and drug–drug interactions. As such, those systems are believed to potentially reduce the incidence of medical errors in general, and medication errors in particular. Research has demonstrated that CPOE systems can reduce medication errors (Bates et al. 1999; Kuperman et al. 2007; Kadmon et al. 2009). In addition, the use of CPOE can decrease turn-around time for medication orders as well as radiation and laboratory orders (Mekhjiane et al. 2002) and improve adherence to clinical guidelines (Overhage et al. 1997). A survey of ambulatory care providers assessed attitudes toward CPOE and e-prescribing systems and found that the majority of such providers reported improved quality of care and efficiency, prevention of medical errors, and increased patient satisfaction as advantages to the system. Despite this, only 47% of providers reported satisfaction with the system. Providers expressed dissatisfaction with alert fatigue, and alerts inappropriately identifying drug interactions (Weingart et al. 2009).

Despite the demonstrated advantages, in 2007 only an estimated 12.0% of hospitals were using CPOE with decision support, and less than a quarter were using bar-code medication administration (Pedersen and Gumpper 2008). One may conclude that CPOE systems are not a panacea. In some cases, their use has resulted in negative outcomes, including increased physician order entry time (Bates, Boyle, and Teich 1994; Shu et al. 2001) and an increased coordination load on clinical care teams (Cheng et al. 2003). Physicians have also reported that CPOE adds additional burden on the physician because it requires many clicks and screen navigations instead of simply writing an order (Holden 2010).

For computerized physician-order entry systems to be fully successful, physicians need to use them. However, as the studies previously discussed indicate the gains achieved come at a cost, frequently imposed on the physicians using the system. This leads to issues of HCI design, usability, and integration within the care delivery processes to ensure that the burden on these users is minimized. The importance of addressing these issues has also been highlighted in several recent studies showing that the potential for new types of prescribing errors can be created by usability problems in the interface and/or lack of integration of the system with clinical work practices (Koppel et al. 2005). In certain care situations, such as critical-care environments, this lack of integration between the clinical processes and patient care needs (i.e., urgency of care) can have dire consequences for patients (Han et al. 2005). This emphasizes the importance of identifying and resolving potential usability problems prior to implementation, continually monitoring their use, and incrementally improving their usability in the context of the needs of specific clinical care environments.

30.3.6.2 Patient Monitoring Systems

Gardner and Shabot (2001) defined patient monitoring as “repeated or continuous observations or measurement of the patient, his or her physiological function, and the function of life support equipment, for the purpose of guiding management decisions” (p. 444). Electronic patient monitors are used to collect, display, store, and interpret physiological data. Increasingly, such data are collected using newly developed sensors from patients in all care settings and in patients’ own homes. Although such data can be extremely useful for diagnosis, monitoring, alerts, as well as treatment suggestions, the amount, diversity, and complexity of data collected presents challenges to HCI design. Although advancements have been made in telemonitoring, conclusions from research studies vary immensely. A recent Cochrane review article found that telemonitoring of heart failure patients reduced the rate of death by 44% and the rate of hospitalizations related to heart failure by 21% (Inglis et al. 2010). In a larger study, Chaudry et al. (2010) found that telemonitoring for heart failure patients did not improve outcomes and stress the importance of a comprehensive, independent evaluation of disease management strategies prior to adoption.

30.3.6.3 Imaging Systems

Imaging is a central element of the health care process for diagnosis, treatment plan design, image-guided treatment, and treatment-response evaluation. Greenes and Brinkley (2001) noted that the proliferation in number and kind of images generated in health care led to the creation of a subdiscipline of medical informatics called “imaging informatics.” In their review and summary of the field, Greenes and Brinkley noted that

> as processing power and storage have become less expensive, newer, computationally intensive capabilities have been widely adopted. Widespread access to images and reports will be demanded throughout health care delivery networks.... We will see significant growth in image-guided surgery and advances in image-guided minimally invasive therapy as imaging is integrated in real time with the treatment process. Telesurgery will be feasible. (pp. 534–536)

They also highlight that such ambitious evolution of imaging systems will be in part dependent on continued advances in user interfaces and software functionality.

Picture archiving and communication system (PACS) has revolutionized the practice of radiology over the last 15 years (Huang 2010). These complex systems require knowledgeable radiologists as end-users and a team of HIT professionals to keep the systems running. Large quantities of data pass through any PACS (over 50 GB per day), while radiologists and clinicians demand constant access to the images (Branstetter 2007).

30.4 CLINICAL AND PATIENT DECISION-SUPPORT SYSTEMS

DSS are computer systems used to support complex-decision making. The goal of DSS is to improve the efficiency and/or effectiveness of decision-making processes (Shim et al. 2002). As such, many of the complex-decision processes in health care can benefit from the use of DSS. One class of DSS in health care is clinical decision-support systems (CDSS), which provided decision support to clinical users during the process of providing patient care. Another class of DSS, patient decision-support systems (patient DSS), is designed to educate and support patients as they make decisions that affect their health care. Described here are two types of health care-related DSS.

Musen, Shahar, and Shortliffe (2006) defined a CDSS as "any computer program designed to help health professionals make clinical decisions" (pp. 707–708). They characterized CDSS on five dimensions as follows:

1. System function
2. Mode for giving advice
3. Style of communication
4. Underlying decision-making process
5. HCI

A large number of applications already exists and can be further developed. The opportunities are almost unlimited. Bates et al. (2001) proposed that appropriate increases in the use of information technology in health care, especially the introduction of CDSS and better linkages in and among systems, could result in substantial reduction in medical errors. For example, studies have demonstrated that implementation of CPOE systems that include CDSS functions (i.e., drug interaction checking, allergy checking, etc.) have reduced medication errors and adverse drug events in both general-care settings (e.g., Bates et al. 1999) and pediatric-care settings (i.e., Potts et al. 2004; Cordero et al. 2004).

However, as noted by Musen, Shahar, Shortliffe (2006), "systems can fail … if they require that a practitioner interrupt the normal pattern of patient care" (p. 712). Clinicians often have to perform a manual intervention due to data mismatch, a common issue within the DSS community (Acosta et al. 2010). Thus, new technologies (mobile devices, wireless networks, and distance-communication technologies) and novel HCIs (based on speech, gestures, and virtual reality) offer huge potential to maximize usability and permit seamless integration of CDSS within complex, dynamic work processes.

A roadmap for national action on clinical decision support (CDS) was created in 2005 by the American Medical Informatics Association with assistance from the Office of the National Coordinator and the Agency for Health care Research and Quality. The three pillars for realizing the potential of CDS were identified as: (1) best knowledge available when needed; (2) high adoption and effective use; and (3) continuous improvement of knowledge and CDS methods (Osheroff et al. 2007; Lyman et al. 2010). Great progress has been made toward these goals over the past several years. More health care organizations are utilizing HIT and CDS to improve the quality of patient care. Research articles highlight HIT success with alerting and reminder systems, dosing calculators, and order sets. As many of the strategic objectives of the 2005 roadmap have been met, it is important to redefine the goals and objectives to continue making progress in CDS.

The medical industry has increasingly acknowledged the need to enable patients to participate in making health-related decisions. To effectively participate in decision making, most patients need to become better informed about the options available and need help assimilating that information to apply it to the decision at hand. These health-related decisions range from choosing a health-insurance plan to working with their doctor to select a treatment for cancer.

Patient DSS are one of several types of decision aids used to help patients participate in health-related decisions. Decision aids are interventions provided to assist individuals as they make a deliberative choice between two or more alternatives (Bekker, Hewison, and Thornton 2003). Patient DSS supports a patient in one or more stages of making a health-related decision. Much of the past and current patient DSS research and development efforts have targeted patients with life-threatening or chronic diseases. Most have focused on supporting decisions regarding treatment options (i.e. medical or surgical therapies), although a few have examined early detection and other issues (O'Connor 1999). Patient DSS that support patients faced with treatment decisions provide one or more of the following functions that facilitate patient participation in decision making (O'Connor 1999; Scott and Lenert 1998):

Educate the patient. Provide the patient with information about the treatment alternatives and outcomes, especially highlighting risks and benefits associated with each treatment alternative.

Tailor information. Tailor information content and/or presentation based on patient characteristics such as their health and demographics factors.

Assess preferences. Use preference-elicitation methods to assess the patient's values/preferences for the possible intervention outcomes.

Optimize decision. Optimize the decision outcome based on context, heuristics, probabilities of outcomes, and algorithms.

Reviews of patient decision aids including patient DSS (i.e., Molenaar et al. 2002; O'Connor 1999; O'Connor et al. 1999; O'Connor et al. 2003) have revealed that "decision-support strategies have received generally consistent positive ratings by patients in terms of feasibility, acceptability, length, balance, clarity, amount of information, and usefulness in decision making" (O'Connor 1999, p. 260). Additionally, they demonstrate a number of benefits for patients, including improved decision-relevant knowledge, reduced decisional conflict, improved congruence between values and choice, more realistic expectations, more active patient participation, and fewer patients who are unable to make a decision. Bekker, Hewison, and Thornton (2003) proposed that many observed benefits are a result of decision aids enabling patients to use more effective cognitive and emotional strategies. Note that the reviews do not indicate a consistent, significant effect of decision aids on decision satisfaction, although a generally positive impact on satisfaction with the decision process is indicated. Use of decision aids tends to reduce the number of patients who take a passive role in decision making and the number who are undecided (O'Connor et al. 2003).

Patient comprehension of medical terminology is an issue for patient DSS. Patient vocabularies and knowledge of medical terminology have been demonstrated to affect comprehension (Keselman et al. 2007). To improve patient understanding, research is now being conducted to assist patients in understanding clinical information such as laboratory reports and discharge summaries. Successful techniques have included using prototype translators (Zeng-Treitler et al. 2007) and supplementing online discharge summaries with automatically generated hyperlinks and embedded readability support (Adnan, Warren, and Orr 2009; Adnan et al. 2010). As patient DSS continue to advance, it is important to ensure that the information the patients are accessing is comprehensible.

In addition to being used to support patients faced with treatment choices, similar support systems can be used to help healthy individuals make health-related choices. For example, DSS can support health care consumers as they make the important choice of choosing health insurance. Considerable effort has been made to educate consumers about health insurance. One system available for learning about health insurance plans is the health plan report card created by the NCQA (The National Committee for Quality Assurance, 2011). The report card is, in effect, an interactive decision-support tool that helps consumers compare and select a health plan. The report card provides information on a variety of attributes for each plan and enables consumers to identify plans that meet their specifications. This system provides access to plan quality information and uses an easily comparable matrix format and a "star" rating system to simplify comparisons of plans. Despite the increasing availability of information on health plans, many consumers still find the information confusing and the decision difficult. By presenting health-plan information in a way that supports and, perhaps, adapts to a consumer's characteristics and their health-plan preferences, we may improve the usability of the information and enable consumers to make more informed decisions about their health insurance coverage.

30.4.1 Patient Preferences

Patients' preferences and priorities regarding their health and health care are applied each time they participate in making health-related choices. However, an individual's stated preferences can be influenced by external factors. For example, researchers have found that framing of information about treatments is handled (positive, negative, or neutral) has affected patients' treatment preferences (Llewellyn-Thomas, McGreal, and Thiel 1995). It is likely that these tendencies for external factors to influence individual preferences will hold for a variety of health-related choices. Therefore, presenting decision makers with information previously not considered in their decision may cause them to change their preference structure. Slovic (1995) viewed "preference construction as an active process" (p. 369). Taking this view, it is important for patient DSS designers to take a patient-(user) centered approach to the design of these systems to ensure that patient decision outcomes are improved and to avoid introducing systematic biases into the decision process. By structuring the education and decision process to help the patient develop a comprehensive picture of relevant facets of the decision, we can help the patient develop a more comprehensive, rational set of preferences to apply to his or her health choices. In this way, DSS can help patients/health care consumers make more informed decisions.

30.4.2 Human–Computer Interaction Challenges in Patient Decision-Support Systems

The heterogeneity of patient/health care consumer population presents a number of challenges to patient DSS designers. Patients/consumers vary greatly in age, physical ability, mental ability, computer experience, health care/health condition knowledge, and, as discussed previously, decision-related preferences. They also use different decision strategies when faced with a multiattribute decision tasks such as many of those faced in health care. These decision strategies influence what information the patient (decision maker) wants to see and how he or she views that information. Decision makers frequently use either compensatory or noncompensatory strategies to evaluate alternatives and make a decision. Compensatory strategies are those in which the information about every alternative is weighed and compared (Johnson 1990). Comparatively, in noncompensatory strategies, alternatives may be eliminated after an incomplete search, thereby reducing the cognitive load of the decision task (Johnson 1990). Selection of a decision strategy is related to a number of factors, including age (Johnson 1990) and personality type. In addition to the characteristics of the individual, selection of a decision strategy is also influenced by decision-task characteristics such as the complexity of the decision (Payne 1976) and the type of decision aids available (Todd and Benbasat 2001).

Because of the differing information and decision-support needs of various user populations, designing effective decision support for a broad range of patients/health care consumers is challenging. Therefore, it is imperative that patient DSS designers model the needs of their target user population and design systems to meet those needs. For example, certain patient populations may suffer from limited physical or cognitive abilities, making it vital to create accessible designs that meet their special needs.

30.5 EVALUATING COMPUTERIZED HEALTH CARE APPLICATIONS

Although there has been a proliferation of web-based health care, applications available for consumers and patients, the issue of evaluating applications and guiding users in choosing the best applications has become extremely important. Although evaluation is obviously also important for applications targeted at health care professionals, the issue is not as critical because health care professionals are experts and can exercise their own judgment in the suitability and quality of applications designed to assist them in their work. However, consumers and patients have no or limited basis for exercising such judgment.

Concerned that the growth of the Internet was leading to too much health information with vast chunks of it incomplete, misleading, or inaccurate, Silberg, Lundberg, and Musacchio (1997) proposed the following four standards for websites:

1. Authorship: Authors and contributors, their affiliations, and relevant credentials should be provided.
2. Attribution: References and sources for all content should be listed clearly, and all relevant copyright information noted.
3. Disclosure: Website "ownership" should be prominently and fully disclosed, as should any sponsorship, advertising, underwriting, commercial funding arrangements or support, or potential conflicts of interest. This includes arrangements in which links to other sites are posted because of financial considerations. Similar standards should hold in discussion forums.
4. Currency: dates that content was posted and updated should be indicated.

Murray and Rizzolo (1997) pointed out that

> somehow, just the fact that information is traveling quickly through space and being presented on the computer screen lends it an air of authority which may be beyond its due. Sites with official-sounding names can dupe the inexperienced or uncritical into unquestioned acceptance of the content.

In addition to the standards identified by Silberg, Lundberg, and Musacchio (1997), Murray and Rizzolo (1997), others have cited other criteria for evaluating websites. These include the authority of the author/creator, the accuracy of information and comparability with related sources, the workability (user friendliness, connectivity, search access), the purpose of the resource and the nature of the intended users, whether criteria for information inclusion are stated, the scope and comprehensiveness of the materials, and the uniqueness of the resource.

Jadad and Gagliardi (1998) identified a number of instruments used to provide external ratings of websites. These ratings are used to produce awards or quality ratings, provide seals of approval, identify sites that are featured as the "best of the web" or "best" in a given category, and/or to declare sites as meeting quality standards. They attempted to determine what criteria were used to establish these ratings and to establish the degree of validation of these rating instruments. However, few organizations listed the criteria behind their ratings and none provided information on interobserver validity or construct validity. Jadad and Gagliardi (1998) also discussed the following:

- Whether it is desirable to evaluate information on the Internet due to concerns over freedom of expression, excessive regulatory control, and so on.
- Whether it is possible to evaluate information on the Internet due to the lack of a gold standard for quality information and the controversy surrounding its definition.

The authors also pointed out the differences between Internet information and that of a peer-reviewed journal. These differences include who is exchanging the information (i.e., vendors, healthcare professionals, consumers, insurance companies), the type of format content is delivered in (i.e., Adobe Flash, Javascript, text, sound/video files), and the type of browser and version being used to view the information. They also note that website content is rapidly modified and often linked in a complex web of Internet sites. The complexity of the relationships and links between websites often makes it unclear to the end user that they have left one website for another. They concluded that with respect to external independent evaluation of sites it is not clear:

- Whether evaluation instruments should exist in the first place
- Whether they measure what they claim to measure
- Whether they lead to more good than harm
- Whether users may ever notice, or if they notice, whether they will ignore evidence in support or against desirability, feasibility, or benefits of formal evaluations of health information on the Internet

Robinson et al. (1998) focused more on internal evaluation of applications such as self-evaluation by the sponsors or developers of interactive health communication applications. They pointed out a number of barriers to evaluating these applications. These include the fact that the media and infrastructure underlying applications is in a dynamic state; applications themselves change frequently; many applications are used in situations where a variety of influences on health outcomes exist, few of which are subject to easy assessment or experimental controls; developers lack familiarity with evaluation methods and tools; and developers often believe that evaluation will delay development, increase front-end costs, and have limited impact on sales.

Patrick and Koss (1995) suggested that the effectiveness of consumer health information should be measured by how rapidly and completely desired messages are communicated and how completely intended changes in behavior occur. Saying that Silberg et al.'s criteria (explicit authorship and sponsorship, attribution of sources, and dating of materials) are not enough, Wyatt (1997) provided far more specific direction for evaluating websites. He believes that evaluation of websites should go beyond mere accountability to assess the quality of their content, functions, and likely impact. Evaluating the content should include the following:

- Determining the accuracy of web material by comparing it with the best evidence, that is, for effectiveness of treatment—randomized trials, for risk factors, cohort studies, or for diagnostic accuracy—blinded comparisons of test with a standard.
- Determining timeliness by checking the date on web pages but recognizing that material may not have been current at that time, so need independent comparison with most up-to-date facts is preferable.
- Determining if people can read and understand web material, asking visitors to record satisfaction is unlikely to reveal problems with comprehension since visitors may not realize they misunderstood something or may blame themselves. So, need a minimum reading age for material for the public. However, more accurate to ask users questions based on the web content.

Evaluating the functions of websites should include determining how easy it is to locate a site, how easy it is to locate material within the site, and whether the site is actually used and by whom. For those investing resources in a website, with respect to evaluating the impact, he suggests looking at the impact on clinical processes, patient outcomes, and its cost effectiveness compared with other methods of delivering the same information. He recommended using randomized control trials as the most appropriate method for determining impact. Finally, with respect to evaluation methodology, he pointed out the importance of choosing appropriate subjects (not technology enthusiasts) and the need to make reliable and valid measurements. Wyatt (1997) believed that

> Ideally, investigators would have access to a library of previously validated measurement methods, such as those used for quality of life. However, few methods are available for testing the effect of information resources on doctors and patients, so investigators must usually develop their own and conduct studies to explore their validity and reliability. (p. 1880)

The Science Panel on Interactive Communication and Health (SciPICH) was convened by the Office of Disease Prevention and Health Promotion of the U.S. Department of HHS to examine interactive health-communication technology and its potential impact on the health of the public. The panel was comprised of 14 experts from a variety of disciplines related to interactive technologies and health, including medicine, HCI, public health, communication sciences, educational technology, and health promotion. One of the products of the SciPICH products is an evaluation reporting template (Robinson et al. 1998) for developers and evaluators of interactive health-communication applications to help them report evaluation results to those who are considering purchasing or using their applications. The template has four main sections: (1) description of the application, (2) formative and process evaluation, (3) outcome evaluation, and (4) background of evaluators. The panel defined the three different types of evaluation as follows:

1. Formative evaluation. Used to assess the nature of the problem and the needs of the target audience with a focus on informing and improving program design before implementation. This is conducted prior to or during early application development, and commonly consists of literature reviews, reviews of existing applications, and interviews or focus groups of "experts" or members of the target audience.
2. Process evaluation. Used to monitor the administrative, organizational, or other operational characteristics of an intervention. This helps developers successfully translate the design into a functional application and is performed during application development. This commonly includes testing the application for functionality and may be known as alpha and beta testing.
3. Outcome evaluation. Used to examine an intervention's ability to achieve its intended results under ideal conditions (i.e., efficacy) or under real-world circumstances (i.e., effectiveness), and its ability to produce benefits in relation to its costs (i.e., efficiency or cost effectiveness). This helps developers learn whether the application is successful at achieving its goals and objectives and is performed after the implementation of the application.

Evaluating the effectiveness of web-based applications designed to relay information and/or enable informed decision making is complicated because the "success" of these particular types of applications is (1) not necessarily always related to observable behaviors; (2) based on the quality and usability of the information within the application; and (3) a function of the application itself and the users. In terms of outcome-evaluation applications, Robinson et al. (1998) gave the following examples of the types of questions that such evaluation should address:

1. How much do users like the application?
2. How helpful/useful do users find the application?
3. Do users increase their knowledge?
4. Do users change their beliefs or attitudes (i.e., self-efficacy, perceived importance, intentions to change behavior, and satisfaction)?
5. Do users change their behaviors (i.e., risk factor behaviors, interpersonal interactions, compliance, and use of resources)?
6. Are there changes in morbidity or mortality (i.e., symptoms, missed days of school/work, physiologic indicators)?
7. Are there effects on cost/resource utilization (i.e., cost-effectiveness analysis)?
8. Do organizations or systems change (i.e., resource utilization, and effects on "culture")?

However, for websites designed primarily to provide information or enable informed decision making, only the first three questions apply. Other potential outcomes related to change in behavior might be applicable depending on the nature of decisions made. Consequently, the evaluation of these types of web guides needs to focus on the use of the guides (assuming that users who "like" an application will use it more than those who do not), the usefulness of the guides, the usability of the guides, the ability of the guide to increase knowledge, and the contribution of the guide to decision making. These elements can be integrated into a conceptual framework as shown in Figure 30.1. Part of this framework draws from the Agency for Health Care Policy and Research reported on CHI and patient decision making (1997) as well as Sainfort and Booske (1996).

The framework suggests that to evaluate the effectiveness of web-based health applications, at least three perspectives (at the bottom of the figure) can be taken individually or in combination: (1) the consumer, (2) the site sponsor, and (3) outside experts. The framework posits that the characteristics of the system under evaluation primarily influence accessibility and usability of information. Then, accessibility, in conjunction with consumer/patient characteristics, influence actual access to information. In turn, the usability of this information, again in conjunction with consumer characteristics, will influence actual use of information by the consumer. Use of information is a complex construct. The framework emphasizes three main uses of information: (1) knowledge (inquiry, verify, learn, augment, etc.), (2) decision making,

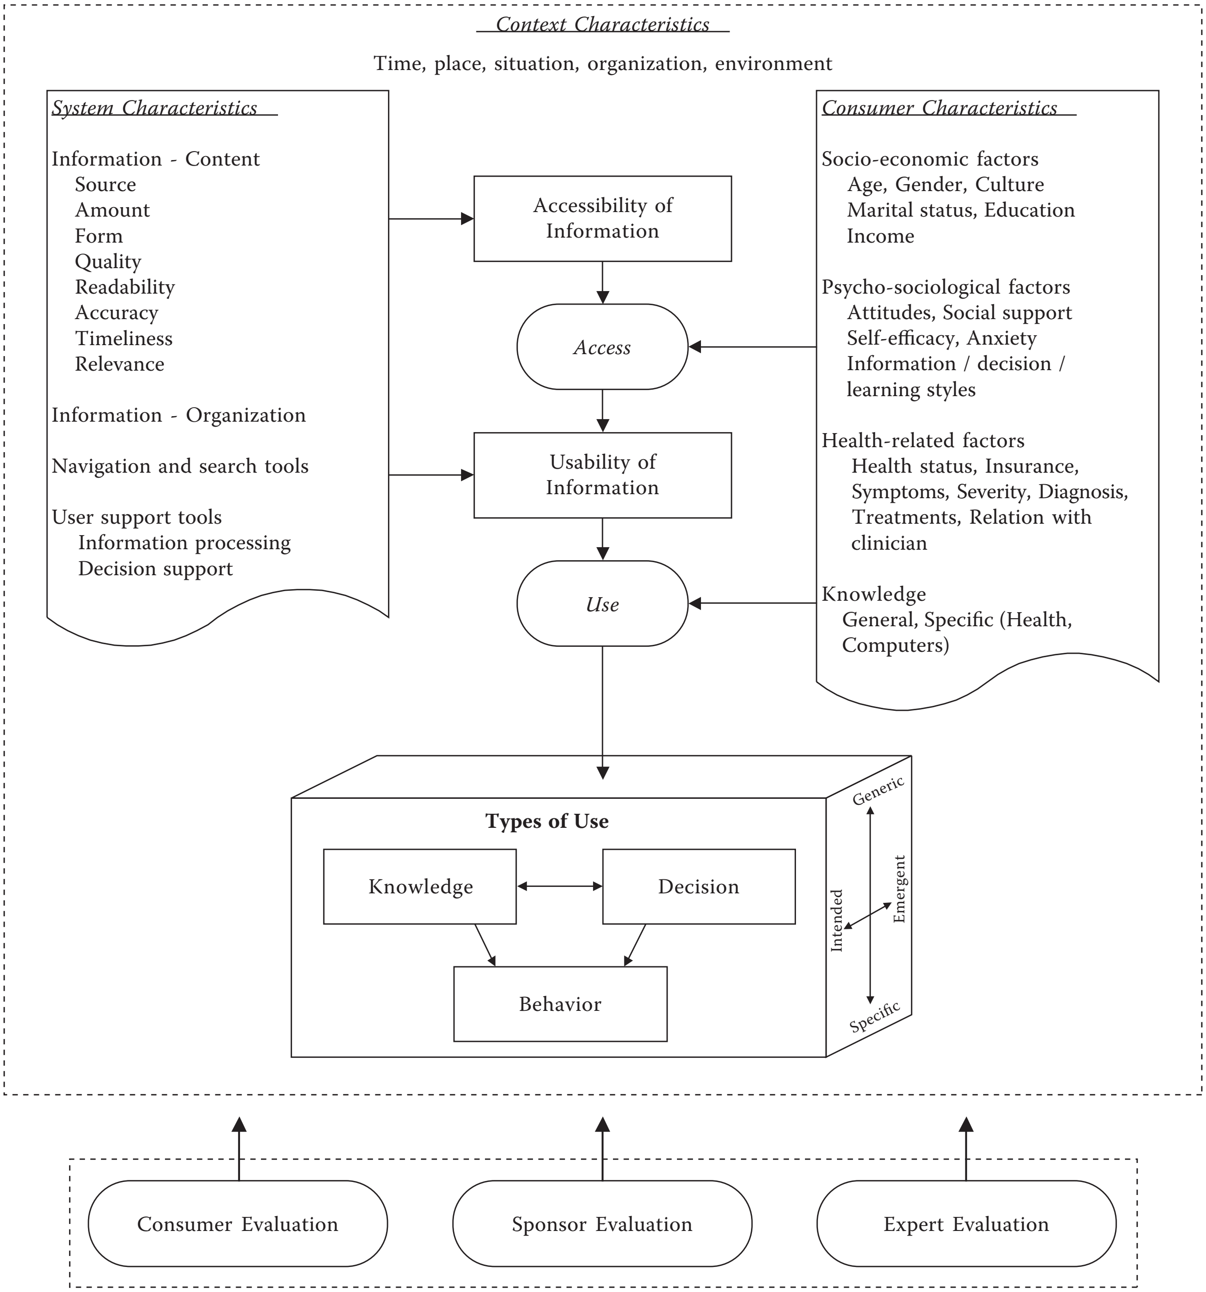

FIGURE 30.1 Conceptual framework.

and (3) behavior (intentions and actual behavior change). All three uses are generally interconnected, with behavior usually following knowledge and/or decision making (whether explicitly or implicitly). Also emphasized in the framework is the fact that "use" can be generic (common to most web-based health applications) or specific (to the application) and also that use of information accessed can be intended (i.e., the information was sought to accomplish a specific purpose or use) or emergent (i.e., a piece of information accessed triggers a new use). Finally, the framework shows, surrounding this entire process, that the context (the situation, time, place, organization, etc.) can influence all key elements: accessibility, access, usability, and use. Consumer evaluations are formed because of the experiences they have using the system over time. Expert evaluation usually involves assessment of the system itself and its content, as well as an assessment of its (anticipated) impact on users. Sponsors evaluation involves both consumer and expert evaluations as well as consideration of organizational resources expended in the design, development, implementation, and operation of the system.

It is important to differentiate information access and quantity from use and usefulness (Booske and Sainfort 1998). Indeed, while many studies primarily address attempts to measure the "quantity" of information used, others have acknowledged the need to consider the "quality" of information. The introduction of the web as a source of information has introduced a number of additional considerations in evaluation of the use and usefulness of information. The most common measure of information use on the web is the number of "hits" or "visits" to a particular page. Most of these counts do not differentiate between multiple visits by a single user versus multiple users nor do they consider the amount of time spent on a particular page, that is, whether the page is merely used as a link to elsewhere or as a source of information itself.

In describing three general approaches to information systems evaluation (i.e., the system's output, behavior, and architecture), Orman (1983) defined the quality and quantity of information as the relevant variables in defining an information system's output. However, he went on to say that both quantity and quality of information were "of considerable theoretical interest but of little practical value since neither can be defined or measured with acceptable precision" (p. 309). Orman defined the quality of information produced by a system in terms of "its contributions to the quality of the decisions it aids" and points out that this is "highly influenced by the style and the behavior of the information user and the state of the environment" (p. 309).

This ties with the concept of the "value" of information, an important part of traditional decision and economic analysis. Within the field of decision science, the primary use of information is to help make decisions. However, an examination of literature from other disciplines has shown that there are other ways to conceptualize the value, and thus the effectiveness of information and its usefulness (Orman 1983). Although it can be thought that the term "information usefulness" could be an analogue for value of information, within the field of HCI, the concept of usefulness includes additional dimensions. The concepts of "perceived usefulness" and "usability" of information systems are both receiving more attention as more systems are developed for novice users. For example, Davis, Bagozzi, and Warshaw (1999) developed scales to measure perceived usefulness and ease of use to evaluate specific software in the work setting. They defined perceived usefulness as "a prospective user's subjective probability that using a specific application system will increase his or her job performance within an organizational context." Ease of use was defined as "the degree to which the prospective user expects the target system to be free of effort." Using a seven-point Likert scale, potential users of software responded to six items addressing perceived usefulness and six to assess perceived ease of use.

Of particular relevance in considering the usability, and potentially the usefulness, of information is the manner of display. Although technological advances continue to increase the number of possible methods for disseminating information, the primary output media for health care information are still print, video, and sound. Print information is often categorized as text, tables, graphs, and figures. There is a quite extensive body of literature comparing the effectiveness of displaying information in tables versus graphs (Jarvenpaa and Dickson 1988; Dahlberg 1991 provided comprehensive summaries of this empirical work). Many of these studies rely on elicited "directed interpretations" where subjects are given specific questions about the information in tables and graphs. In contrast, a more recent study by Carswell and Ramzy (1997) elicited spontaneous interpretation of a series of tables, bar graphs, and line graphs to find out "what information subjects choose to take away from a display rather than their ability to extract information when promoted."

Within the context of decision making, Schkade and Kleinmuntz (1994) found that different characteristics of information display affected aspects of choice processes. They found that organization of information (such as a matrix vs. a list) influenced organization acquisition; form (numeric vs. linguistic) influenced information combination and evaluation; while sequence had only a limited effect on acquisition. Johnson, Payne, and Bettman (1988) and others have provided evidence of preference reversals because of different information displays.

Many of the issues surrounding the use of the Internet are issues of usability. Usability is a central notion of the HCI field. Simply put, Shackel (1991) defined usability as the "the capability to be used by humans easily and effectively," whereas his more formal operational and goal-oriented definition said, "for a system to be usable, the following must be achieved":

Effectiveness. The required range of tasks must be accomplished better than some required level of performance (i.e., in terms of speed and errors); by some required percentage of the specified target range of users; and within some required proportion of the range of usage environments.

Learnability. Within some specified time from commissioning and start of user training; based on some specified amount of user training and support; and within some specified relearning time each time for intermittent users.

Flexibility. With flexibility allowing adaptation to some specified percentage variation in tasks and/or environments beyond those first specified.

Attitude. And within acceptable levels of human cost in terms of tiredness, discomfort, frustration, and personal effort; so that satisfaction causes continued and enhanced usage of the system. (p. 48)

In an attempt to place system usability in relation to other system concepts, Shackel (1991) suggested that

> utility (will it do what is needed functionally?), usability (will the users actually work it successfully?) and likeability (will the users feel it is suitable?) must be balanced in a trade-off against cost (what are the capital and running costs and what are the social and organizational consequences?) to arrive at a decision about acceptability (on balance the best possible alternative for purchase). (p. 50)

These concepts are all relevant in a decision to purchase or accept an information system, but may not be all relevant when the resource or product under consideration is information. As Orman (1983) pointed out the value of an information system is different from the value of its information content, "just as the value of a candy machine is different from the value of the candy it dispenses." Furthermore, usability of information is a necessary but not sufficient criterion for information to be useful. (p. 312).

In the context of informing health care consumer decisions, Hibbard, Slovic-Jewett, and Jewett (1997) asked how much information is too much. In response to this question, they determined that the critical element is the ability to interpret and integrate information items: integration is a very difficult cognitive process. They suggest that for a consumer, more information is not necessarily better and that the simple provision is not sufficient when the information is complex. In complex-decision situations, it is important to pay particular attention to human information processing capabilities and differences across individuals. For example, specifically addressing information presentation format, Togo and Hood (1992) found a significant interaction effect between gender and format. Personality differences have also been found to contribute to variation in information processing. The way people gather and evaluate information is at least in part based on their psychological type (Slocum and Hellriegel 1983). Some people are driven to know details before decisions are made, whereas others feel more comfortable assuming what is not known. Individuals vary on how they receive messages, seek information, organize information, and process information. One approach to categorizing cognitive style, the Myers-Briggs Type Indicator, is based on Jung's typology (Myers 1987).

Other models of learning styles can be used to differentiate among individuals and their preferred methods or strategies for taking in and processing information. Felder (1996) provided a useful summary of these models. For example, Kolb's learning-style model classified people as having a preference for (1) concrete experience or abstract conceptualization (how they take information in) and (2) active experimentation or reflective observation (how they internalize information). The Hermann Brain Dominance Instrument classified people in terms of their relative preferences for thinking that are based on the task-specialized functioning of the physical brain, that is, left brain versus right brain, cerebral versus limbic. The Felder-Silverman learning style model classified learners on five dimensions: (1) sensing or intuitive, (2) visual or verbal, (3) inductive or deductive, (4) active or reflective, and (5) sequential or global.

In addition to individual differences, other factors that can affect information processing reflect characteristics of the information itself (John and Cole 1986), that is, information quantity, information source, information format (mode of presentation, organization, order), information complexity, nature of access (i.e., voluntary vs. mandatory), instructions in the use of the information, response formats (i.e., recognition, recall, judgment, choice), and the interface itself.

Understanding cognitive processes involved in accessing, processing, interpreting, and using health care information is critical to the successful design and implementation of web-based health care applications. This particular point extends to applications targeted at providers and other health care professionals. In looking at the impact of computer-based patient record systems on data collection, knowledge organization, and reasoning, Patel et al. (2000) indicated that exposure to computer-based patient records was associated with changes in physicians' information gathering and reasoning strategies. They concluded that such technology could have profound influence in shaping cognitive behavior. In such systems, the HCI itself can have a strong influence on information gathering, processing, and reasoning strategies. Recently, Patel, Arocha, and Kaufman (2001) surveyed literature on aspects of medical cognition and suggested that

> cognitive sciences can provide important insights into the nature of the processes involved in human–computer interaction and help improve the design of medical information systems by providing insight into the roles that knowledge, memory, and strategies play in a variety of cognitive activities. (p. 324)

30.6 FUTURE OPPORTUNITIES AND CHALLENGES

Information and communication technologies have only begun to impact the health care industry. Regarding the use of the Internet, a number of applications will be at the leading edge. Mittman and Cain's (1999) prediction that these applications would include consumer health-information services, online support groups for patients and caregivers, health care-provider-information services, provider-patient e-mail, communications infrastructure and transaction services, and EMRs appears to be true. Similarly, the barriers they predicted would impede or slow down the development of the Internet in health care have largely proven true as well: security concerns, weaknesses inherent to web interfaces (especially browsers, search-engine technology, and inability to interact with legacy systems), mixed or lack of quality of information, physician ambivalence, disarray of current health care-information systems, lack of resources for web development, and lack of unified standards for electronic communications and transactions.

For information technology to fully impact health care delivery with a focus on both patients and providers, these barriers need to be overcome. We believe that the greatest benefits will be reached in the short term by focusing on the following five areas.

30.6.1 Supporting/Enhancing the Patient-Provider Interaction

The Internet will become a critical element of the physician-patient encounter. Organizational websites will evolve from publishing generic consumer content to providing personalized, online services to all consumers (individuals, patients, providers, etc.). The Internet needs to provide for technology that truly supports two-way interaction between patients and providers and directly impacts care delivery.

Effective technologies need to be developed to fully support, enhance, and extend the patient–physician interaction so as to increase the efficiency of care delivery, increase the quality of care received by patients, and increase the effectiveness of the work performed by the physician. This latter point is important since a study by Linzer et al. (2000) showed that time stress, defined as reports by the physician that they needed more time for patients than they were allotted, was significantly related to burnout, job dissatisfaction, and patient-care issues. This study was performed with a national sample (n=5, 5704) of physicians in primary-care specialties and medical and pediatric subspecialties. It demonstrates that the ability to spend sufficient and quality time with each patient is critical to ensure long-term job satisfaction, avoid physician burnout, and increase quality of patient care.

In developing such technologies, as we mentioned earlier, one would need a full understanding of the various cognitive processes involved in information gathering, knowledge acquisition and organization, reasoning strategies, and decision making. Of particular importance is the recognition of various users with various characteristics potentially using technologies in a variety of situations, contexts, organizations, and environments.

30.6.2 Supporting/Enhancing Collaborative Work among Providers

The nature of the physician/associate provider (nurse, physician assistant) relationship is evolving from mere interaction to true collaboration with technologies allowing associate providers to increase involvement in clinical decision making and implementation. Technologies to support collaborative work environment in fast-pace, mobile environment are needed.

As mentioned earlier, the health care work environment is very complex and involves a variety of health care professionals, all with varying needs for information, knowledge, and support. Designing technologies supporting both individual needs and collaboration among individuals presents a number of challenges. A study by Jacko, Sears, and Sorensen (2001) showed that different health care professionals (physicians, pharmacists, nurses) exhibit very different patterns of use of the Internet for clinical purposes and have very different perceptions of needed enhancements to support their respective needs. The patterns differed in terms of the range and type of information as well as the depth and specificity of information.

Health care organizations will be faced with technology integration challenges and will make use of the Internet and Intranet technologies to manage and organize the variety of applications in use by providers and their patients. Of critical importance for health care organizations will be the design of systems to support clinical decisions, knowledge management, organizational learning, administrative transactions, and supply chain.

30.6.3 Developing and Utilizing New Information and Communication Technologies

Wireless, handheld, and nanotechnologies will drive higher adoption rates of the Internet in clinical settings, patient monitoring, and disease management. Both the number of interactive wireless device users and the number of devices will increase significantly in the next few years. New applications for such technologies need to be developed, based on fundamental research conducted to investigate usage of such devices.

Mobile computing and wireless technologies will increasingly become an important part of health care's information technology. Turisco and Case (2001) initially reported that mobile computing applications for health care began with reference tools and then moved to transaction-based systems to automate simple clinical and business tasks. In 2004, Goldsmith argued that mobile computing was a promising emerging IT innovation with the potential to fundamentally transform the way health care services are delivered. We have in fact seen a transformation in health care due to mobile computing with improvements in CPOE (Junglas, Abraham, and Ives 2009) and patient monitoring (Sneha and Varshney 2009). Mobile computing technologies will continue to advance due to increasing improvements in bandwidth that allow medical images to be transmitted easily, and a variety of new vendor applications and wireless initiatives.

30.6.4 Designing and Utilizing Adaptive Human–Computer Interactions

The development and integration of information and communication technologies designed to support, facilitate, and enhance patient/provider interactions are critical. In particular, research is needed to design optimal HCIs. A dual focus on (1) increasing job satisfaction and effectiveness for the medical personnel and (2) increasing quality of care and safety for patients is needed. To support these objectives, the HCI must possess at least the following four qualities:

1. Multimodal, that is, have the ability to display and accept information in a combination of visual, aural, and haptic modes
2. Personalized, that is, tailored to respond in a manner best suited to the current user and his or her needs
3. Multisensor, that is, have the ability to detect and transmit changes in the user and/or situation
4. Adaptive, that is, have the ability to change its behavior in real time to accommodate user preferences, user disabilities, and changes in the situation/environment

Optimal interfaces are critical to virtually all applications connecting people to information technologies and people to people via information and communication technologies. Current research is underway to develop intelligent adaptive multimodal interface systems. In the future, interfaces will automatically adapt themselves to the user (capabilities, disabilities, etc.), task, dialogue, environment, and input/output modes to maximize the effectiveness of the HCI.

This is especially critical in health care for both types of users: consumers/patients and providers. Consumers/patients present a number of challenges regarding the interface. In addition to presenting different personal and socio-demographic characteristics, users in health care present varying degrees of health status: healthy consumers, newly diagnosed patients, chronically ill patients, and/or their caregivers will use the same devices in potentially very different ways. Similarly, different providers will have very different characteristics and will perform a multitude of varying and highly dynamic tasks in different contexts and environments.

30.6.5 Moving to e-Health

The opportunities for improving service and decreasing cost via e-commerce technologies and the supply chain are tremendous. In addition, modern information and communication technologies (including sensors, wireless communication, and implant technologies) will enable electronic delivery of health care. This is far more comprehensive than the mere electronic delivery of health information to patients and providers and includes new developments such as telemedicine and virtual reality. Krapichler et al. (1999) claimed that “virtual environments are likely to be used in the daily clinical routine in [the] medicine of tomorrow” (p. 448). However, a number of barriers will need to be overcome. Organizational barriers to e-Health include infrastructure, organization, culture, and strategy, systems integration, and workflow integration. Technological barriers include integration and security, interface design, connectivity, speed, reliability, and usability issues.

The evolution toward e-Health will involve a number of major changes. For example, organizational websites will evolve from publishing generic consumer content to providing personalized, online interactive services to profitable patient segments. Delivery organizations will focus on direct-to-patient relationship building, migrating to a health system truly centered on patients and communities. Communities of interest will rapidly expand to become a force in health care navigation. Wireless and handheld technologies will drive higher adoption rates of the Internet in clinical settings. The Internet will become a critical element of the physician–patient encounter and will support and enhance the patient–provider interaction. Social media will play an increasing role, as well, but further exploration into the appropriate role of social media in health care education and care delivery is needed. These changes will lead to a restructuring of the health care industry. Digital health plans will emerge and compete or threaten the traditional health care-payer business model. Virtual networks will begin to emerge around specialty services to provide efficient personalized health care.

31 Why We Play

Affect and the Fun of Games—Designing Emotions for Games, Entertainment Interfaces, and Interactive Products

Nicole Lazzaro

CONTENTS

31.1 WITHOUT EMOTION THERE IS NO GAME

Shakespeare designed the emotional space between characters; game developers design the emotional space between players and game.

Researchers have only just begun to explore the role emotion plays in human activities. In designing emotional responses, most aesthetic disciplines treat audiences as consumers of content and pay little attention to designing emotions from interaction or contribution. Whether it is a movie, a bottle of perfume, or a website advertisement, a broadcast model is used to elicit emotions from observers rather than participants. Scientific research is now beginning to show how emotion influences cognition and behavior offering new opportunities to solicit emotion through action. Emotion emerges from and plays a part in most activities, from following a goal to just goofing around (Damasio 1994; Ekman 2003; Norman 2004; Lazzaro 2004b). Video games lead the way as interactive products that create emotion. More emotional than software and more interactive than films, games manipulate player affect to create poignant experiences. How they do this provides lessons for the design of games, entertainment interfaces, and other interactive products.

Emotion is essential to maintain player focus, make decisions, perform, learn, and enjoy the process of play. Emotion-rich stimuli grab players' attention, such as a swashbuckling adventure in *Sid Meier's Pirates!* The emotions surrounding swordplay increase players' immersion and negative affect or mindset focuses players on applying effort to overcome obstacles. Meanwhile, positive affect from finding pirate treasure improves exploration of alternatives. Exploring options to get the player's sticky ball up on top of a table in *Katamari Damacy* is made easier by the positive affect created as it squashes and picks up cutely rendered bon-bons, toys, and other items. Strong emotional states also allow easier formation and recollection of memories, especially if the user's emotion matches the emotion of the item to be remembered (Ekman 2003). Special moves in *Top Spin Tennis* that offer an emotional response in an opponent are easier to remember and motivate the search for more. Games are innovators in the design of emotional responses integrated into the activity to accelerate it or provide friction for game goals. Each affective state, each emotion, carves a unique signature into a player's psychology, physiology, and behavioral state to create a player experience. Hoping that graphic realism alone will create emotions is nearly the same as adding more background color to fix a usability issue.

Lessons about game experiences inform entertainment interfaces and other product experiences. Games are not just entertaining; they are self-motivating activities. User-experience designers for all types of products can take advantage of how games create these emotions from participation. To transition from interface design to user experience design, interfaces need to be more than "transparent." In games, the interface that makes everything easy robs the player of the fun. Pushing a button for a car to drive itself is less thrilling than winning the Grand Prix. In software, the interface cannot do it all because it does not have the user's knowledge. Therefore, not only must interfaces get out of a user's way, they should allow the user to express him or herself by motivating and supporting the cognitive and behavioral functions required for use. Designers can take inspiration from games to fashion emotional responses during interaction; for instance, computers can detect and respond to user emotion, such as "being more helpful" when software detects frustration in a user's face or fingertips. Like interchangeable colored lenses, games employ emotion-producing attributes to support human performance: rose-colored here for a mood boost, yellow for sharper vision later on, green night vision with a distance indicator for the dark corners, and black to win style points from others. Current usability methods (increasing efficiency, effectiveness, and satisfaction) mostly remove frustration points; they do not yet include techniques to measure and craft other emotions. To exaggerate, a 100% usable product would be boring once it eliminates all the challenge. Customers strap software onto their boots like a crampon, but it should not do the job so well that it climbs the mountain for them (Lazzaro 2004a). It is not a productivity tool if one button-click creates the whole spreadsheet. User experiences should focus on making the process of the task not only easier, but also more enjoyable.

31.1.1 Forget Usability: Make It Fun

> "I don't want to feel like the game just wasted two hours of my life."
>
> **—A *Might and Magic* player**

Wasting time has a whole different meaning to a gamer. Unlike a spreadsheet, the outcome of a game is in the experience of play rather than in the quality of the end result and so is harder to quantify. Traditionally, productivity focuses more on designing a process that creates a better end-product or result. Game design, on the other hand, focuses mostly on designing interactive play that is enjoyable in its own right. Rather than efficiency, game enjoyment requires the pure pleasure of the experience and a fair degree of frustration (Lazzaro 2004a). Similar to user experiences, player experiences are created when what happens in the game affects the player internally as well as externally. Player experiences are

Productivity Software Goals	Game Goal
Task completion	Entertainment
Eliminate errors	Fun to beat obstacles
External reward	Intrinsic reward
Outcome-based rewards	Process is its own reward
Intuitive	New things to learn
Reduce workload	Increase workload
Assumes technology needs to be humanized	Assumes humans need to be challenged

FIGURE 31.1 The goals of productivity and game experiences have several important differences. (From Lazzaro, N., and K. Keeker. *Proceedings Association for Computing Machinery (ACM) Special Interest Group on Computer-Human Interaction Conference (CHI)*, Vienna, Austria, 2004. With permission.)

the combination of emotion, thoughts, and other sensations that occur inside and in between players during play. Beyond usability, player experiences design focuses on affect as well as ease of use (Figure 31.1).

The interactive entertainment offered by games provides unique opportunities to create emotions in the player and unique challenges for the design professional. A game must be usable enough to play but not so usable as to allow someone to push a button and win. Players crave the illusion of superior control that allows them to accomplish more than others including out-thinking the game designer, but not so much control that they lose their way and do not have a good time.

31.1.2 Emotions Are for More than Entertainment

> "Experience is the feeling of what happens."
>
> **—Damasio 1994**

Playing games in their discretionary time, gamers mainly play for the emotions the games create. Recent neuropsychology research suggests that two interconnected information-processing systems continually scan the environment to create a person's experience of the world. A person's *cognitive system* interprets and represents the world internally in order to reason, understand, and interact with it. A person's *affective system* interprets external and internal stimuli relative to goals and needs. This affective system kicks in with an emotional and physiological reaction before a cognitive response is ready. Ideas, thoughts, memories, and knowledge are components of cognition; emotions, moods, sentiments, and other internal sensations comprise a person's affective response (Damasio 1994; Norman 2004). From a cognitive-psychology perspective, cognition understands the world and affect evaluates it (Norman). On a basic level, we bring items with positive affect (sweet-tasting, soothing voices, warm to the touch) closer to us. We push (generally speaking) objects with negative affect (bitter, bloody, sharp, diseased) away from us. In the context of games, the study of affect must also include the discussion of enjoyment.

Player experiences emerge inside the player from the process of interacting with the game. Player-experience design crafts these cognitive and affective responses in conjunction with user behavior. Therefore, the design of player experiences must refine not only the gamer's cognitive response to a system, for example, by reducing complexity; it must also design the gamer's affective response, for example, by inspiring interest or rewarding success in order to increase engagement and support cognitive tasks. For the purposes of game design, affect supports cognitive as well as behavioral tasks, because emotion has a significant effect on enjoyment, attention, memory, learning, and performance.

Emotion and cognition walk hand in hand. According to Ekman, beyond entertainment, emotions are about goals and the things we care about (2003). This makes the creation of emotions ideally suited for game design because most gameplay offers goals with levels and scores to indicate progress. In films, we feel emotions only if we somehow identify with the characters on the screen and vicariously feel their emotions (Boorstin 1990). This also happens in games, but more central to interactive entertainment is when players feel emotions from what they accomplish and fail at during the game. In productivity, feedback on effectiveness, such as creating a sales presentation, happens after the task of creating it is complete. In games, the success-feedback loop is immediate and built into the process of play.

31.2 REQUIREMENTS FOR A PLAYER EXPERIENCE FRAMEWORK

31.2.1 Emotion's Five Impacts on Play

> "Emotions prepare us to deal with important events without us having to think about what to do."
>
> **—Ekman 2003, p. 20**

Games entertain with emotions so players enjoy the ride.

Emotions impact player experiences in five ways. What players like most about games is not the packaging, graphics, or the artificial intelligence (AI), but the total experience that the game creates for the player. This experience lies in the cognitive, affective, and behavioral changes gamers create for themselves as they play. Emotion generates a big part of the entertainment value, the opportunity for challenge and mastery, the thrill from novelty, the ticket to relaxation, and the opportunity to hang out with friends. Customers buy this ride designed by game designers. These emotions create moving gameplay and make a victory taste sweet (Figure 31.2).

Not only does the act of play produce emotions, but also emotions and affect substantially influence the player and how he or she plays. Unlike user experiences, the primary aim of player experiences is to move the player emotionally along with or counter to the game goal. Such techniques heighten the emotional response in the player. Emotions entertain players, focus their attention, help them decide, aid their performance, and assist and motivate learning. Enjoyable emotions from gameplay increase motivation to play further in order to experience more emotions, which makes games self-motivational. Emotions are there from the first click to final volley.

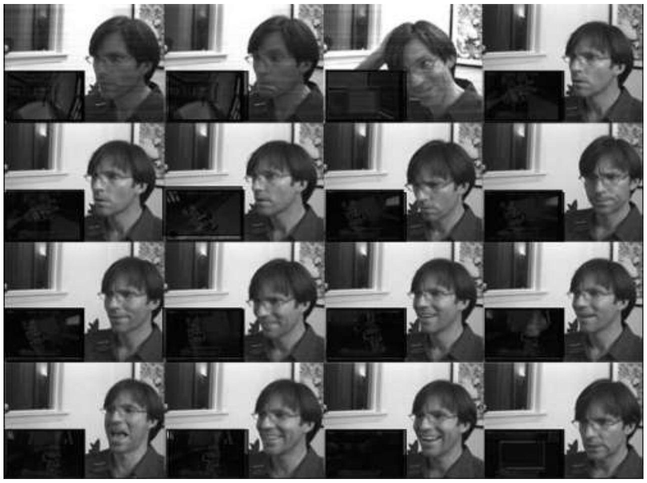

FIGURE 31.2 Game interaction involves and creates many emotions that are clearly visible on the face during play, as seen here during the tutorial for a popular action game. (Courtesy of XEO Design. Copyright © 2004 XEODesign, Inc. All rights reserved.)

31.2.2 Emotion during Play Helps Gamers

1. *Enjoy:* Creates entertainment from strong shifts in internal sensations
2. *Focus:* Directs effort and attention
3. *Decide:* Aids decision making
4. *Perform:* Supports different approaches to action and execution
5. *Learn:* Provides motivation for learning, aids in memory, and rewards progress

Games heighten emotional responses to increase *enjoyment*. *Mario Kart*, for example, adjusts speed of players to keep them together for "close" races; likewise, *Jak and Daxter* keeps players just ahead of rolling boulders. A choice between certain death and escape via a narrow window ledge in *Tom Clancy's Splinter Cell* provides *focus* to fill attention in a way that scrolling through options in a word processor's drop-down menu or walking down an office corridor of options does not. Strong exaggerated affect aids player *decisions* whether it is to attack a goblin in *Worlds of Warcraft* (*WOW*) or grant a Sim bathroom privileges in *The Sims*. Gameplay creates moods that aid players to perform; negative affect during a fire fight in *Battlefield* improves pursuing a narrow course of alternatives such as stopping a sniper, while positive affect from munching letter sounds in *Bookworm* improves identification of new word patterns in this *Scrabble*-like tile game. A player *learns* to keep diners happy in *Diner Dash* when an angry customer empties the tip jar.

1. *Enjoy:* Emotions create strong shifts in internal sensations to heighten and refresh player experiences.

Suspend players over boiling lava or confront them with hideous boss monsters and the game heightens their emotions. Players look for emotional rewards as well as a high score. Much of the enjoyment comes from the player's affective response and ultimately separates player experiences from user experiences. In games, player participation is essential. The emotions come from the players' efforts in accomplishing a task and game enjoyment centers on the experience of strong emotional shifts from their actions. Games provide the environment where the player becomes the central hero to accomplish the extraordinary. The buddy rescued or the enemy vanquished in *Battlefield* is no more real than in film, but the player's role in the achievement is. An interactive medium, the choices offered by the game (including the graphical user interface) must sharply enhance the experience. A poor interface reduces interactivity and harms the game experience. Therefore, a large part of good game design lies in creating effective interfaces that also create emotional responses. Movies, by comparison, invite the audience to share in the joys and sorrows of characters on screen. Where games move beyond film to claim their true power is by rewarding player action with emotions. Movies can never hand the audience a jet ski for the thrill of stopping the impending global thermonuclear war. As part of their unique value proposition, games have to

2. *Focus:* Emotion directs effort and attention aids or influences many aspects of cognition by focusing attention, providing immediate feedback and rewards.

Emotion supports cognitive tasks by directing, focusing, and holding attention, creating absorbing engagement, and at the same time allowing emotion-laden ideas to dominate thought (Clore and Gasper 2000 as cited in Brave and Nass 2003). Events are filtered through mood, we attend more to thoughts that match the current mood, and ideas similar to a user's current mood are remembered better (Ekman 2003; Thorson and Friestaad 1985 as cited in Brave and Nass 2003). Emotional stimuli rewards more detailed analysis.

In games, tight feedback loops reward player actions with immediate visual and audio feedback that motivate the player to want to take another action. This rewarding-stimulus-response loop is a powerful motivating force that reaches a wide mass-market audience. Several game-design techniques magnify the effect emotions already have to focus players on a task. For example, game obstacles sometimes use negative affect to increase player focus and, at other times, they use positive affect to increase creativity and problem solving to provide interesting behaviors or situations to encourage players to explore (using positive affect to increase creativity and problem solving). Emotions reward attention. Game feedback provides new stimuli to interpret and creates new experience. Rewards create positive and negative affect. Failures create negative affect with the hopes that players will double their efforts and try again.

3. *Decide:* Emotion is vital to decision making in games.

Humans use both thought and emotion to make decisions. Experimental evidence suggests that people with damage to brain structures involved in emotions can generate appropriate logical options and discuss each decision's impacts and tradeoffs with great clarity, but are unable to make the actual choice itself (Damasio 1994; Norman 2004). When we select an entrée from a restaurant menu, it is what we "feel" like having. There are also logical components to that choice (calories, fiber, who's paying, etc.), but there is something other than logic that happens inside that helps us choose and "feel" good about the selection. Some people even feel that their car drives better after it has been washed or had the oil changed (positive affect). Emotions also let people make snap decisions (Ekman 2003; Norman 2004). Emotions help players decide and combine with logic to make these decisions interesting. Because positive and negative affect guides players, it is easier to choose between options with strong emotional stimuli. Game interfaces that supply strong emotional responses also have this effect. Games also use affect to add conflict. Either the emotions support the objective or make achieving it more difficult as players resist the urge to run away. Recognizing this initial role emotion plays in decision making offers a crucial way to improve decision-support products.

4. *Perform:* Emotion supports different approaches to action and execution.

Emotions are a key component in most tasks. This is easy to see in games, which are often designed to create a particular affective state, which sometimes requires following strict detailed procedures with zero tolerance for error or creative exploration of alternative options. The lesson for human–computer interaction (HCI) is that properly designed emotions support the right affective state to get the job done as well as increase appeal. In productivity software, this is important for both the task (such as struggling to find the right word while writing) and the software (such as struggling to find the right feature), and both create frustration. Like a car's seatbelt alarm, certain levels of frustration create mild negative affect in the user and direct the user toward a certain action. Too much negative affect (such as when players cannot keep cars on the racetrack) makes players feel like they will fail and quit. Software needs aspects that create emotions to support tasks, and allow options that let users balance their own levels of frustration. Like cycles of hard and easy things to do in a game, users need to experience new emotions to refresh their experiences. Emotion creates moods that persist and help the player perform. The emotion the designer chooses should help the actions required. Negative affect narrows attention on aspects relevant to the problem, while positive affect opens it to explore new alternatives. Positive moods influence creativity and flexible thinking for problem solving. Relaxed and happy thought processes expand and become more creative and imaginative, and make players more tolerant of minor difficulties (Norman 2004). Moods with a negative affect focus attention, while positive moods help players generate new options. Cycling between moods creates variety to refresh the experience, and offers the option of approaching a problem with a different problem-solving strategy related to the new mood.

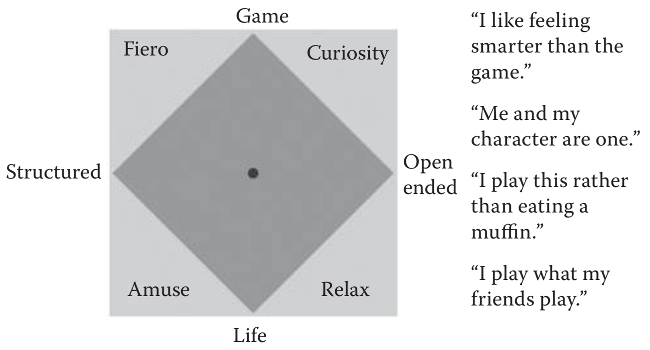
5. *Learn:* Emotion provides motivation and rewards progress.

Played for pure enjoyment, game emotion motivates players to pay closer attention and repeat an action, enabling them to master highly complex interfaces and interactions, learn countless features and strategies, and spend hours doing this even though they may fail repeatedly. To increase product mastery, many game methods apply nongame interfaces. While productivity software users prefer to learn the bare minimum number of features to accomplish their work rather than achieving level 42 in spreadsheet wizardryness, game-like motivation may increase exploration of additional product features. All games involve learning. Emotions reward changes and growth inside players as they master what they could not do before. Learning and remembering are easier for emotional stimuli, and when experiencing an emotion or a mood, it is easier to remember thoughts that have a matching emotional context. Improved performance such as learning a new skill or high score is a big part of the enjoyment of play.

31.2.3 Requirements for an Emotion Framework for Games

> "The problem with the words 'enjoyment' and 'happiness' is that they're not specific enough; they imply a single state of mind and feeling, in the same way that the terms 'upset' and 'negative' don't reveal whether someone is sad, angry, or disgusted."
>
> **—Ekman 2003, p. 190**

A practical methodology for designing emotions should support designers as well as researchers to build better player experiences. More than a model, a practical method for designing and examining player experiences should take into account four perspectives: (1) what players like most, (2) what creates emotions, (3) what game designers can control, and (4) what researchers can measure. The method's components must be observable, salient to the player, relevant to the player's experience of fun, and apply to a wide variety of game genres and hardware platforms. It must account for how activities offered by best-selling games make them more popular than others with similar features. It should track internal and external aspects of play including complex emotions and their impact on players' lives. A framework must capture emotions' role in enjoyment, maintaining player interest, decision making, performance, and learning. Designing for emotion in games should build on the research and theories of several disciplines. It must cover differences in expectations and play patterns such as Bartle who first classified players as (a) Achievers, (b) Explorers, (c) Socializers, or (d) Player Killers (Bartle 1996). It must measure emotion from play from different game components such as challenge and fantasy (Malone 1981) and biometrics such as heart rate, control pressure, and facial expression (Mandryk 2004; Sykes and Brown 2003; Hazlett 2003), and specific emotional states such as pleasure and aggression using FMRI (Weber, Ritterfeld, and Mathiak 2006). It should



Game
Fiero
Curiosity
Structured
Open ended
Amuse
Relax
Life
"I like feeling smarter than the game."
"Me and my character are one."
"I play this rather than eating a muffin."
"I play what my friends play."

FIGURE 31.3 Players play for "the ride" that games take them on. Player experiences (PX) generate emotions from reactions along two axes: goal-directed versus open-ended play, what happens inside the game versus how gameplay relates to other aspects of the player's life. (Courtesy of XEO Design. Copyright © 2004–2007 XEODesign, Inc. All rights reserved.)

cover emotions from game goals, open-ended play, as well as emotions from game events and those that happen in real life. Most importantly, the method must describe which gameplay mechanisms produce specific emotions that are central components of the player experience (Figure 31.3).

31.2.3.1 Evaluating Relevant Frameworks for Emotion, Products, and Entertainment

A limitation shared by current models of emotions and products is that they focus more on positive and negative affect than on how to create specific emotions from interaction; and even less attention is given to how the actions of a game player create specific emotions. To be useful to game and product designers, player-experience methodologies must identify more emotions than simply positive and negative affect. Affective states grow and change during gameplay.

Many emotions are enjoyable, such as curiosity, which can also lead to other positive emotions such as wonder and even love. However, players also enjoy play experiences containing negative emotions. The pleasure that comes from many game designs requires mastering difficult situations or experiencing unpleasant emotions. How emotions grow and change during play is a critical part of player experiences. During game testing, designers need more information than whether an action was or was not fun. Player observation leads to the design of better games, but this requires a deeper understanding of the player experience and better techniques on how to measure it (Figure 31.4).

31.2.3.2 Flow the Optimal Experience: Csikszentmihalyi

The most relevant and influential psychological research outside of games is Csikszentmihalyi's model of on optimal experiences or "flow" (Csikszentmihalyi 1990). He found that people are happiest when engaged in intrinsically motivating activities such as rock climbing, dancing, and gardening. These activities offer long-term, deep, memorable experiences that require concentration and growth. He noted that optimal experiences carefully balance skill with difficulty to create a deeply enjoyable mental and physical state. Without challenge, an activity becomes routine and boredom sets in. With too much challenge, the person becomes too anxious and leaves because he or she feels frustrated (Csikszentmihalyi 1990). The activity should aim to achieve flow through experience design and create forward movement and personal development through pleasurable engaging experiences. With its balance of difficulty and user skill, flow clearly describes a critical component of play experiences. However, Csikszentmihalyi's model only took into account two emotions: (1) anxiety (frustration) and (2) boredom, and ignored several other emotions essential for gameplay. While these first two emotions are important in games, many other emotions play an important role in player engagement. Csikszentmihalyi grouped together physical, mental, and aesthetic challenges, which prevented discussing emotional effects of art and audio separately from the challenge of gameplay. A model for emotions in games should connect the emotions most important to games to how games create them.

31.2.3.3 Pleasure from Products: Jordan, Norman, and Boorstin

Pleasure comes from different aspects of experiencing a product. To define what he calls the new human factors, Jordan expanded on anthropologist Tiger's Four Pleasures model to create a framework for thinking about pleasure from products. Jordan discussed (a) the ideo-pleasure, (b) physio-pleasure, (c) psycho-pleasure, and (d) socio-pleasures of a product (or emotions from a product's idea, physical, psychological, and social attributes). Each of these Four Pleasures describes enjoyment from a different perspective including how the use, ownership, or identification with a product produces emotion (Tiger 1992, as cited in Jordan 2000; Jordan 2000). Changing an aspect can strengthen a desired emotional response. Norman built on and simplified Jordan's model to three layers of mental processing: (1) the Visceral (an automatic biological response), (2) the Behavioral (learned actions), and (3) the Reflective (involving thought, self-image and relationship to others) (Norman 2004). Interestingly, filmmaker Jon Boorstin also proposed three ways that films delight audiences: (1) the Visceral Eye (enjoyment on the biological level such as automatic sensory reactions to explosions or speed), (2) Voyeuristic Eye (enjoyment through seeing events unfold), and (3) the Vicarious Eye (enjoyment through identification with people on screen) (Boorstin 1990). Unfortunately, none of these frameworks go deeply into what actions create specific emotions.

31.2.3.4 Enter Ekman and Facial Expressions

Through his research of universal facial gestures, Paul Ekman's Facial Action Coding System (or FACS) and a compilation of others' research, Ekman's work has increased understanding of specific human emotions' cross-cultural boundaries. His fascinating and highly accessible book *Emotions Revealed* described how to identify emotions through facial gestures and the important roles emotions play in our lives (Ekman 2003) (Figure 31.5).

Comparison of Models and Methods to Create Affect from Products and Entertainment Experiences

XEODesign Four Fun Keys Model	Hard Fun Fiero	Easy Fun Curiosity	Serious Fun Relaxation	People Fun Amusement
	Challenge Game, Goal	Novelty, Fantasy Game, Open Ended	Real World Purpose Life, Open Ended	Social Life, Goal
Bartle's Original 4 Player Types (1996, 2003a, 2003b)	Achiever Player Killer	Explorer		Socializer Player Killer
Boorstin (1990)		Voyeuristic Eye Visceral Eye		Vicarious Eye
Csikszentmihalyi (1990)	Enjoyment, flow	Pleasure, microflow		
Ekman (2003)		Auto appraisal, memory of emotion, imagination, reflective appraisal		Empathy with another, Violation of social norm, talking about emotion, making facial expression of emotion
Hassenzahl et al. (2000)	Ergonomic quality	Hedonic quality		Community
Kim (2000)				
LeBlanc, Hunicke, and Zubek (2004)	Mechanics, dynamics Aesthetics	Aesthetics		
Malone (1981)	Challenge	Curiosity Fantasy		
Norman (2004)	Behavioral		Reflective visceral	Reflective
Piaget (1962)	Formal games with rules	Sensory-motor play Pretend play		
Tiger (1992)		Physio-pleasure	Ideo-pleasure	Socio-pleasure
Jordan (2000)		Psycho-pleasure		
Wright, McCarthy, and Meekison (2003)	Spatial-temporal thread	Compositional thread Sensual thread Emotional thread		
Common Drama and Theater Constructs	Character "motivation," plot points, objectives 3-act structure	Setting, plot, story, character, suspension of disbelief	Catharsis, music, set and costume design	Character Dialog Acting

FIGURE 31.4 Several frameworks describe the emotion resulting from entertainment experience or the use of a product. Comparing their similarities and differences provides interesting insight into the basic requirements for entertainment and product emotions. (Courtesy of XEODesign. Copyright © 2004–2007 XEODesign, Inc. All rights reserved.)

Six Plus One Universal Emotions with Universal Facial Gestures

Emotion	Example
Frustration:	Figuring out how to get character off a roof in *Tom Clancy's Splinter Cell* (and all-too-often created by usability issues that detract from the player experience)
Fear:	Falling into boiling lava, fast-moving projectiles aimed at the player in *Doom*
Surprise:	Using *Myst's* linking books for the first time to transport to a new world
Sadness:	When the young magician *Aerith*, in *Final Fantasy* VII, is murdered
Amusement:	When two Sims get married in *The Sims*, or rolling over and picking up sumo wrestlers in *Katamari Damacy*
Disgust:	Becoming a social outcast (social disgust) after losing the dancing challenge in *Sid Meier's Pirates!*
Curiosity:*	Wanting to know what happens by driving the race track the wrong way in *Project Gotham Racing 3*

* Not all researchers (including Ekman) considered curiosity a universal emotion with a unique facial gesture. I include it here as a seventh emotion because of its importance in games and ease of observation.

FIGURE 31.5 Researchers generally agree that there are at least six emotions with universal facial gestures.

Because of its specificity, the FACS coding system for facial gestures offers promise as an emotional measure for games and software, and is the basis for many of XEODesign's observational studies. However, Ekman's work focused on the identification of individuals' experience of specific emotions and stops short of discussing how products or their use can create these emotions. What game designers need is a method that connects specific emotions to player actions in the game.

All of these models lay the groundwork for what is ultimately needed by game designers—a method for producing specific emotions from the interactions players most appreciate during goal oriented and open ended play. To do this the game industry needs an expanded method to create specific captivating emotions from the best-loved types of gameplay. This is a core focus of XEODesign's independent research.

31.3 PLAYER EXPERIENCE FRAMEWORK

31.3.1 Why We Play Games: Four Fun Keys Model

XEODesign conducted independent research to identify four key processes that create emotion in best-selling games (Figure 31.6). Each experience involves a different emotion to create a different Player Experience Profile. By presenting a goal and breaking it into small achievable steps, games create emotions from *Hard Fun*, where the frustration of the attempt is compensated by the feelings of accomplishment and mastery from overcoming obstacles. Outside of goals, games provide novel opportunities for interaction, exploration, and imagination, which create *Easy Fun*. Games that use emotions in play to motivate real-world benefits to help players change how they think, feel, and behave or to accomplish real work create *Serious Fun*. Finally, games that invite friends along get an interpersonal emotional boost from *People Fun* (Lazzaro 2004b). The Four Fun Keys are a collection of related game interactions (game mechanics) that deliver what players like most about games. Each offers a key to "unlock" unique emotions such as frustration, curiosity, relaxation, excitement, and amusement. Best-selling games provide features that support at least three of these Four Fun Keys to create a wider emotional response in the player. To keep things fresh during a single-play session, gamers move between the four different play styles (Lazzaro 2004b). Developing each key focuses and rewards the player with emotion from a self-motivating experience that deepens the game's player-experience profile. Designers of products and productivity software can also use these Four Fun Keys to increase emotional engagement for applications outside of games.

Only some of the emotions from playing basketball in the real world come from the Hard Fun of making baskets. Close examination reveals that all four Fun Keys are part of this popular sport. Dribbling the ball or doing tricks like a Harlem Globetrotter offers Easy Fun from novelty and role play. Intentionally blowing away frustration and getting a workout creates Serious Fun. Competition and teamwork make the game even more emotional from People Fun. All four types of fun make basketball's player experience more enjoyable. None of these require story or character. Through examination of how each type of fun creates emotions, designers and researchers can create better and more emotional player experiences (Figure 31.7).

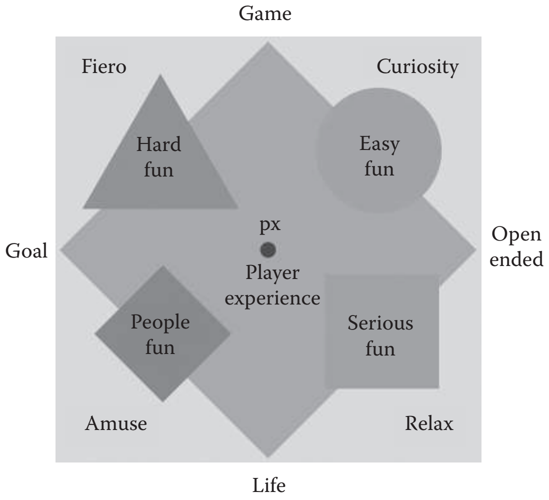


FIGURE 31.6 Each Fun Key is a collection of game mechanics that create a favorite aspect of gameplay. Emotions prepare players for action and reward players. These Four Fun Keys each contribute a unique set of emotions to the game. Changing one of the four key mechanisms will change the Player Experience profile of the game. (Courtesy of XEO Design. Copyright © 2004–2007 XEODesign, Inc. All rights reserved.)

Four Fun Keys to More Emotion through Gameplay

Lead Emotion	Fun Key	Key Game Mechanic
Fiero*	Hard Fun	Affect related to challenge, strategy, and mastery
Curiosity	Easy Fun	Affect related to novelty, ambiguity, detail, fantasy, role-play, and absorbing attention
Relaxation	Serious Fun	Affect related to purposefully changing oneself, learning, or doing real work
Amusement	People Fun	Affect related to competition, cooperation, and socializing with others

* Personal triumph over adversity

FIGURE 31.7 Game mechanics create emotion from what players like most about play. To this group of easily observable emotions, we add frequently reported emotions collected through verbal descriptions of internal sensations as well as player's body language during play. (Courtesy of XEO Design. Copyright © 2004–2007 XEODesign, Inc. All rights reserved.)

31.4 FIERO FROM HARD FUN GAMEPLAY

Gameplay that rewards effort through challenges to create fiero.

31.4.1 Desire for Fiero Helps Players Master Challenge

> "It's easy to tell what games my husband enjoys the most. If he screams 'I hate it. I hate it. I hate it,' then I know two things: a) he will finish it and b) buy version two. If he doesn't say this, he'll put it down after a couple of hours."
>
> **—Wife of a hard-core PC gamer**

The most obvious enjoyment in games comes from mastering a challenge and reaching a goal. Hard Fun is a self-motivating activity that keeps the user focused and enthusiastic by providing an obstacle, an objective, and a score. Hard Fun game mechanics challenge a player to overcome an obstacle to achieve a goal. Hard Fun experiences reward mastery, either explicitly with points and bonuses or implicitly through new levels or abilities. Because this type of play requires application of effort, we call this Hard Fun. In our research, we expand on this phrase (Csikszentmihalyi 1990; Papert 2005) to define Hard Fun as the rewarding process of mastering a challenge that involves the creation and testing of strategies and the application of effort. Hard Fun rewards effort and discourages failed approaches. Hard Fun creates the emotions of frustration and boredom. More importantly, it produces *fiero*, the Italian word Isabella Poggi and Ekman used to describe the personal feeling of triumph over adversity (Poggi, as cited in Ekman 2003). One of the most important game emotions, fiero is a strong feeling of personally accomplishing something difficult such as defeating the boss monster (Figure 31.8).

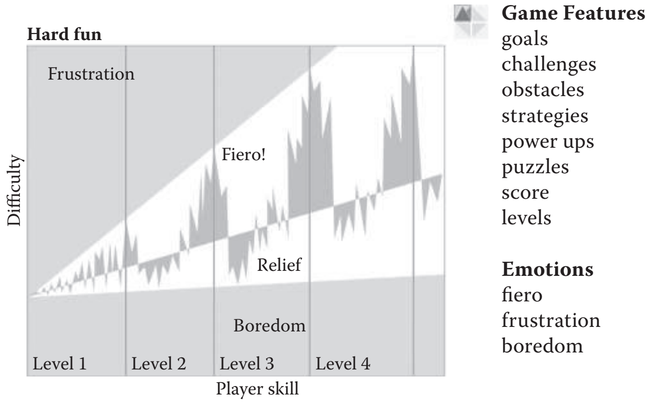

FIGURE 31.8 Similar to Csikszentmihalyi's concept of flow, games must balance difficulty with player skill and provide enough variety of challenges, strategies, and puzzles. If the player gets too frustrated or bored, he or she leaves the game. Charting a player's progress through a game onto Csikszentmihalyi's flow model illustrates that in addition to the requirements for flow, games can be made more emotional from sharp changes in the level of difficulty for game challenges. Game difficulty increases to the end of a level and then resets at the start of the next. When players succeed at the point where they are about to quit, they are more likely to experience fiero. In this figure, fiero occurs at the end of level two before continuing to level three of this game (modified from Csikszentmihalyi 1990). (Courtesy of XEO Design. Copyright © 2004–2007 XEODesign, Inc. All rights reserved.)

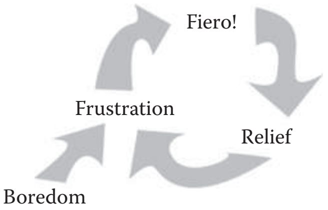
Hard Fun requires a high investment of energy from the player. By perfectly balancing player skill with game difficulty, Hard Fun meets many of the characteristics and requirements for flow (Csikszentmihalyi 1990; Lazzaro 2004b). For example, *Pac Man's* simple game mechanic (eat dots and avoid ghosts) offers clear long-term and short-term goals, the opportunity to concentrate, achievable tasks, an uncertain outcome, and immediate feedback to player decisions. It creates a deep sense of control through tight feedback loops between player input and action in the game. All of these enhance players' absorption into a challenging activity and improve their ability to perform. Beyond flow's balance of difficulty and skill, game designers do other things to change how players feel about their progress in the game. According to game designer Steve Meretzky, rewards along the path to the goal enhance enjoyment such as power ups, big jumps in score, animations and sounds (Lazzaro 2005a). For example, the power ups in *Pac Man* create super-charged feelings as players turn the tables to chase ghosts.

Hard Fun focuses player attention on achieving results by providing opposition and constraints, such as removing an alien threat in *Halo* or aligning puzzle pieces in *Tetris*. Often games provide a choice of strategy, and games with high replay ability offer a choice of goals. For example, *The Sims* offers several winning conditions such as the best-looking house, the most friends, or the most money. The new obstacles, constraints, and tradeoffs from different goals suggest multiple strategies and enhance the challenge. These emotions facilitate achievement of a goal, focus play effort, and reward accomplishment. Negative affect increases focus and concentration (Norman 2004), such as when the player encounters resistance to the goal through failed attempts. Sometimes Hard Fun emotions run counter to what needs to be done. For example, performing well or moving toward something rather than running away is more challenging when surrounded by negative affect. Other Hard Fun emotions, such as fiero from achievement, put the player into a positive affective state by rewarding the player's efforts. Unlike many emotions, fiero does not require an audience (Poggi as cited in Ekman 2003) and is a powerful emotion unavailable in film or novels. Players enjoy these emotions from Hard Fun, including the mental focus provided by frustration that helps players concentrate (Figure 31.9).

While general enjoyment results from emotions that provide motivation, other emotions impact the player's response to the game's stimulus. Decision making is aided or made more challenging by affect, whether it is the positive affect of collecting *BeJeweled*'s colored gemstones or the negative

Chain of Hard Fun Emotions Increases Enjoyment

Goal-directed gameplay creates Hard Fun emotions that focus and reward players for overcoming obstacles.



Hard Fun emotions involve obstacles, strategy and success and help players accomplish a goal by focusing and rewarding effort.

Emotion	Common Themes and Triggers
Frustration	Opposition to an important goal, sudden reversal, feeling of being thwarted, physical restraint. Anger prepares the body to remove an obstacle by force (Ekman 2003).
